flora and fauna reflect the water and air temperature differences on either side of the boundary.

ANTARCTIC FRONT. See **Meteorology**.

ANTARCTIC REGION RESEARCH. See **Polar Research**.

ANTARCTIC WATERS. Water masses in or associated with the Antarctic Ocean, including:

Antarctic Bottom Water. An oceanic water mass arising close to the margins of the Antarctic continent. It is particularly dense due to the cold and to the fact that the surface waters freeze over in winter, leaving the salt behind to increase the density of the remaining water. Sinking to the bottom of the ocean, the water creeps north until it encounters the North Atlantic Deep Water, with which it is believed to merge.

Antarctic Circumpolar Water. Also called West Wind Drift, this is the oceanic water mass with the largest volume transport (approximately 110×10^6 cubic meters per second) ($3{,}883 \times 10^6$ cubic feet per second) and the swiftest current. It flows from west to east through all the oceans around the Antarctic continent. The flow is locally deflected from its course, particularly by the distribution of land and sea and partly by the submarine topography. Besides the bends that are associated with the bottom topography, the effects of the distribution of land and sea and of the currents in the adjacent oceans are also evident. On its northern edge, it is continuous with the South Atlantic current, the South Pacific current and the eastward-flowing extension of the Agulhas current in the Indian Ocean. Salinity maxima occur at depths ranging from 700–1300 meters (2,310–4,290 feet), averaging 34.8%. The temperature range is 0 to 2 °C (32° to 35.6 °F). It is surface water in some regions; a deep mass in others.

Antarctic Intermediate Water. This is the oceanic water mass originating in the northern part of the Antarctic closest to the equator. The water moves northward as a surface current until it meets the warmer waters of the South Atlantic Ocean. Because it is colder and thus heavier, the Antarctic water sinks below the surrounding warm water to a depth of approximately 600–900 meters (1,980–2,970 feet) and continues northward until it returns to the surface between 20° and 30° north latitude.

Antarctic Surface Water. A relatively shallow oceanic water mass extending from the Antarctic convergence, where it meets the Sub-antarctic Water, to the shores of Antarctica. Its depth increases from about 80 meters (264 feet) in the Atlantic and 150 meters (495 feet) in the Pacific to 300–400 meters (990–1,320 feet) as it nears Antarctica. Temperature range is from −2 to 3.5 °C (28.4° to 38.3 °F); salinity from 32.8% to 34.5%.

Sub-antarctic Water. An oceanic water mass extending on the surface from the South Atlantic Central Water and the South Pacific Central Water to the Antarctic Surface Water in the south. In the Atlantic, it extends only from about 52° to 53° south latitude (from the subtropical convergence to the Antarctic convergence). In the Pacific Ocean, it covers a much larger area. Temperature range at the surface is 3 to 10 °C (37.4° to 50 °F); salinity from 33.8% to 34.8%.

ANTARES *(α Scorpii)*. A star, whose name is derived from two Greek words signifying that it is "similar to" or the "rival of" Mars, doubtless because of its distinctly reddish hue. In fact, this reddish color has always made Antares an object of interest and importance in the ancient religions, and many of the Egyptian temples are so oriented as to indicate that this star played an important part in their ceremonials. Antares was one of the four royal stars of the Persians about 3000 B.C., and some writers claim that it is the "lance star" referred to in the 38th chapter of the Book of Job.

The diameter of Antares has been determined with the stellar interferometer and found to be about 7.5×10^8 kilometers, or slightly greater than the distance of Mars from the sun. It is a typical M spectral-type giant star of very low density.

Ranking sixteenth in apparent brightness among the stars, Antares has a true brightness value of 5,000 as compared with unity for the sun. Estimated distance from the earth is 400 light years. See also **Constellations**; and **Star**.

ANTECEDENT STREAM. A stream that has maintained its consequent course in spite of localized uplifts that, if they had proceeded rapidly in relation to the cutting power of the stream, would have caused diversion of the stream. A good example of an antecedent stream valley is one that cuts across a ridge or several ridges. Excellent examples occur, in the valley and ridge province of the Appalachian Mountains. On the other hand, it has been suggested that the Appalachian antecedent stream valleys may be really superimposed. Figure 1 illustrates the origin of the present topography and stream pattern of the Appalachians. It is postulated that the folds were reduced to a peneplain on which flowed a few master streams. Uplift of the peneplain caused the rejuvenation of the master streams which were able to maintain their courses across the upturned edges of the more resistant strata, while the new tributary stream pattern was largely determined by the less resistant formations.

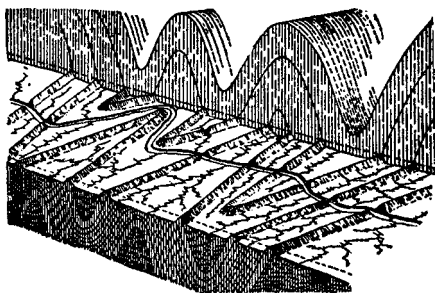

Fig. 1. Structural and erosional history of the Appalachian Range. (*W.M. Davis*.)

ANTELOPE *(Mammalia, Artiodactyla)*. The antelopes (*Antelopines*) comprise one of the larger groups of the order *Artiodactyla* (even-toed hoofed mammals). In anatomy, physiology, appearance, and habits, the antelopes lie between the oxen and the sheep and goats. Many species occur in Africa and some in India and Tibet. The Pronghorn Antelope of western North America belongs to a separate group (*Antilocaprines*). The horns of the pronghorn are hollow; the horns of true antelopes are almost solid. See **Pronghorn Antelope**.

The horns, in fact, are one of the most interesting features of the antelopes. The horns consist of a structure of bone covered with keratin, which is harder than bone and grows out from the animal's skull. Horns of older rams grow into nearly complete circles. It has been reported that the noise from clashing horns during fights between the males of certain species of antelopes can be heard sometimes for a distance of two miles. The shape and size of the horns frequently serve as an excellent index of the subfamily or species. For example, the Kudii has large corkscrew horns; the Giant Sable, crescent-shaped horns; the Oryx, rapier like horns, etc. Rings on the horns form yearly, but the age is often difficult to determine with accuracy by counting the rings because there is some overlapping.

As a general observation, the various species of antelopes can run fast, but not always fast enough to avoid death on the open plains where large carnivorous animals consider the antelope good eating. Most species of antelopes are quite alert looking, with head held high, ears erect, large eyes, short hair, graceful build, and frequently attractive and distinguished horns. Size ranges from about that of a goat to as large as a horse. Some antelopes have markings on the face and head that also are indicative of species. In several species, the coats blend in well with the surrounding habitat. Some people in antelope-inhabited areas consider antelope flesh as good meat, even a delicacy.

The general organization of the *Antelopines* group is given in Table 1. Only the most important species are indicated. The following descriptive paragraphs follow the general organization of the table.

With the exception of a few species, the antelopes are almost exclusive to Africa where they prefer savanna, grassland, scrub, and semidesert as a habitat. The term *antelope* is sometimes used loosely for the related bovines and caprines.

The Horse-Antelopes are large-hoofed animals with horse-shaped bodies. The Giant Sable antelope is known only in Angola and considered quite rare. Coloration is purplish-black. The rapier-horned antelopes are small and very horselike in appearance. See Fig. 1. The Oryx is found in the desert regions of Africa and thence to Syria. All species have very long horns, straight or slightly recurved. The screw-horned antelopes are natives of the Sahara. The species is known for going long periods with absolutely no water.

Several species of the hartebeest make up a significant portion of the group of Deer-Antelopes. Generally they have large, ringed horns,

TABLE 1. GENERAL ORGANIZATION OF THE ANTELOPES ANTELOPINES

HORSE-ANTELOPES (*Hippotraginae*)
Sabre-horned Antelopes (*Hippotragus*)
— Giant Sable Antelope (*H. tariani*)
— Common Sable Antelope
— Roan Antelope
Rapier-horned Antelopes (*Aegoryx* and *Oryx*)
— White Oryx (*A. algazel*)
— True Oryxes
— Gemsbock
— Beisa
— Beatrix Oryx
Screw-horned Antelopes (*Addax*)

DEER-ANTELOPES (*Alcelaphinae*)
Hartebeests (*Alcelaphus*)
— Coke's Hartebeest
Damalisks (*Beatrugus* and *Damaliscus*)
— Hunter's Hartebeest (*B. hunteri*)
— Korrigum
— Topi
— Sassaby
— Blexbok
— Bontebok
Gnus (*Connochaetes* and *Gorgon*)
— White-tailed Gnus
— Brindled Gnus
— White-bearded Gnus

MARSH-ANTELOPES (*Reduncinae*)
Waterbucks (*Kobus*)
Lechwes (*Onotragus*)
Kobs (*Adenota*)
— Kob
— Puku
Reedbucks (*Redunca*)
The Rhebok (*Pelea*)

BLACKBUCK (*Antilopinae*)

PIGMY ANTELOPES (*Neotraginae*)
Klipspringers (*Oreotragus*)
Oribis (*Ourebia* and *Raphicerus*)
— Steinboks
— Grysboks
Sunis (*Neostragus*)
The Beira (*Dorcatragus*)
Dik-Diks (*Madoqua Rhynchotragus*)
Royal Antelopes (*Nesotragus*)

GAZELLES (*Gazellinae*)
Impalla (*Aepyceros*)
The Gerenuk (*Litocranius*)
The Dibatag (*Ammodorcas*)
The Springbuck (*Antidorcas*)
The Addra (*Addra*)
True Gazelles (*Gazella*)
Goat-Gazelles (*Procapra*)

Fig. 1. Oryx or besia antelope. (*American Museum of Natural History*.)

irregularly spiraled with the tips pointing back. These animals are graceful and the horns of some species are described as resembling a lyre. The animals are about 4 feet high (1.2 meters) at the withers (ridge between shoulder bones). The forequarters are heavier and much higher than the hindquarters. Possibly the first hartebeest to be recognized was the Titel or Bubal, which roamed across North Africa in the days of the Roman Empire and was frequently called a horned horse. This animal, smaller than most hartebeests and with relatively short thick horns, ringed and black in color, became extinct in the early 1900s. Another member of the hartebeest group is the Konzi, with small horns, pale color, and black tail and front of legs black. It is a very lively animal, living in small parties, often in company with zebra and waterbuck, usually in the flat wooded districts of Zambia and Rhodesia along the Zambezi. Another hartebeest is the Korigum of central Africa, also sometimes called the Senegal antelope. The Sassaby is sometimes called the bastard hartebeest. The animal stands about 4 feet high (1.2 meters), with horns up to 15 inches (38 centimeters) long. Coloration is deep red, blending into black on the back. Hunter's hartebeest is very rare, found only in the environs of southern Somaliland. The term *hartebeests* is often used in describing both hartebeests and the damalisks.

Gnus are sometimes called *wildebeests*. The animals generally have a large head, strong curved horns, an erect bristly mane and a bristly muzzle. The withers are high and the tail is hairy throughout its length. In some species, the horns resemble those of a Cape buffalo. The animals are known for their hilarious behavior.

The Marsh-Antelopes appear and behave more like deer than horses, the qualities of both of the latter animals tending to blend in antelopes. The Waterbuck is a large antelope of southern and eastern Africa. It frequents rocky hills in the vicinity of rivers. The horns are more than 2 feet long, slightly curved and ringed almost to the tips. The Reedbuck is a comparatively small antelope. The male has small horns that turn forward. Also known by the Dutch equivalent, *reitbok*. The Rhebok also is small and is found in hilly sections of eastern and southern Africa. Some authorities have compared this animal with the chamois in its habits.

The Blackbuck, as indicated by the accompanying table, does not fit into the other large subfamilies of the antelopines. Of the antelopines, the blackbuck appears to be more closely related with the gazelles. The animal was known in Europe since the Middle Ages. Its present habitat is India and it prefers the open plains from the foothills of the Himalayas to Cape Comorin; and western Pakistan to lower Assam.

As indicated by their name, the Pigmy Antelopes are very small animals, probably the smallest of the ungulates (having hoofs). The Royal antelope of west Africa is only about 8 inches (20 centimeters) high. However, the other species of pigmy antelopes are considerably larger. The Klipspringer is a great jumper, sure-footed, and known for tripping about on its toes. The Oribis is of dainty build, standing less than 2 feet high (0.6 meter), with sharply pointed horns from 4 to 5 inches (10 to 13 centimeters) in length. The color is tawny above and white below. The Sunis is black with white rings around the eyes and white underparts and ears. The horns are long and thin.

The Gazelles comprise the largest group of antelopines. To all but zoologists and keen sportsmen, most gazelles appear very much alike. They are small, delicate, with preference for the desert, grassy plains,

scrub zones, and parklands. The Impala is moderately large and of several species; most of these animals have long, slender horns, slightly spiraled and ringed through most of their length. The Gerenuk inhabits eastern Africa and has a very long neck and moderate-spiraled horns, turned forward sharply at the tips. Also called Waller's gazelle. The Addra or true gazelles are found all over Africa outside the forest zones, as well as in Syria, western Arabia, the plains of India, and central Asia, from Turkey eastward to the Gobi desert of Mongolia. The affinity between the antelopines and the caprines is found in the so-called Gazelle-Goats. Among these are the Chiru, the Saiga, and the Goa. The latter animal prefers the high plateaus of Tibet. The gazelle-goats travel in small herds with a diminishing population because of hunting. The gazelle-goats are not to be confused with goat-gazelles, which are described under **Goats and Sheep**.

ANTENNA (Communications). Characteristically, communication systems consist of cascaded networks, each network designed to carry out some operation on the energy conveying the information. In radio communication systems, antennas are the networks serving to transfer the signal energy from circuits to space and, conversely, from space to circuits. In circuits, the flow of energy is restricted to one or the other of two directions. The effectiveness of transfer of energy between the antenna and the adjacent circuit element is, therefore, determined solely by the terminal impedance of the antenna and that of the adjacent circuit. The knowledge of the antenna terminal impedance over the desired frequency range, therefore, fully describes the joint performance of the antenna and the circuit energy.

At one time, antennas were used mainly in connection with radio transmission and reception. In recent years, antennas have been developed for other portions of the radiation spectrum, including light waves.

The relationship between the antenna and space, however, is much more complex. The distribution of the radiated energy varies with the direction in space and with the distance from the antenna. This gives rise to the directive properties of the antenna. Further, the energy is radiated in the form of an electric and a magnetic field. These are vector quantities which, at a distance from the source, are at right angles to each other and to the direction of propagation. The planes in which these vectors are located, and whether they are stationary or rotate with time determine the polarization of the radiated field. The performance of an antenna can, therefore, be fully described only by specifying several parameters, such as radiation pattern, gain, and polarization.

It is convenient, in discussing antenna properties, to consider the antenna as a radiating rather than a receiving network. The antennas are, however, linear networks and are subject to the law of reciprocity. (As used here, radiation intensity has the dimensions of power flow per unit area, normally, watts per square meter. Electric field strength, on the other hand, is in volts per meter.)

The performance of an antenna in terms of radiation pattern, gain, or polarization is the same, irrespective of whether the antenna radiates or absorbs radiation.

Except for the immediate neighborhood of the antenna, referred to as the "near-field region" of the antenna, radiated energy propagates radially from the antenna, and the radiation intensity varies inversely as the square of the distance from the antenna. This is a propagation effect. In discussing the antenna performance, it is customary to disregard this and to represent the distribution of the radiated power as a function of the two direction angles only. Such a distribution is commonly represented graphically and is then known as the radiation pattern of the antenna. See Fig. 1.

The radiation patterns can take a variety of forms. Sometimes they are in the form of a polar diagram, with the radial distance proportional to either field strength or intensity. The intensity may be represented linearly, as power, or logarithmically, in decibels. For representing the directive properties of an antenna in all directions, contours of equal radiation intensity may be plotted, with the two direction angles as abscissas and ordinates, respectively. See Fig. 2.

The directive properties of an antenna also lead to the concept of antenna "gain." The directive gain of an antenna in a specified direction is the radiation intensity in that direction compared to what it would be if the total radiated power were distributed equally in all directions. For some applications, such as point-to-point communication, high values of antenna gain are desired because such antennas concentrate the available power, thus effectively increasing it. Conversely, in receiving applications, such antennas are more responsive to radiation arriving from one direction. For other applications, such as broadcasting, antennas with low directivity may be desired.

The gain of an antenna is dependent principally upon the size of the antenna, expressed in wavelengths. The larger the antenna, the greater is likely to be its gain. The values of gain for different antennas range from 1.5 for an electrically small dipole to hundreds and even thousands times that. In practice, antenna gains are usually expressed logarithmically, in decibels. For the low-frequency end of the radio spectrum (15 kHz to 3 MHz), antennas, although large physically, are relatively small in terms of wavelengths. Therefore, the directive gains of these antennas seldom exceed 3 (4.8 dB). In the high-frequency band (3 to 30 MHz), used principally for long-distance communication, antenna gains of 10 to 100 (10 to 20 dB) are frequently encountered. At microwave frequencies, where the wavelengths are a fraction of a meter, gains of several hundred, and even thousand times (20 to over 30 dB) are common.

When an antenna has one or more of its dimensions significantly larger than a wavelength, its radiation pattern is likely to have more than one maximum. The radiation pattern, in such cases, is said to have a lobe structure. That part of the radiation pattern that encompasses the direction of the largest maximum and the radiation immediately to each side of it, is referred to as the main lobe. The radiation about the minor maxima is referred to as the secondary or side lobes. One of the frequent goals in antenna design is the reduction in the levels of secondary lobes. These may, at times, be a source of interference to other transmissions.

In common with light, radio waves consist of electric and magnetic fields at right angles to each other and to direction of propagation. In radio terminology, the orientation of the electric vector of a radio wave is taken as the direction of polarization. Thus, if the electric field vector is parallel to the ground, the radio wave is termed "horizontally polarized." Although the polarization of the energy radiated by an antenna, in general, varies with the direction, an antenna is usually designated as being horizontally (or vertically, circularly, etc.) polarized, depending on the polarization of its radiation in the direction of the main lobe maximum.

The importance of polarization in radio engineering lies principally in the different reflective properties of the ground for waves with electric field parallel to the ground and those normal to the ground. Different radio services are served best by different polarizations. Antennas for use in the low-frequency end of the radio spectrum, as previously defined, are almost invariably vertically polarized. This includes the AM broadcast band. In the high-frequency band, both horizontal and vertical polarizations are used. For FM and television broadcast service in the United States and many other countries (but not in the United Kingdom), horizontal polarization is employed.

Antenna Configurations

The types and variations of antennas are extremely numerous. Each type has some particular advantage over the others for some specific requirement. Among some of the more important and frequently encountered requirements are those for operating bandwidth, directivity, whether high

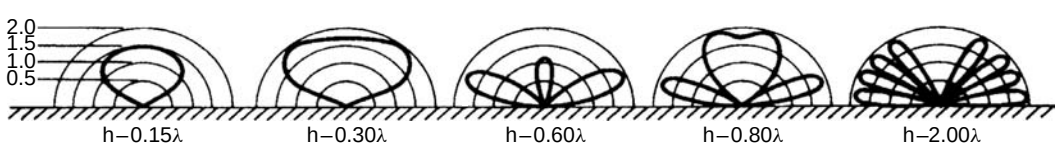

Fig. 1. Vertical polar radiation diagram in plane normal to a horizontal dipole antenna. h is height above ground, electrical degrees; λ is wavelength.

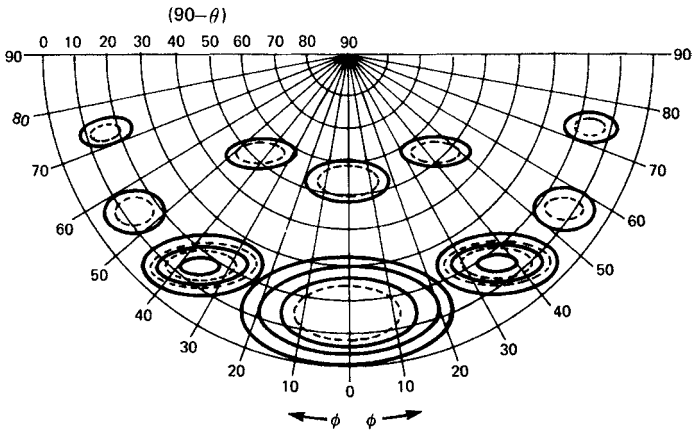

Fig. 2. Directive patterns for a rhombic antenna. Apex angle is 18°. Height above ground h is 0.8 λ (wavelength).

or low, and polarization. Mounting factors for receiving antennas, as in land vehicles, aircraft, and spacecraft, also pose problems of size, weight, air resistance, etc.

A few of the representative types of antennas frequently encountered in practice are shown in Figs. 3, 4, and 5. Two very elementary radiators, a monopole and a dipole, are shown in Fig. 3. A monopole in one form or another is employed almost exclusively throughout the low-frequency end of the radio spectrum. The dipole is somewhat more versatile, as it can be oriented to give either horizontal or vertical polarization. It is frequently used as an elementary radiator in large array-type antennas.

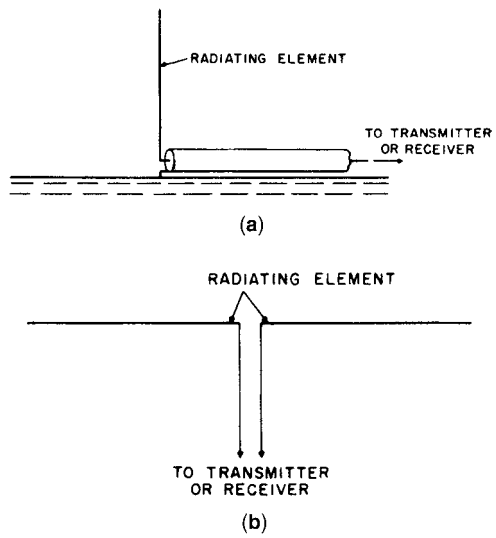

Fig. 3. Two types of elementary radiators: **(a)** monopole over ground; **(b)** dipole.

Figure 4 presents two highly directive, but otherwise radically different types of antennas. The rhombic antenna has broadband properties and is used widely in point-to-point communication service. The Yagi antenna is a relatively compact antenna with high gain for its size. Its operating frequency band is quite narrow. Two antennas used at microwave frequencies are shown in Fig. 5. The horn antenna is used generally where moderate directivity suffices. The parabolic antenna is used for high-gain applications and is a quasi-optical device.

Specific antenna configurations are described briefly in the following listing, arranged alphabetically for convenience.

Achromatic Antenna — An antenna whose characteristics are uniform over some band of frequencies.

Adcock Antenna — A form of radio antenna which in its simplest form (see Fig. 6) consists of two spaced vertical antennas. This type of antenna finds use in radio direction finding where it displays a significant advantage over the loop antenna. When the latter is used to obtain a bearing, incorrect results may be obtained because horizontally polarized descending radio

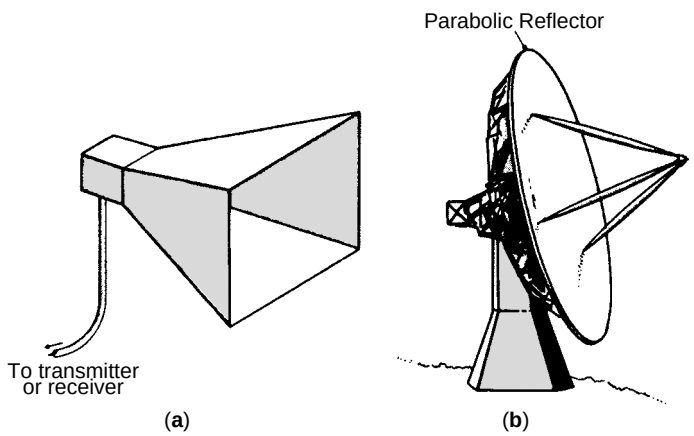

Fig. 5. Microwave-type antennas: **(a)** horn antenna; **(b)** parabolic reflector antenna.

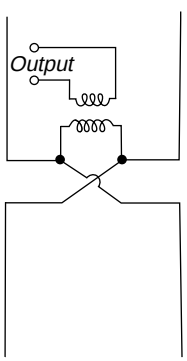

Fig. 6. Elementary Adcock antenna.

waves will induce different voltages in the two horizontal members of the loop. In the Adcock antenna, on the other hand, horizontally polarized waves induce voltages in the horizontal elements that cancel in their effect on the output voltage.

Alford Slotted Tubular Antenna — A horizontally polarized antenna developed for FM broadcast work. It consists of a sheet of metal bent

into the form of a cylinder that is not quite closed, hence a straight narrow slot extends the full length of the cylinder or tube. It is so dimensioned that the distribution of potential across the slot has very nearly the same phase throughout the entire length of the slot. The currents produced flow in horizontal circles around the cylinder so that the latter operates something like a stack of small, in-phase loops.

Aperiodic Antenna — A non-resonant, and thus frequently insensitive antenna.

Base-Loaded Antenna — An antenna (usually vertical) whose electrical height is increased by the addition of inductance in series with the antenna at the base.

Biconical Antenna — An antenna formed by two conical conductors, having a common axis and vertex, and excited at the vertex. When the vertex angle of one of the cones is 180°, the antenna is called a discone.

Broadband Antenna — An antenna which will function satisfactorily over a bandwidth in the order of 10% or more of its center frequency.

Cage Antenna — An antenna in which the radiating members are parallel rods arranged in a cylindrical fashion.

Capacitor Antenna — An antenna in which the capacitance between two conductors or systems of conductors is the essential characteristic. Also called a dielectric antenna.

Cheese Antenna — A cylindrical parabolic reflector enclosed by two plates perpendicular to the cylinder, so spaced as to permit the propagation of more than one mode in the desired direction of polarization. It is fed on the focal line.

Cloverleaf Antenna — An antenna for transmission or reception of horizontally polarized radiation in a non-directional pattern in a plane normal to the axis of the antenna. Its name arises from the fact that it is comprised of a cluster of four half-wave, curved, radiating elements arranged in the pattern of a four-leaf clover.

Coaxial Antenna — An antenna comprised of a quarter wavelength extension to the inner conductor of a coaxial line, and a radiating sleeve which, in effect, is formed by folding back the outer conductor of the coaxial line for approximately one-quarter wavelength.

Conical Antenna — A wide band antenna in which the driven element or elements are conical in shape.

Cosecant-Squared Antenna — A type of radar antenna which provides constant field strength at a given altitude over an appreciable range. So-called because the power in the antenna pattern on one-way transmission decreases at a rate proportional to the square of the cosecant of the elevation angle. This radiation pattern may be approximated by using a parabolic reflector with several radiators arranged in a line perpendicular to the axis.

Dielectric Antenna — An antenna which employs a dielectric as the major component in producing the required radiation pattern.

Dipole Antenna — A straight radiator, usually fed in the center, and producing a maximum of radiation in the plane normal to its axis. The length specified is the overall length. Common usage in microwave antennas considers a dipole to be a metal radiating structure which supports a line current distribution similar to that of a thin straight wire, a half-wavelength long, so energized that the current has two nodes, one at each of the far ends. See Fig. 3(b).

Directional Antenna — For the usual radio-broadcast service, it is desirable to transmit the signal in all directions equally, but for special broadcast services, such as international short-wave or microwave relay transmission, it is often desirable to direct the radiation in some specific direction and avoid radiation in other directions. The need for directed radiation is even more pronounced in other types of radio service. The radio signals may be directed by the use of directional antennae, or, as often called when consisting of more than one element, directional arrays. Any antenna is directional to a certain extent, e.g., the common tower antenna for broadcast stations does not radiate directly upward, but in the sense used here a directional antenna is one having marked characteristics of this type. Basically the directional antennae all depend upon radiation from two or more components adding vectorially. If the waves radiated from various elements add in a certain direction the signal will be strong in that direction, while if they tend to cancel, or subtract, in a given direction the signal will be zero or weaker in that direction.

One of the simplest directional antennas is the loop such as used with many portable receivers. Here the two elements whose effects add vectorially are the two vertical sides of the loop. The result is a Fig. 8 radiation pattern, i.e., if lines are drawn to scale in various directions so their lengths represent the strength of the signal in each direction, the ends will all lie on a Fig. 8 curve with the antenna at the center. These antennas are used for many radio ranges, and, since the directional characteristics of any antenna are the same for transmission and reception, for radio compass use. The directional pattern can be altered by adding the radiation from a separate vertical antenna.

For broadcast use where it is necessary to decrease the signal in certain directions, usually to avoid interference with another station, systems consisting of two or more vertical antennas are quite common. By proper spacing of the elements and proper choice of the phase of the currents (which can easily be adjusted by circuit values) a wide range of radiation patterns may be obtained.

For international short-wave broadcasts and for point-to-point communication, more elaborate extensions of the same principle are used. Since the more elements in an array, the sharper the pattern, the radiation may be beamed at will, the type of service and economics being the usual limiting factors. By stacking systems one above the other in a vertical plane the radiation may be directed vertically as well as horizontally. It should be mentioned that it is not desirable to have the beam too sharp even for point-to-point service since the variations in the ionosphere may cause the signal to miss the receiver if the beam is too sharp.

Sometimes the elements of an array are not all fed directly from the transmitter, but some are fed and others pick up energy radiated by the first and reradiate it. By proper choice of the spacing and the antenna dimensions these various radiations may be made to give the desired pattern. The fed antennas are often referred to as driven antennas or elements and the others as parasitic antennas. There are many other types of directional antennas, such as rhombic, V, herringbone, binomial, broadside, continuous-spaced, linear, etc., but all depend upon vector addition of the radiation to give the pattern.

By the use of directional arrays the signal transmitted in a given direction may be increased many-fold over its value for the same transmitter with a nondirectional antenna. A measure of this is the gain of the array, which is the signal with the array divided by the signal in the same direction for one element of the array serving as antenna. Where the type service permits their use, directional arrays are the most economical means of obtaining increased signal strength at the receiver. In reception the directional antenna allows the reception of a signal from the desired direction and suppresses signals and noise from other directions.

Discone Antenna — An antenna of a disk and a cone whose apex approaches and becomes common with the outer conductor of the coaxial feed at its extremity. The center conductor terminates at the center of the disk, which is perpendicular to the axis of the cone. Its most important characteristic is its ability to operate over a very wide bandwidth without a substantial change of input impedance or radiation pattern. The radiation pattern is omnidirectional in a plane perpendicular to the axis of the cone.

Dummy Antenna — A substitute for an actual antenna which is used for test purposes. In making comparative tests, calibrations, etc., on receivers, it is highly desirable to have conditions as near as possible to actual used conditions, yet have them standardized so they may be reproduced or the results on different units accurately compared. To do this a standard dummy antenna is used. The make-up of the antenna varies with different types of sets, being a series circuit with an inductance of 20 micro-henries, capacitance of 200 micro-microfarads and resistance of 25 ohms for regular broadcast receivers. For auto radios, short-wave sets, etc., other circuit combinations are standard. The dummy antenna is connected between the set and the standard signal generator that supplies the radio-frequency test voltages. A dummy antenna consisting of just resistance is frequently used as a load on radio transmitters for making preliminary adjustments without radiating a signal. The output power of the transmitter is dissipated as heat in the resistance.

Fanned-Beam Antenna — A unidirectional antenna so designed that transverse cross sections of the major lobe are approximately elliptical.

Fishbone Antenna — An antenna consisting of a series of coplanar elements arranged in co-linear pairs, loosely coupled to a balanced transmission line.

Franklin Antenna — An antenna consisting of a number of half-wave dipoles placed end-to-end, all operating in phase. Also called a co-linear antenna.

Helical Antenna — An antenna used where circular polarization is required. The driven element consists of a helix supported above a ground plane. If the circumference of one turn is approximately one-half wavelength, the radiation is said to be in the axial mode and is directed

predominately along the axis of the helix. In this mode, the antenna has good efficiency and relatively broad bandwidth.

Horn Antenna — A circular or rectangular electromagnetic horn can be used for providing unidirectional pattern coverage with either linear or circular polarization. Circular polarization can be achieved by exciting a square waveguide with a signal polarized at 45° and placing a quarter-wave plate between the feed point and the aperture. The waveguide and transition feeding it essentially determine the bandwidth of a horn. The bandwidth can be increased by using ridge waveguides and other broadbanding techniques. See Fig. 5(a).

Image Antenna — An antenna located close to the earth's surface (assumed to be a perfectly conducting plane) transmits a direct ray and a ray reflected from the earth's surface. It is convenient to represent the reflected ray as originating from an image antenna identical to the original, and located inside the earth by a distance equal to the height of the original above the earth.

Isotropic Antenna — Sometimes referred to as a unipole, this is a hypothetical antenna radiating or receiving equally in all directions. A pulsating sphere is a unipole for sound waves. In the case of electromagnetic waves, unipoles do not exist physically, but represent convenient reference antennas for expressing directive properties of actual antennas.

J Antenna — A half-wave antenna, end-fed by a parallel-wire, quarter-wave section having the configuration of a letter J.

Lazy H Antenna — An antenna array where two or more dipoles are stacked one above the other for the purpose of obtaining greater directivity.

Leaky-Pipe Antenna — External radiation is produced by providing a hole or slot in a waveguide propagating electromagnetic power. Proper choice of the size and location of a series of holes in the waveguide may lead to quite directional radiation patterns.

Lens Antenna — To satisfy high directivity requirements, a lens is often placed in front of another radiator, such as a dipole or horn. In much the same manner as an optical lens focuses light waves, these microwave lenses focus the high-frequency energy into a sharp beam.

Logarithmic Antenna — In logarithmic antennas, the radiating elements are in geometric progression in accordance with their resonant frequencies. This results in effectiveness at a wide range of frequencies. Sometimes used for special purposes in the high-frequency field. The radiating elements are folded dipoles. The aperture efficiency is comparatively low because only those elements that are fairly close to resonance will contribute to the radiation.

Log-Periodic Antenna — The geometry of this antenna repeats periodically so that the electrical properties of the antenna also repeat periodically with the logarithm of the frequency. These antennas are essentially frequency-independent and capable of bandwidths of 10:1 or greater, and with little change in patterns.

Loop Antenna — A loop antenna, when used with radio transmitters or receivers, possesses valuable directional properties.

On ships and airplanes, a loop antenna equipped with a compass card, whose 000°–180° line is parallel to the longitudinal axis of the ship, may be used to obtain relative bearings of radio stations. In using the loop, the position of minimum intensity is sought. In other words, the indicating needle on the compass card is in a direction perpendicular to the plane of the loop, and the observer rotates the antenna until the position of minimum signal intensity is found. The reading of the dial will then give a line of position through the ship and the radio station. With the simple loop there is no method for telling on which side of the instrument the station is located. To overcome this difficulty, the loop antenna is combined with a non-directional antenna.

Loop-Vee® Antenna — A broadband antenna that produces a circularly polarized pattern. Pattern coverage of the grounded Loop-Vee is practically identical to that produced by a quarter-wave stub in conjunction with a current loop above the ground plane. The azimuth patterns are nearly perfect circles for all polarizations. In another design, the balanced Loop-Vee incorporates a second element similar to the single element of a grounded antenna and produces a butterfly-shaped pattern.

Marconi Antenna — An antenna that has one end of its radiating surface grounded (a grounded antenna). It may be considered a transmission line open-circuited at the far end and driven at the sending end, which is the junction between antenna and ground.

Marconi-Franklin Antenna — This array, one of the first used for high-speed short-wave point-to-point communication, consists of a front curtain of vertical radiators, each consisting of several co-phased dipoles in series, and another curtain of reflecting wires of the same construction situated one-quarter wavelength to the rear. There are twice as many reflectors as radiators.

Monopole Antenna — Any one of several configurations of very simple design, often applied to vehicles, which protrude vertically from the vehicle, such as a whip, spike, blade, cone, or sleeve. See Fig. 3(a).

Multiple-Tuned Antenna — A low-frequency antenna having a horizontal section with a multiplicity of tuned vertical sections.

Musa Antenna — A "multiple-unit steerable antenna" consisting of a number of stationary antennas, the composite major lobe of which is electrically steerable.

Omnidirectional Antenna — An antenna producing essentially constant field strength in azimuth, and a directive radiation pattern in elevation.

Oscillating Doublet Antenna — A reference standard against which the directional characteristics of an antenna may be compared. Ideally it consists of two closely spaced charges of opposite sign, both oscillating in the same phase. Also, it may be regarded as an infinitely short, linear current-element.

Parabolic Antenna — A directional antenna using some form of a parabolic mirror either to convert plane waves into spherical waves or to convert spherical waves into plane waves. The reflector is fed or "illuminated" by the use of dipoles, waveguide feed system, or horns. The simple parabolic mirror is truly a broadband device. See Fig. 5(b).

Pencil-Beam Antenna — A unidirectional antenna so designed that cross sections of the major lobe by planes perpendicular to the direction of maximum radiation are approximately circular.

Pill-Box Antenna — A cylindrical, parabolic reflector enclosed by two plates perpendicular to the cylinder, so spaced as to permit the propagation of only one mode in the desired direction of polarization. It is fed on the focal line.

Pocket Antenna — A non-protruding slot antenna developed for aircraft.

Quarter-Wave Antenna — An antenna which is electrically one-quarter of a wavelength long. It may be physically longer or shorter than one-quarter wavelength in free space.

Rhombic Antenna — An antenna composed of long-wire radiators comprising the sides of a rhombus. The antenna usually is terminated in an impedance. The sides of the rhombus, the angle between the sides, the elevation, and the termination are proportioned to give the desired directivity. See Fig. 4(a).

Scanning Antenna — A directional antenna employed in radar which mechanically or electrically causes its radiation to periodically scan a given arc or solid angle.

Series-Fed Vertical Antenna — A vertical antenna which is insulated from ground and energized at the base.

Shaped-Beam (Phase-Shaped) Antenna — A unidirectional antenna whose major lobe differs materially from that obtainable from an aperture of uniform phase. A $\mathrm{cosec}^2\theta$ beam is a shaped beam whose intensity in some plane varies as $\mathrm{cosec}^2\theta$ over a prescribed range, where θ is a polar angle in that plane. The half-power width in planes perpendicular to this plane is approximately constant for the prescribed range of θ.

Shunt-Fed Vertical Antenna — A vertical antenna connected to ground at the base and energized at a point suitably positioned above the grounding point.

Slot Antenna — A radiating element formed by a slot in a metal surface.

Steerable Antenna — A directional antenna whose major lobe can be readily shifted in direction.

Top-Loaded Vertical Antenna — A vertical antenna so constructed that, because of its greater size at the top, there results a modified current distribution giving a more desirable radiation pattern in the vertical plane. A series reactor may be connected between the enlarged portion of the antenna and the remaining structure.

Tridipole Antenna — An omnidirectional, horizontally polarized antenna consisting of three dipoles displaced from each other by 60° in the horizontal plane. The radiators are curved, causing the array to have a circular appearance.

Turnstile Antenna — An antenna composed of two dipole antennas, normal to each other, with their axes intersecting at their midpoints. Usually, the currents are equal and in phase quadrature.

V Antenna — A V-shaped arrangement of conductors, balanced-fed at the apex, and with included angle, length, and elevation proportioned to give the desired directivity.

Yagi Antenna — An array with one or more parasitic elements in addition to the driven element or elements. Currents induced in the parasitic element from the field produced by the driven antenna cause radiation in a phase (relative to the phase of the radiation from the driven unit) that is a function of both the spacing of the elements and the length of the parasitic element. If the resultant radiation pattern has its maximum in the direction of the driven element, the parasitic element is called a reflector, whereas if the maximum radiation is in the direction of the parasitic antenna, it is called a director. See Fig. 4(b).

Special Antennas

An antenna custom-designed for use with the *large radio telescope* at the Arecibo Observatory (Arecibo, Puerto Rico) is shown in Fig. 7. As illustrated further in the entry on **Radio Astronomy**, a triangular platform measuring 216 feet (66 meters) on each side, is 500 feet (152 meters) in the air and above a 1000-foot (305-meter) diameter reflector bowl. The output of the transmitter is 450,000 watts. This power is maximized by the positioning of the transmitter in a carriage house of the suspended platform, instead of on the ground. At the short wavelengths (S-Band), much power would be lost if the signal had to travel a considerable distance from the ground to the platform even through the most efficient S-band waveguide obtainable. Thus, the decision to put the transmitter on a suspended platform was made. The transmitter had to be extremely compact. The transmitter, despite its high efficiency gives off as much heat energy as it does radio energy. Heat exchangers were built on the platform to dissipate this energy, with coolant water circulating between the platform and the carriage house through a long, articulated piping system.

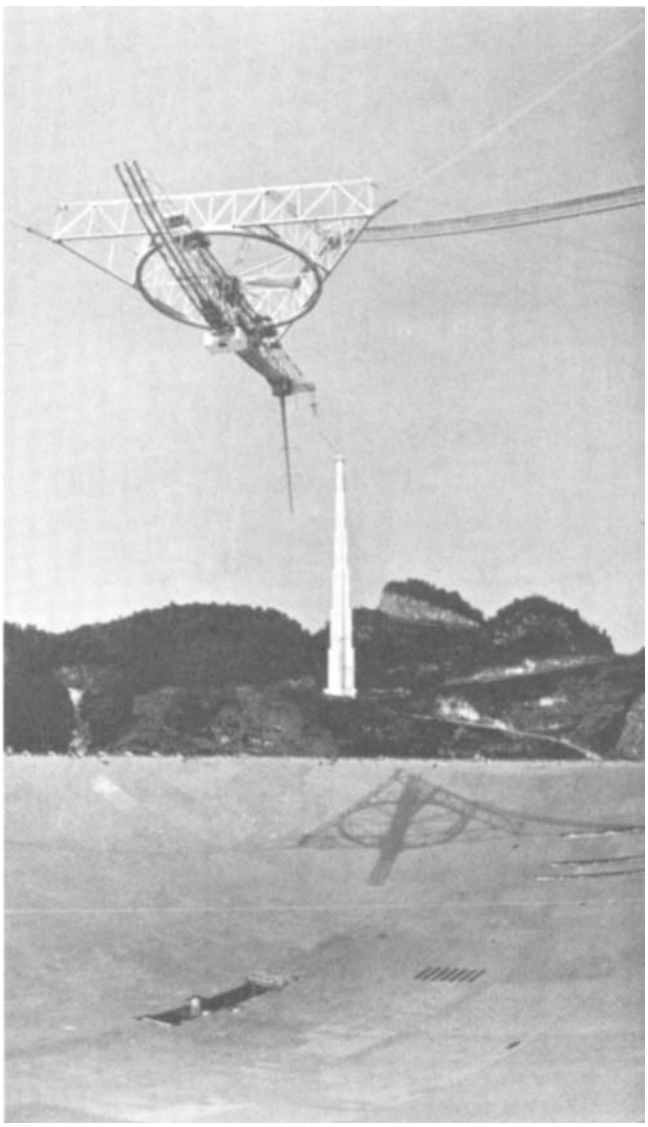

Fig. 7. Special antenna for use with large radio telescope (Arecibo, Puerto Rico). (*The National Astronomy and Ionosphere Center*, Cornell University.) (*Photo by Russell C. Hamilton.*)

Deep Space Network

An international network of antennas in support of interplanetary spacecraft missions, as well as radio and radar astronomy observations, and certain Earth-orbiting missions is called the Deep Space Network (DSN). The DSN is the largest and most highly sensitive scientific telecommunications system in the world.

See also **Deep Space Network**.

ANTENNA PATTERN. A graphical representation of the radiating properties of an antenna as a function of space coordinates. Also called *radiation pattern*, *beam pattern*, and *lobe pattern*. Typically, the antenna pattern is a diagram showing the radiant intensity, the electric field strength, or the radiant power density emitted from an antenna as a function of the direction from the antenna, in the far-field region unless specified otherwise. The direction of maximum intensity defines the main lobe of the antenna pattern. Other local maxima, weaker than the main lobe, define the secondary lobes or sidelobes of the antenna. In the main lobe, the angular separation in a given plane between the directions at which the intensity falls to one-half its maximum value defines the half-power or 3-dB beamwidth in the plane. The directional sensitivity of an antenna to incoming signals is described by a function identical to the antenna pattern for transmission. Antenna patterns are also used to depict properties of the emitted electromagnetic field other than intensity, for example, the polarization as a function of position in the main lobe.

See also **Lobe**.

AMS

ANTENNA TEMPERATURE. In radio astronomy, a measure of the power absorbed by the antenna. In an ideal, loss-free radio telescope, the antenna temperature is equal to the brightness temperature if the intensity of the received radiation is constant within the main lobe. If the angular dimension of the source is small compared to the main lobe, the antenna temperature is equal to the brightness temperature multiplied by the ratio of the solid angle subtended by the source to the effective solid angle of the antenna.

ANTENNA (Zoology). A jointed sensory appendage of the head found in several classes of *Arthropoda*. Crustacea have two pairs, while insects, centipedes, and millipeds have one pair. See also **Diplopoda**.

ANTHER. The terminal part of a stamen, containing the pollen sacs.

ANTHERIDIUM. The structure that gives rise to the sperm. In the algae it is a single cell, the contents of which may become a single sperm or divide to produce many sperms. In the higher divisions of plants, the antheridium is a multi-cellular body that contains the sperms.

ANTHESIS. That stage in the flowering development of a plant when pollen is being produced.

ANTHOCYANINS. A group of water-soluble pigments that account for many of the red, pink, purple, and blue colors found in higher plants. Most plants contain more than one of these pigments and they occur most prevalently as glycosides. Several hundred different anthocyanins are known. Anthocyanins have been isolated and some have been found to be acylated with substituted cinnamic acids. The site of attachment of these acids to the anthocyanins has not been fully defined. The natural role of the anthocyanins in plants to date has not been related to any factor of plant metabolism;many authorities believe that the pigments play more of an ecological role with regard to pollination and seed dispersal through their ability to act as an insect and bird attractant.

The anthocyanins are part of the larger group of aromatic oxygen-containing, heterocyclic compounds, known as flavonoids, most of which have a 2-phenylbenzopyran skeleton as their basic ring system. Although widely distributed among higher plants, including ferns and mosses, they are not found in algae, fungi, bacteria, or lichens.

There has been considerable interest and research activity in connection with anthocyanins during the past decade or so, stemming principally from the tighter restrictions, including banning, of several synthetic colorants. See also **Colorants (Foods)**. Representative of the food processing industry's desire to find colorants that are beyond suspicion as health deterrents, scientists have been investigating various sources of anthocyanins. They have found that pigments from roselle plants (*Hibiscus sabdariffa*) native to the West Indies can be used for coloring apple and pectin jellies. A cranberry pomace extract has been found useful in coloring cherry pie filling. The potential of blueberry as a source of anthocyanin pigments also has been investigated. The berry is rich in non-acylated anthocyanins, but presently appears to be too costly as a coloring substitute.

Grape anthocyanins have been intensely investigated and have been found reasonably satisfactory, for example, in carbonated beverages. Although to date the grape anthocyanins are not as stable as Red No. 2, research continues, encouraged by the large amounts of grape wastes produced in the production of wine and grape juice. Red cabbage also has been seriously considered as a source of anthocyanin pigments. Anthocyanins are most stable at a pH range of 1.0 to 4.0, and this acidity dictates the products in which they can be used.

Much more detail on this topic can be found in the references listed below. See also **Colorants (Foods)**; **Glycosides**; and **Pigmentation (Plants)**.

ANTHOPHYLLITE. The mineral anthophyllite is an orthorhombic amphibole essentially $(Mg, Fe)_7Si_8O_{22}(OH)_2$ with aluminum sometimes present. This mineral corresponds to enstatite and hypersthene in the pyroxene group. It has a prismatic cleavage; hardness, 5.5–6; sp gr, 2.8–3.57; luster, vitreous; color, gray, yellow, brown, green or brownish-green; transparent to translucent; probably always a metamorphic mineral in magnesium-rich rocks, often associated with talc; very common in schist. Found in Norway, Austria, Greenland, Pennsylvania, Georgia, and elsewhere. The name is derived from the Latin *anthophyllum*, clove, because of its usual brownish shades. See also **Amphibole**.

ANTHOZOA. The sea anemones, corals, alcyonarians and related forms. A class of the phylum *Coelenterata* in which the polyp form gains its highest development and the medusa is unknown.

Like the hydrozoan polyps, these animals have relatively thin walls, due to the thin middle layer (mesogloea), and are approximately cylindrical in form. The base is a disk by which the animal is attached to some support and the opposite end forms an oral disk bearing numerous hollow tentacles surrounding the mouth. The mouth leads into a long tube lined with ectoderm, known as the stomodaeum. In it ciliated grooves serve for the passage of currents of water into and out of the enteric cavity. In this cavity, radiating partitions, the mesenteries, pass from the wall to the stomodaeum, which they hold in place. Others extend into the cavity from the wall without reaching the stomodaeum. The edges of the mesenteries bear mesenteric filaments with stinging cells. They are important in digestion and respiration. Reproductive bodies also develop in the mesenteries and slender acontia with many stinging cells arise from their edges. Muscle bands in the mesenteries and in the body wall contract the entire animal and close the margins of the oral disk in over the tentacles.

The class is divided into two subclasses:

Subclass Alcyonaria. Polyp with eight tentacles, pinnately branched. Colonial forms, usually supported by a hard skeleton. The sea fans, precious coral, and sea feathers.

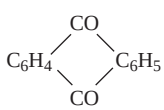
Subclass Zoantharia. Colonial or solitary. Polyp with few to many tentacles, not pinnately branched. Hard deposits formed under the basal disk in some species. The stony corals and sea anemones.

ANTHRACENE. [CAS: 120-12-7] A colorless solid; melting point 218 °C, blue fluorescence when pure; insoluble in water, slightly soluble in alcohol or ether, soluble in hot benzene, slightly soluble in cold benzene; transformed by sunlight into para -anthracene $(C_{14}H_{10})_2$.

Anthracene reacts: (1) With oxidizing agents, e.g., sodium dichromate plus sulfuric acid, to form anthraquinone, $C_6H_4(CO)_2C_6H$. (2) With chlorine in water or in dilute acetic acid below 250 °C to form anthraquinol and anthraquinone, at higher temperatures 9,10-dichloroanthracene. The reaction varies with the temperature and with the solvent used. The reaction has been studied using, as solvent, benzene, chloroform, alcohol, carbon disulfide, ether, glacial acetic acid, and also without solvent by heating. Bromine reacts similarly to chlorine. (3) With concentrated sulfuric acid to form various anthracene sulfonic acids. (4) With nitric acid, to form nitroanthracenes and anthraquinone. (5) With picric acid $(1)HO{\cdot}C_6H_2(NO_2)_3(2,4,6)$ to form red crystalline anthracene picrate, melting point 138 °C.

$C_{14}H_{10}$ or 
Anthracene is obtained from coal tar in the fraction distilling between 300° and 400 °C. This fraction contains 5–10% anthracene, from which, by fractional crystallization followed by crystallization from solvents, such as oleic acid, and washing with such solvents as pyridine, relatively pure anthracene is obtained. It may be detected by the formation of a blue-violet coloration on fusion with mellitic acid. Anthracene derivatives, especially anthraquinone, are important in dye chemistry.

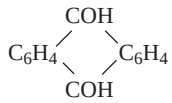
ANTHRAQUINONE. [CAS: 84-65-1] Anthraquinone (9,10) is a yellow solid, melting point 286 °C; can be sublimed;



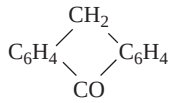
forms monoxime, melting point 224 °C, by heating under pressure at 180 °C with hydroxylamine chloride; forms no phenylhydrazone with phenylhydrazine; with strong oxidizing agents reacts with difficulty to yield phthalic acid $C_6H_4(COOH)_2(1,2)$; with reducing agents, such as sodium hyposulfite, zinc in sodium hydroxide solution, tin or stannous chloride in hydrochloric acid (but not sulfurous acid), is reduced to anthraquinol, anthrone, dianthrol and dianthrone, depending on the conditions.

Anthraquinone is obtained by oxidation of anthracene using sodium dichromate plus sulfuric acid, and is purified by dissolving in concentrated sulfuric acid at 130 °C and pouring into boiling water, whereupon anthraquinone separates as pure solid, and is recovered by filtration. Further purification may be accomplished by sublimation or crystallization

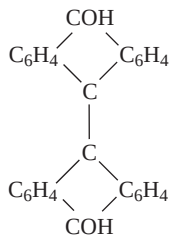
anthraquinol



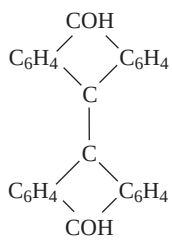
anthrone



dianthrol



dianthrone



from nitrobenzene, aniline or tetrachloroethane. Anthraquinone is used as the material from which many dyes are made, notably alizarin $C_6H_4(CO)_2C_6H_2(OH)_2$ and related substances. These are vat dyes, that is, insoluble colored substances which are readily reduced to a substance having marked affinity for the fiber to be dyed and which upon exposure to the air are readily re-oxidized to the original dye. Anthraquinone may be detected by the appearance of a red color on treatment with alkali, zinc powder, and water. See also **Coal Tar and Derivatives**.

ANTHRAX. This is a highly infectious disease caused by the gram-positive *Bacillus anthracis*. The disease is of historical importance because the anthrax bacillus was the first microorganism proved definitely to be the cause of an infectious disease. Anthrax mainly is a serious disease of cattle. It is capable of transmission to humans by way of meat and animal products. In a number of countries, extensive cattle vaccination programs have been very effective. These programs have virtually eliminated reservoirs of infection in the United States, where only minor outbreaks involving very few cases may occur, usually in the Great Plains, the lower Mississippi Valley, and Texas. Infection of humans usually occurs in persons who work with animal products, such as hides. In other parts of the world, anthrax in animals persists as a major problem, notably in Asia, Africa, and South America. The Russian literature also has reported outbreaks over many years. Outbreaks were particularly severe in 1923 and 1940, but the most disastrous of all occurred in and around the city of Sverdlovsk in 1979. Over 1000 fatalities were reported in an epidemic that lasted about one month. Even though the soil of Sverdlovsk province has been infected with anthrax for a century or more, the characteristics and extent of the 1979 outbreak have baffled scientists. Rather than the mild cutaneous form, or the intermediately serious intestinal form, sketchy reports from Sverdlovsk indicated that it was the inhalation form of the disease that proved so potent. Questions, which remain unresolved, were immediately raised concerning the possibility of anthrax spores being released to the atmosphere as the result of an accident at a biological warfare facility.

The pathogenesis of *B. anthracis* stems from both the nature of its capsule and from toxin production. The former establishes the infection and the latter contributes to the characteristic edema around an anthrax lesion and to toxemia.

The most common form of anthrax is *cutaneous*. The cutaneous lesion is sometimes referred to as a malignant pustule. The bacillus forms spores in the external environment, and in culture, but not in animal tissues. Spores can linger in the soil and in animal products for many years. A cutaneous infection is usually the result of introducing spores through an abrasion. The cutaneous form can be successfully treated with antibiotics.

The intestinal form results from ingesting anthrax-contaminated meat, notably sausage. Inhalation anthrax, previously known as Wool-Sorter's disease, gained prominence as the result of the Sverdlovsk incident. The disease begins with a high fever, malaise, and non-productive cough. Dyspnea, cyanosis, hemoptysis, and chest pain follow. A striking feature is an extensive hemorrhagic mediastinitis. Before antibiotics were available, mortality from cutaneous anthrax ranged up to 20%. The mortality rate for untreated inhalation anthrax and anthrax meningitis is nearly 100%.

In the early part of this century, prior to the availability of antibiotics and the initiation of cattle vaccination programs, there were about 125 cases per year of cutaneous anthrax in the United States. For several years, the number of cases per year has been 10 or fewer.

Penicillin over a week is the treatment of choice, with tetracycline as an alternative for patients allergic to penicillin. Anthrax lesions should not be incised and drained because pus is usually absent and infection may be disseminated by this procedure. See also **Bacterial Diseases**.

ANTHRAXOLITE. A coal-like metamorphosed bitumen, often closely associated with igneous rocks. Commonly associated with "Herkimer Diamond" type quartz crystals in dolomitic limestones in Herkimer and Montgomery counties in New York State.

ANTHROPOGENIC. Relative to the activities of humans as contrasted with the actions of natural forces and events. Thus, the addition of dust to the atmosphere from aerial crop spraying is anthropogenic, as contrasted with dust clouds produced by a volcano (natural); the pollution arising from an oil spill is anthropogenic, versus the seepage of crude oil into the oceans from cracks in undersea rock formations (natural).

ANTHROPOGENIC HEAT. See **Meteorology**.

ANTHROPOIDS *(Mammalia, Primates).* This division of Mammalia includes a number of medium-size and large animals which have comparatively large brains and which have no tails. Zoologically, Hominidae are also placed in this category. The subdivisions of apes include:

Lesser Apes (*Hylobatidae*)
- The Siamang (*Symphalangus*)
- Gibbons (*Hylobates*)

Greater Apes (*Pongidae*)
- Gorillas (*Gorilla*)
- The Chimpanzees (*Pan*)
- Orangutans (*Pongo*)

The lesser and greater apes are found in the forests of Africa and in the Oriental Region (eastern India to Hainan and southward to Borneo, Java, and Sumatra).

There are about six species of gibbons, of which one, the siamang, is confined to Sumatra. Of the lesser apes, the siamang is the largest, having a finger-tip-to-finger-tip spread across the chest of nearly 6 feet (1.8 meters) and a height of about 3 feet (1 meter) when sitting in an upright position. Siamangs prefer high forest country and only infrequently travel on the ground where they do so in a rather awkward manner. When required, they are good swimmers, keeping their heads well out of the water. They are known for their frightening howling which occurs at dawn and sundown. Their preferred diet is fruit. They have a coat of long, rather shaggy black hair with the exception of gray beards in the males. These animals feature a pouch connected to the throat, which can be inflated to appear as a rather large red balloon.

Gibbons are smaller and of more slender build than the other apes and are among the most agile of all primates in the trees. See Fig. 1. They have extremely long arms with which they swing distances up to 20 feet (6 meters) from bough to bough. Their movements are quite rapid. This arm-swinging process is known as *brachiation*. Gibbons, as do spider monkeys, have features in addition to their long limbs that further the

Fig. 1. Mother gibbon and baby. (*A. M. Winchester*.)

effectiveness of brachiation, including: the bone structure of the hand formed in what might be termed a "hook" or "grapple"; a reduction of the thumb, such that it does not interfere with rapid release when going from one tree limb to the next; a curling-inward position of the hand when at rest; and exceptional elongation of the fingers and palm of the hand, to provide increased surface area for contacting a tree limb as a leap is being completed. Some authorities consider the tree-swinging agility of the gibbon as unsurpassed.

A feature not found among other anthropoid apes is the presence of ischial callosities (small, naked, hardened, and thickened places) on the buttocks. For their diet, gibbons prefer leaves and fruits. The whooping noises of the siamang are also made by the gibbons, particularly for a few hours after dawn. Gibbons are well known for their intelligence, cleanliness, and gentility. Gibbons are monogamous and known for their exceptional fidelity and family cooperation. B.B. Beck (*Science*, **182**, 4112, 594–596 (1973)) reports that a bonded pair of hamadryas baboons developed use of a cooperative tool without training. The male could get food with the tool, but first had to get the tool from an adjoining cage which he could not enter. The female learned to give him the tool.

Specific variations of gibbons include: Hoolock (central Himalayas — gray to brown in color); White-handed Gibbon (Burma, Malay Peninsula — brown to black); Agile Gibbon (Sulu Archipelago and Borneo — cream-to-dark-brown color); Unkaputi (Malaysia — often taken as pets); and the Wow-Wow or Silvery Gibbon (Sumatra).

Certain generalizations can be made pertaining to all of the Greater Apes: Bodies are short and obese; small eyes, close together, pointing forward; wide and very flaring nostrils with sunken nose-bridge; protuberant muzzle; thin, mobile lips; small, fully opposed thumbs; very long arms; and short hind limbs.

Gorillas are the largest of the Greater Apes and are terrestrial. In walking, they rest partly on the backs of the bent fingers. According to Akeley's observations, they are rather poor climbers. The head of the gorilla is distinguished by the strong jaws and large teeth, the heavy ridges over the eye sockets, and the small ears. Two species are the common gorilla, *Gorilla gorilla*; and the mountain gorilla, *G. berringei*. See Fig 2.

Gorillas live in the forests of Africa, with numbers of them found in a wide area of Cameroon and Gabon, north of the Congo, and in Katanga and Zaire. Pockets or "nations" of gorillas also are found in the northwestern portion of Nigeria, and in the volcanic mountains of Kivu. There apparently is no communication between these very isolated communities.

A large male gorilla may stand over five feet high and weigh in excess of 500 pounds (227 kilograms). The lowland dwellers usually have a rusty-gray coat, whereas the mountain dwellers have a black coat. See Fig. 3.

At one time, gorillas would not live long in captivity. This difficulty has been mastered by careful attention to diet and by protecting the animals from the respiratory diseases of humans, to which they are very susceptible. As mentioned by explorer Paul D. du Chaillu, the gorilla has a habit

Fig. 2. Mountain gorilla.

Fig. 3. Lowland gorilla. (*New York Zoological Society*.)

of beating the chest with both hands and displays a very self-centered personality. Psychologist R.M. Yerkes found the gorilla more slow in adaptability to surroundings and also lacking in initiative, when compared with orangutans and chimpanzees of the same age.

An interesting article pertaining to gorilla behavior is "Conversations with a Gorilla," by Francine Patterson (*National Geographic*, **154**, 4, 438–465 (October 1978)). During the past decade, researchers have successfully taught several chimpanzees to converse with signs. In this project, partly funded by the National Geographic Society, Koko is the first gorilla to achieve proficiency. After six years of study, Francine Patterson evaluates Koko's working vocabulary at about 375 signs.

Even today, there remains much to be learned concerning the gorilla, particularly pertaining to the behavior of this animal in its natural habitat. There have been numerous observations made, many scientific, some with legendary overtones. Although obviously all communities of gorillas have not been observed let alone located, it has been established that at least some of them construct platform-type homes or nests, built in trees a few feet above ground level. Some authorities have observed true knots used in the doubling over and twisting of tree and root gnarlings in the construction of such platforms. This evidences a superior intelligence, which has not been observed in the comparatively few observations of animals in captivity. The strength of the gorilla always has been a topic of some controversy, although all observers agree that it is quite tremendous. There are reports of bending of heavy steel bars and gun barrels. Natives and scientific observers generally agree that gorillas prefer to spend most of their time on the ground, occasionally tree climbing for fruits, and that, when unmolested, are retiring and not ferocious as popularly reported.

Because the chimpanzees most people see on television, in the movies, or at a zoological garden are usually relatively small, sight is lost of

the fact that chimpanzees can be quite large, some older male animals rivaling some of the gorillas in proportions. In their natural habitat, they can easily attain a height of five feet and a weight between 150 and 200 pounds (68 and 91 kilograms). Females are usually slightly smaller. These animals live over a large area of Africa, with particular population concentrations around Lake Victoria and in Tanzania. One authority is reported to have observed several hundred of these animals within visual range of a walking path of some 15 miles (24 kilometers) between villages in Cameroon.

In recent years, chimpanzees have become favorites for various types of animal behavior experimentation and observation. E.W. Menzel (*Science*, **182**, 4115, 943–945 (1973)) reports of a study of juvenile chimpanzees, which were carried around an outdoor field and shown up to 18 randomly placed hidden foods. The animals remembered most of the hiding places and the type of food that was in each. Their search pattern approximated an optimum routing, and they rarely rechecked a location that they had already emptied of food. As reported, the chimpanzees appeared to directly perceive the relative position of selected classes of objects and their own position in a scaled frame of reference. They proceeded on the strategy, "Do as well as you can from wherever you are," taking into account the relative preference values and spatial clusters of the foods as well as distances. As investigator Menzel concludes, "Especially in the light of other recent research, one is struck again by the parallels between chimpanzee and human behavior, the necessity for including representational processes in any adequate formulation of learning and memory, and the apparent evolutionary independence of representational ability and verbal language."

Investigators D.M. Rumbaugh, T.V. Gill, and E.C. von Glasersfeld (*Science*, **182**, 4113, 731–733 (1973)) reported that four studies revealed that a $2\frac{1}{2}$-year-old chimpanzee, after 6 months of computer-controlled language training, proficiently read projected word-characters that constituted the beginnings of sentences and, in accordance with their meanings and serial order, either finished the sentences for reward or rejected them.

The animal is considered to be an extrovert, learning fast from certain types of information and appears to thrive on showing off. However, if it is pushed too hard in learning experiments, tantrums can be expected as well as moodiness. In nature, the male leads the family group as it travels. See Fig. 4.

Fig. 4. Chimpanzee. (*A. M. Winchester*.)

In nature or captivity, there appear to be no special breeding seasons. The life span is about 35 years and adulthood is achieved at about 11 years. Chimpanzees feed on fruit, bird eggs, and plant shoots.

In semi-erect position, the chimpanzee walks on all fours. The arms are used for swinging. In walking, the animal leans on its hands propped by the knuckles, and when it stands erect, its arms reach to just below the knees.

Varied forms of chimpanzees include: The Masked Chimpanzee (*Pan satyrus verus*) found in Upper New Guinea; the Choga (*P. s. satyrus*) found in Lower Guinea; the Koola-Kamba found in Nigeria and environs; and the long-haired Eastern Chimpanzee (*P. s. schweinfurthi*) found in Tanzania and Uganda. But, as mentioned before, these animals are found in many other parts of Africa. In nature, chimpanzees build nests with half-roofs for protection against the elements. These are deftly placed in tree branches several feet above the ground.

Orangutans are found in Borneo and Sumatra. The adult animal may reach a height of 5 to $5\frac{1}{2}$ feet (1.5 to 1.7 meters) and weigh in excess of 150 pounds (68 kilograms). The sharply depressed bridge of the nose accentuates the prominence of the rounded muzzle. For some years, the zoological gardens were more successful in boarding orangutans than gorillas. However, the orangutans can be considered delicate when in captivity, particularly in northern climates. These animals, like the chimpanzee to some extent, have been found to be very intelligent, but they are less desirable as subjects because of their uncertain temper, a characteristic particularly true of older males. The term orangutan (or *Orang-Utan*) is Malayan for "man of the woods."

Orangutans are usually brownish-red in coloration, with a broad, flat face, and long, coarse hair. A sac extending from the front of the throat extends to the armpits. This feature, plus the depressed nose-bridge, the huge cheek flaps, comparatively small legs, disproportionately long and heavier forelimbs, and obese stomachs, particularly in older specimens, gives them a rather grotesque appearance. See Fig. 5. If adopted into a human household, the orangutan demonstrates amazing adaptability often showing, as with a dog for example, definite preferences for certain people, while also demonstrating a marked antipathy for others.

Fig. 5. Adult orangutan. (*New York Zoological Society*.)

In nature, the animals are vegetarians, preferring fruit (particularly of the palm nut tree), but tolerate a wider diet when in captivity. They also are "sleeping platform" builders as some of the other apes described. Even the heavier adults can travel rapidly among the tree tops and display brachiation as previously defined. See also **Mammalia**; and **Primates**.

ANTIBIOTIC. A biochemical drug, derived from one or more kinds of microorganisms, which has the ability to (1) inhibit the growth (*bacteriostatic agent*), or (2) to kill (*bactericidal agent*) a number of other microorganisms and thus of immense value in treating a number of diseases that result from microbial infection. Major antibiotics administered today are listed in Table 1.

TABLE 1. CLASSIFICATION OF DRUGS USED IN THE CHEMOTHERAPY OF MICROBIAL DISEASES

Bacteriostatic Agents	Bactericidal Agents
Sulfonamides	Penicillins (penicillin G, penicillin V, methicillin, oxacillin, cloxacillin, nafcillin, ampicillin, amoxicillin, carbenicillin)
Trimethoprim	Cephalosporins
Tetracyclines	Aminoglycosides (streptomycin, neomycin, kanamycin, gentamicin, tobramycin, amikacin)
Chloramphenicol	Vancomycin
Erythromycin	Polymyxins (polymyxin B, colistin)
Lincomycin or clindamycin	Bacitracin

Effective chemotherapy in the use of antibiotics depends upon *selective toxicity*. This may be defined as the ability of the drug to inhibit microorganisms at concentrations tolerated by the host. It has been found that those antimicrobial agents that are most effective target their action on the anatomic structures or biosynthetic functions that are unique to microorganisms. Some antibiotics interfere with the synthesis of the mucopeptide layer of the bacteria cell wall. This structure is not present in the cells of the host. The penicillins, cephalosporins, and vancomycin act in this manner. Other drugs, such as colistin and polymyxins, alter the permeability of the bacterial cell membrane. This allows the cell contents to leak out. The aminoglycoside antibiotics and the tetracyclines are believed to act upon a ribosomal sub-unit, thus interfering with the target microorganism's ability to synthesize protein at the translational level. Chloramphenicol, erythromycin, and lincomycin act in a similar manner, but on a different sub-unit of the bacterial ribosome. Rifampin selectively inhibits bacterial DNA-dependent RNA polymerase, but fortunately does not affect this same enzyme in the host cell. Inhibition of the microbial synthesis of folic acid and of the precursors of folic acid are the principal actions of the sulfonamides.

With a wide variety of antimicrobial drugs available, the following guidelines are frequently followed in determining the most effective drug to use: (1) define the infecting organism; (2) consider the antimicrobial susceptibility pattern of the microorganism; (3) consider the relative merits of bactericidal versus bacteriostatic drugs; (4) define the site of infection; (5) consider the possible advantages of using a combination of antibiotics; (6) consider the clinical pharmacology, including dosages, route of administration, possible adverse reactions, drug interactions, serum levels, among other factors; (7) estimate the optimal duration of therapy; and (8) if the drug(s) are to be administered in a hospital, check if there are any limitations on the use, particularly of new drugs.

Development of Antimicrobial Drugs

The first scientific demonstration of microbial antagonism was made by Pasteur and Joubert in 1877 when they observed that certain common bacteria inhibited the growth of anthrax bacilli. This basic phenomenon by which one microorganism destroys another to preserve its own life was, at that time, called *antibiosis* by Vuillemin (1889). In the decades that followed, the therapeutic efficacy of antibiotics to control infectious disease was eventually demonstrated, after which the pursuit of microbial antagonists rapidly became an organized applied science.

Pyocyanase was the first microbially derived antibiotic product to be used in treating bacterial infections in humans. Although it had only limited clinical use, it is interesting historically because it demonstrated as early as 1906 the principle of selective toxicity, i.e., specificity of action against the invading pathogen and a correlative lack of toxic action in the host. Following the decline in use of pyocyanase, it was almost a quarter of a century before interest in anti-infective agents from microbial sources was renewed.

In 1929, the British bacteriologist Alexander Fleming published his observations on the inhibition of a staphylococcus culture by growing colonies of *Penicillium notatum*. This report went largely unpursued for a decade, after which Florey and Chain reinvestigated Fleming's work and, in 1941, demonstrated the clinical usefulness of penicillin. In 1939, Dubos, by careful, well-planned studies, obtained the antibiotic tyrothricin from the soil organism *Bacillus brevis*. Although tyrothricin found only limited use, the work of Dubos on the chemical, biological, and physical properties of this antibiotic contributed immensely toward forcing a realization of the potentialities of antibiotic substances. Similarly, Waksman undertook a systematic search for antimicrobial substances in a group of soil-inhabiting microbes known as *Streptomyces* and announced the discovery of streptomycin in 1944.

The foregoing discoveries stimulated worldwide interest, and the discovery of useful new antibiotics during the period 1939–1959 was prolific. During this period, the major classes of antibacterial antibiotics were recognized. Many specific drugs that presently occupy places in therapeutic practice were discovered directly in microbial fermentation. The later work in the field had consisted principally of chemical modifications of antibiotic substances previously known.

See separate article on **Sulfonamide Drugs**.

Classification of Antibiotics

The antibiotics comprise a widely diverse group of substances, differing not only in chemical structure, but also in their mode of action, antibacterial spectra, origin, and other features. Grouping of antibiotics in accordance with their toxic action on target microorganisms, as previously mentioned, bears little resemblance to their classification according to origin and chemical structure. The latter classification is presented in Table 2. Among the most important of the antibiotics used in current medical practice are: (1) the beta-lactams, which include the penicillins and cephalosporins; (2) the tetracyclines; (3) the macrolides; and (4) the aminoglycosides.

TABLE 2. CLASSES OF ANTIBIOTICS ON BASIS OF BIOGENETIC ORIGIN AND CHEMICAL STRUCTURE

Amino Acid Units	Acetate/Propionate	Sugar Units
Amino acid cogeners	Fused-ring systems	Aminoglycosides
D-Cycloserine	Tetracyclines	Streptomycin
Chloramphenicol	Oxytetracycline	Kanamycins
Beta-Lactams	Chlortetracycline	Gentamicins
Penicillins	Steroidal antibiotics	Neomycins
Cephalosporins	Fusidic acid	Tobramycins
Polypeptides	Griseofulvin	Amikacins
Bacitracins	Antibacterial macrolides	
Polymixins	Erythromycin	
Viomycin	Oleandomycin	
Capreomycin	Leucomycins	
Vancomycin	Spiramycins	
	Polyene macrolides	
	Nystatin	
	Amphotericins	
	Ansa-macrolides	
	Rifamycins	

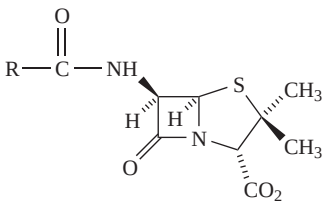
Note: Some of the foregoing are mainly of historical or research interest.

Penicillins. The penicillins are chemically characterized by a four-membered lactam ring fused to a thiazolidine ring and are differentiated by the side-chain (R) attached to the bicyclic nucleus. See Table 3. Penicillins are sometimes named by attaching the chemical name of the R-substituent as a prefix to the word penicillin. Thus, in the case where R is $C_6H_5CH_2-$, the compound may be called *benzylpenicillin*. However, this compound in commerce is more commonly referred to as *Penicillin G*. Similarly, in the case where R is $C_6H_5OCH_2-$, the compound may be called *phenoxymethylpenicillin*, although commercially it is more commonly called *Penicillin V*. Most frequently, the commercial names bear no resemblance to structure.

The naturally occurring penicillins have been discovered in the fermentation broths of *Penicillium* and *Cephalosporium* cultures.

The earliest of the penicillins, simply called penicillin, was benzylpenicillin (Penicillin G). This early product, still used, was shown to have several limitations, including acid instability, allergenicity, and susceptibility to enzymatic inactivation by penicillinases.

TABLE 3. STRUCTURES OF SOME OF THE PRINCIPAL PENICILLINS



Protion of β-lactam ring cleaved by penicillinas (β-lactamase)

Generic or Chemical Name	CAS Registry No.	Substituent Side Chain (R)
Penicillin G (Benzylpenicillin)	[61-33-6]	Penicillin V (Phenoxymethylpenicillin)		Methicillin	[61-32-5]	Oxacillin	[66-74-5]	Cloxacillin	[61-72-3]	Nafcillin	[95-16-0]	Ampicillin	[69-53-4]	Amoxicillin	[26787-78-0]	Carbenicillin	[4697-36-3]	
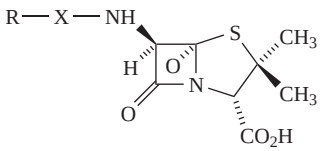
In 1947, it was discovered that addition of phenylacetic acid to penicillin fermentation media increased the yield of benzylpenicillin at the expense of other less desirable natural penicillins. Following this observation, a new generation of *biosynthetic* penicillins was prepared by addition of mono-substituted acetic acid derivatives to penicillin fermentations. The most important of these biosynthetic derivatives is penicillin V, obtained by adding phenoxyacetic acid to penicillin growth media. This widely used antibiotic is relatively stable in dilute acid, is not destroyed by the acidic contents of the stomach, and consequently can be effective by oral administration.

Although the biosynthetic approach created several new penicillins, it was limited in the type of side-chain (R) that could be introduced. Only derivatives with an non-substituted methylene adjacent to the amide carbonyl (X as shown below) could be generated.



The next major breakthrough in penicillin research came in 1959 with the isolation of the penicillin nucleus 6-aminopenicillanic acid (6-APA) from fermentation mixtures to which no side-chain precursor had been added. Although chemical synthesis of 6-APA and its utility for the preparation of new penicillins by acylation were announced by Sheehan in 1958, the fermentation method provided the first practical means of obtaining large quantities of 6-APA. Chemical acylation of 6-APA allowed introduction of almost unlimited varieties of side chains and gave rise to a third generation of penicillins called *semisynthetic penicillins*.

The nature of the acyl side chain has been found to have a profound effect on the properties of the penicillins, influencing such therapeutically important properties as acid stability, oral absorption, serum protein binding, penicillinase resistance, and gram-negative activity.

One of the major developments resulting from the availability of 6-APA was the creation of semisynthetic penicillins that resist destruction by the penicillinases. The empirical finding that triphenylmethylpenicillin was resistant to penicillinase led to the screening of other penicillins with sterically hindered side-chains, partly because the presence of a bulky group near the beta-lactam ring resulted in reduced affinity of these substances for the enzyme. Methicillin and cloxacillin are compounds with such side-chains which have proved clinically useful.

Ampicillin. This drug has a broader range of activity than that of penicillin G. The spectrum includes not only pneumococci, meningococci, and a number of streptococci, but also several gram-negative bacilli.

Amoxicillin. As evident from Table 3, amoxicillin is structurally similar to ampicillin, with the exception of an OH instead of an H in one of the positions of the side-chain. Although this difference does not alter the spectrum of the two drugs, amoxicillin is better absorbed from the gastrointestinal tract, resulting in longer effective concentrations of the drug present in the circulation.

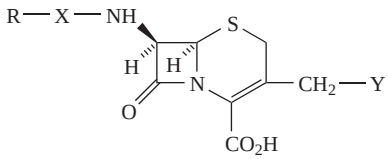
Carbenicillin. This drug has a carboxyl rather than an amino substituent and has greater activity against gram-negative bacilli.

Methicillin. This drug is administered intravenously or intramuscularly. In recent years, the semisynthetic penicillinase-resistant oxacillin and nafcillin have markedly supplanted methicillin for many situations.

Cephalosporins. These drugs constitute another major class of beta-lactam antibiotics and are chemically characterized by a beta-lactam fused to a dihydrothiazine ring. In contrast to the penicillins, where the side-chain of the antibiotic varies, depending upon precursors present in the fermentation mixture, fermentation-derived cephalosporins contain the same side-chain. *Cephalosporin C*, the parent antibiotic of this class, is not useful clinically. For example, it is about 0.1% as active as benzylpenicillin against staphylococci. However, in early research, cephalosporin C exhibited certain interesting properties which provoked further study. Cephalosporin C was more stable toward acid than penicillin; it was unaffected by penicillinases; it exhibited appreciable activity against some gram-negative bacteria, and it appeared to have no cross-allergenicity with the penicillins. Consequently, in the late 1950s, many laboratories investigated both chemical and microbiological methods for removing the aminoadipoyl side-chain of cephalosporin C to obtain the cephalosporin nucleus, 7-aminocephalosporanic acid (7-ACA).

A practical chemical process for accomplishing this transformation was announced in 1962. Like 6-APA, previously described, 7-ACA can be readily acylated, and a large number of semisynthetic cephalosporins thus have been possible. Cephalothin was the first clinically useful broad-spectrum cephalosporin to emerge from synthetic studies. Cephaloridine

TABLE 4. STRUCTURES OF REPRESENTATIVE CEPHALOSPORINS



Generic or Chemical Name	CAS Registry No.	R	X	Y
Cephalosporin C (parent of class — essentially inactive)			C=O	CH_3CO_2-
7-Aminocephalosporanic acid	[957-68-6]	—	H	CH_3CO_2-
Cephalothin	[153-61-7]		C=O	CH_3CO_2-
Cephaloridine	[50-59-9]		C=O	Cephaloghycin	[3577-01-3]		C=O	CH_3CO_2-
Cephalexin	[15686-41-2]		C=O	H

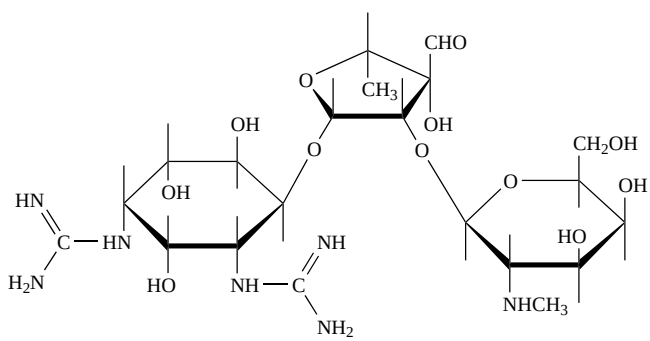
Note: Important cephalosporins not included in table include Cefamandole, cefazolin, Cefoxitin, cephapirin, cephradine.

soon followed cephalothin and was found to be 2 to 8 times more active than the latter against gram-positive organisms. In 1970, cephaloglycin became commercially available as the first orally effective broad-spectrum cephalosporin. Cephalexin is metabolically more stable than cephaloglycin. More recently available cephalosporins have included cephapirin, cephradine, and cefazolin.

The basic structure of the cephalosporins and structures of several of the antibiotics in this family are shown in Table 4.

Aminoglycosides. These drugs comprise a class of potent broad-spectrum antibiotics that are chemically characterized by basic carbohydrate moieties glycosidically bound to a cyclitol unit. In general, the aminoglycosides are effective against most gram-positive and gram-negative bacteria, as well as *Mycobacterium tuberculosis*. Because of their highly ionic nature, the aminoglycosides are not absorbed from the gastrointestinal tract and must be administered parenterally. In a small percentage of patients, prolonged use of this class of antibiotics can adversely affect the eighth cranial nerve, causing some impairment of hearing and balance.

Streptomycin. [CAS: 57-92-1] Discovery in 1944 of streptomycin (Structure 1) drew immediate interest because it was the least toxic of the broad-spectrum antibiotics known at that time. Indeed, streptomycin was used to treat many gram-negative microbial infections, but because of the ease with which organisms developed resistance to it during treatment, many of these applications were abandoned when the tetracyclines, discussed later, became available. Streptomycin was the first parenterally administered antibiotic active against many microorganisms, but during the last several years, its use has been limited essentially to three situations: (1) the initial treatment of serious tuberculous infections, when the principal drugs of choice (isoniazid, rifampin) cannot be used because of their adverse effects on a particular patient; (2) treatment of enterococcal and other infections, in which synergism between a penicillin and an aminoglycoside is desired; and (3) treatment of certain uncommon infections (plague and tularemia).

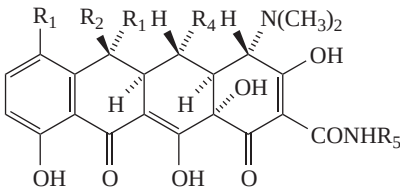


(**1**)

Kanamycin. [CAS: 8063-07-8] Considerably broader in spectrum than streptomycin, kanamycin is more effective against gram-negative bacilli (other than *Pseudomonas*) and also is effective to a degree against *Staph. aureus*. However, it is ineffective against streptococci and pneumococci. The availability of penicillinase-resistant penicillins and cephalosporins essentially obsoleted kanamycin as the primary drug in the treatment of staphylococcal infections. Kanamycin has been essentially replaced by gentamicin and other aminoglycosides which are less ototoxic (adverse to hearing), and which also have a wider range of antibacterial activity.

Gentamicin. [CAS: 14063-66-3] One of the successors of kanamycin, gentamicin possesses essentially the same spectrum as kanamycin, but is also active against *Pseudomonas aeruginosa*. An advantage of gentamicin is its penetration into pleural, ascitic, and synovial fluids where there is inflammation. Although not necessarily the drug of choice, gentamicin has been used in the treatment of acute cholecystitis, acute septic arthritis, anaerobic infections, *Bacillus* infections, gram-negative bacteremia, infective endocarditis, meningitis, osteomyelitis, peritonitis, staphylococcal infections, and tularemia, among others. In some situations, gentamicin acts synergistically with penicillin.

TABLE 5. STRUCTURES OF REPRESENTATIVE TETRACYCLINES



Generic or Chemical Name	R_1	R_2	R_3	R_4	R_5
Tetracycline	H	OH	CH_3	H	H
Chlortetracycline	Cl	OH	CH_3	H	H
Oxytetracycline	H	OH	CH_3	OH	H
Demethylchlortetracycline	Cl	OH	H	H	H
Methacycline	H	$=CH_2$	$=CH_2$	OH	H
Doxycycline	H	H	CH_3	OH	H
Rolitetracycline	H	OH	CH_3	H	
Note: Minocycline is not included in table.

Tobramycin. [CAS: 32986-56-4] Pharmacologically, tobramycin is quite similar to gentamicin. The drug is somewhat more active against *Ps. aeruginosa* than gentamicin. Tobramycin also acts synergistically with penicillin, but to a lesser degree than gentamicin.

Amikacin. [CAS: 37517-28-5] This drug is a semi-synthetic derivative of kanamycin. It is much less sensitive to the enzymes that inactivate aminoglycoside antibiotics. The spectrum is similar to that of gentamicin. Amikacin principally finds use in the treatment of infections arising from bacteria that are resistant to gentamicin and/or tobramycin.

Tetracyclines. These drugs comprise a family of broad-spectrum antibiotics possessing a common perhydronaphthacene skeleton. They have a wider range of antimicrobial activity than other classes of clinically useful antibiotics. See Table 5. The tetracyclines are active against many species of gram-positive and gram-negative bacteria, spirochetes, rickettsiae, and some of the larger viruses.

Chlortetracycline. [CAS: 57-62-5] The first member of this class to be isolated, chlortetracycline, was discovered in 1948 among the metabolites of *Streptomyces aureofaciens*. Oxytetracycline was isolated two years later from a S. rimosus fermentation. Both antibiotics quickly found wide medical use, not only because they were effective orally, but also because they were useful against a much wider spectrum of bacteria than penicillin G.

Chemical studies on chlortetracycline and oxytetracycline, which provided a basis for structure assignment, in general led to products with diminished or no antibacterial activity. In 1953, the first scientific reports appeared describing an active tetracycline prepared by chemical modification of a fermentation product. This was *tetracycline*, the parent member of this family of antibiotics, prepared by catalytic hydrogenolysis of chlortetracycline. It was more stable and better tolerated than its fermentation-produced progenitor, and almost completely displaced chlortetracycline from medical practice. Interestingly, tetracycline was later found in fermentation broths of a mutant strain of *S. aureofaciens* and also may be manufactured by this method.

Following the discovery of tetracycline, useful new drugs from chemical modification of tetracycline antibiotics were slow in coming, for the complexity and chemical lability of the tetracyclines did not render them amenable to facile systematic studies of the relationships between chemical structure and biological properties. Unlike the β-lactam antibiotics, where structural modifications were being sought mainly to improve their antibacterial spectra and potency, superior semisynthetic tetracyclines were obtained, in general, with improved pharmacokinetic properties, i.e., through such factors as rate of oral absorption, degree of serum protein binding, rate of urinary excretion, and biological half-life.

An effective approach to the discovery of superior tetracycline antibiotics stemmed from studies yielding tetracyclines modified at the C-6 position. Thus, demethylchlortetracycline and methacycline were found to be somewhat superior to tetracycline in terms of a longer serum half-life, and later compounds, such as doxycycline, were shown to exhibit near-ideal pharmacokinetics. Doxycycline, among a number of other tetracyclines, remains in wide use today.

Among the many diseases treated with tetracyclines are urinary tract infections, gonorrhea, nongonococcal urethritis, Rocky Mountain spotted fever, other rickettsioses, mycoplasmal pneumonia, chlamydial diseases (psittacosis, trachoma, lymphogranuloma venereum), brucellosis, plague, cholera, granuloma inguinale, syphilis, and gonococcal pelvic inflammatory diseases, particularly in a number of instances where a patient may be allergic to penicillin. Tetracyclines also have been used in the treatment of cystic acne.

Doxycycline has been reported as effective in the prophylaxis of traveler's diarrhea in Kenya. The tetracycline monocycline is sometimes used instead of the sulfonamides against noncardial infections. It is not used in connection with meningococcal infections.

Macrolides. The macrolides comprise a family of antibiotics chemically characterized by a macrocyclic lactone to which one or more sugars are attached. The compounds are often divided into various sub-groupings, but the group with antibacterial properties are known as *antibacterial macrolides*. They are distinguished chemically by having, in addition to the large lactone, various ketonic and hydroxyl functions and glycosidically bound deoxy sugars. A second grouping of commercial importance is known as the *polyene macrolides*, chemically characterized by extended conjugated double-bond systems. The polyenes are devoid of antibacterial activity, but are potent antifungal agents.

A number of the antibacterial macrolides have been found to be clinically useful chemotherapeutic substances, falling generally under the title of *medium-spectrum antibiotics*. This term is taken to mean that these substances are effective against most gram-positive bacteria and have a degree of activity against certain gram-negative organisms, such as *Haemophilus*, *Brucella*, and *Neisseria* species. The antibacterial macrolides also appear to inhibit certain pleuropneumonialike organisms.

Erythromycin. [CAS: 114-07-8] This is the principal drug in this category. Although available as the parent entity, semisynthetic derivatives have proved to be clinically superior to the natural cogener. Like the tetracyclines, synthetic transformations in the macrolide series have not significantly altered their antibacterial spectra, but have improved the pharmacodynamic properties. For example, the propionate ester of erythromycin lauryl sulfate (erythromycin estolate) has shown greater acid stability than the unesterified parent substance. Although the estolate appears in the blood somewhat more slowly, the peak serum levels reached are higher and persist longer than other forms of the drug. However, cholestatic hepatitis may occasionally follow administration of the estolate and, for that reason, the stearate is often preferred.

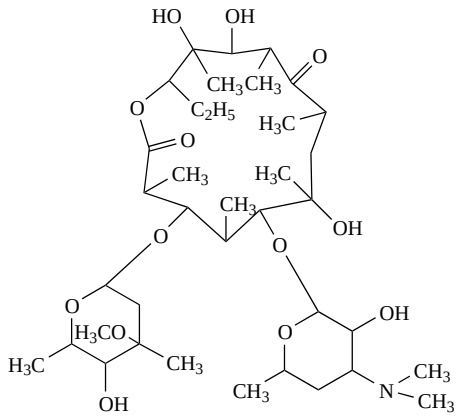
Erythromycin is effective against Group A and other nonenterococcal streptococci, *Corynebacterium diphtheriae*, *Legionella pneumophila*, *Chlamydia trachomatis*, *Mycoplasma pneumoniae*, and *Flavobacterium*. Because of the extensive use of erythromycin in hospitals, a number of *Staph. aureus* strains have become highly resistant to the drug. For this

reason, erythromycin has been used in combination with chloramphenicol. This combination is also used in the treatment of severe sepsis when etiology is unknown and patient is allergic to penicillin.

A structural representation of erythromycin is shown in Structure 2.

Other Antibiotics

Chloramphenicol. [CAS: 56-75-7] This compound is derived from *Streptomyces venezuelae* or by organic synthesis. It was the first substance of natural origin shown to contain an aromatic nitro group. Although the drug is a valuable broad-spectrum antibiotic, its use has been somewhat limited because of the occasional development of aplastic anemia in the patient. Thus, its use has been largely confined to its administration as the drug of choice in patients allergic to penicillin in connection with typhoid fever, nontyphoidal salmonelloses (due to ampicillin-resistant strains), *H. influenzae* meningitis, meningitis arising from *N. meningitidis*, and *Str. pneumoniae*. Because effective and safer drugs are not available, it is used for infections arising from *Bact. fragilis*. The drug is administered orally or intravenously.



(**2**)

Vancomycin. [CAS: 1404-9-6] This is a narrow-spectrum antibiotic and produced by *Streptomyces orientalis* or synthetically. Its effectiveness is essentially confined to the treatment of streptococci (including enterococci), pneumococci, staphylococci, and a few other gram-positive bacteria. Serious side effects include possible hearing loss and renal insufficiency, particularly when the drug is administered with an aminoglycoside.

Polymyxins. This is a generic term for a series of antibiotic substances produced by strains of *Bacillus polymyxa*. Various polymyxins are differentiated by letters A, B, C, D, and E. All are active against certain gram-negative bacteria. Polymyxin B and E (colistin) have been the most important in the past, but currently are only rarely used — because they have been replaced by more effective aminoglycosides. The B and E drugs are effective against most of the common aerobic gram-negative bacilli, but not *Proteus*, *Providencia*, and *Serratia*. Prior to their replacement by aminoglycosides, the polymyxins were used mainly in connection with infections arising from *Ps. aeruginosa*.

Spectinomycin. [CAS: 1695-77-8] This drug finds principal application in the treatment of gonorrhea. It should be noted that the antibiotic resistance among *N. gonorrhoeae* has caused a number of therapeutic problems. It has been found that only by escalating the antibiotic doses and using probenecid to retard the excretion of penicillin and ampicillin (the drugs of choice) has the continued effective use of penicillin, ampicillin, and tetracycline been possible. Even with modifications in the therapy, from 3 to 8% of cases fail to respond to the usual regimens for uncomplicated gonorrhea. Thus, the treatment of uncomplicated gonorrhea that fails to respond to the usual regimen is spectinomycin therapy.

Chemoprophylaxis with Antibiotics

In addition to their use in treating infections arising from bacteria and other microorganisms, antibiotics are also used in chemoprophylaxis, i.e., treating a patient before or shortly after the entry of pathogenic organisms. There are three common situations: (1) preventing infection following exposure to known pathogens; (2) preventing specific infections in highly susceptible individuals; and (3) preventing postoperative infectious complications.

Antibiotics in Feedstuffs

For several years, antibiotics have been used in feedstuffs, not only to lower the incidence of certain diseases in livestock, but antibiotics also play a function in the rate of growth of animals. As of the late 20th Century, the question of whether or not the use of antibiotics in livestock may have an adverse effect on human consumers of meat remained unresolved.

Manufacture of Antibiotics

Generally, most antibiotics and the starting materials for semi-synthetic antibiotics are manufactured by fermentation, with accompanying extraction, purification, crystallization, and packaging operations. Commercial fermenting vessels are stainless- or carbon-steel enclosed tanks with capacities up to several tens of thousands of gallons (many hundreds of hectoliters). Such factors as aeration, agitation, temperature, and pH must be monitored and controlled carefully.

The antibiotic-producing microorganism is grown in submerged culture in a fermentation medium containing various carbon, nitrogen, and trace-metal sources, required by the organism for its nutrition. The organism is grown under conditions of pure culture, that is, other microorganisms excluded from the fermentation inasmuch as the latter will compete for nutrients, may contribute undesirable contamination and reduce yield of the desired product. When the fermentation has reached peak potency (varies with each product), the antibiotic may be recovered by an extraction technique, such as distribution into a water-immiscible solvent, ion-exchange chromatography, or precipitation. Following extraction, purification and crystallization are carried out by procedures compatible with the physicochemical properties of the particular antibiotic being produced. A representative flow sheet is shown in Fig. 1.

ANTIBODY. This article gives a generalized description of antibodies and their role in the body's immune system. More details in terms of the most recent findings in this field are given in the entry on **Immune System and Immunology**. In medicine and physiology, immunity is the ability of the body to resist invasion by pathogenic organisms and substances. Immunity may be initially in place, that is, genetically ordered for a given species. Humans are naturally immune to canine distemper; dogs are immune to measles; rats are immune to diphtheria; and domestic fowls are immune to anthrax. Many other examples could be cited. Immunity may be acquired as the result of exposure to an invasive pathogen, triggering the immune system to construct cells that will be in reserve to resist subsequent invasions by the same pathogen. Immunity also may be acquired artificially through the use of preventive immunization techniques. Immunity is effected through antibodies.

Any substance that can provoke a response by the body's immune system is called an *antigen*. This property of an antigen is referred to as *immunogenicity*. Although the first antigens to be investigated were microorganisms and proteins foreign to the body, research during recent decades has been directed toward understanding the immune response at the molecular level — for it is at this level that the actions and reactions of the immune system occur. At the molecular level, numerous previously unsuspected complexities of the immune process have been revealed and still others are only partially understood, if at all. It has been discovered that several cell types, in addition to the lymphocytes, act cooperatively in effecting what might be called the total immune response. Although the lymphocytes appear to play the dominant role in the immune system, several other cells are now known to cooperate with the lymphocytes, and the functions of these other cells are no longer considered of secondary importance. Study of the antigens at the molecular level also has contributed to a much better understanding of the immune response.

Numerous molecules can evoke an immune response, sometimes when the responses from the standpoint of protecting body functions are not immediately obvious, other than that such molecules do not meet the criteria of "self" and "nonself" described later. In a general way, it may be observed that the immune system tends to have a bias toward suspicion and may, on occasion, overreact, as in cases of autoimmunity. Currently, it is generally hypothesized that recognition of antigens at the receptor sites of the lymphocytes is based upon the shapes of molecules, reminiscent of some of the current hypotheses concerning taste and odor receptors in the tongue and nasal membranes. Until the mechanism occurring at the receptor sites is more fully explained, numerous questions as regards what molecules do and do not evoke immune response will remain unanswered.

Considerable research with synthetic polymers comprised of various amino acids has been undertaken in an effort to determine the requirements of immunogenicity. It has been established, for example, that tyrosine as well as some other aromatic amino acids will confer immunogenicity to certain polypeptides which in they are not or are only slightly antigenic. Further, it has been found in such cases that the antibody is directed against the polypeptide and not the amino acid. Research with synthetic polymers led investigators to the finding that immune response is under genetic control, this based upon the observations that different animal strains and species respond differently to a given polymer. However, in a descriptive fashion, this principle had been demonstrated by the different reactions to antigens by various species many decades ago.

Although not catalytic in the usual sense, certain substances, known as *adjuvants*, are capable of enhancing the immunogenicity of certain antigens. Among the adjuvants are aluminum salts, bacterial endotoxins, bacillus Calmette-Guérin (BCG), *Bordetella pertussis*, and mycobacteria. These materials and this phenomenon have been important in immunity research. Sometimes adjuvants are used clinically in connection with certain immunizations, such as against tetanus.

Where antigens are introduced into the body intravenously, they usually travel rapidly to the spleen, followed by the fast production of an antibody. Subcutaneous or intradermal injection of antigens most frequently localizes in the lymph nodes and antigens that are inhaled favor local sensitization. In some cases, such as tetanus immunization, toxin produced by the bacteria may be slow and insufficient to provoke a significant immunologic reaction. Thus, the requirement for properly timed booster injections.

Clinical Use of Antigens. Without the benefit of understanding the complexities of the immune system, particularly at the molecular level, much progress was made over the years in taking advantage of certain antigens and a qualitative or descriptive understanding of the immune response. This was the early development of vaccines and antitoxins.

The history of the development of antitoxins in combating bacterial infection dates back to the early beginnings of organized bacteriology. Behring was the first to show that animals that were immune to diphtheria contained, in their serum, factors which were capable of neutralizing the poisonous effects of the toxins derived from the diphtheria bacillus. While this work was carried out in 1890 (prior to many of the great discoveries of mass immunization, and, prior to the much later discovery of antibiotics), it is interesting to note that a relatively limited place remains for antitoxins in the modern medical treatment, or prophylaxis, of a few diseases, such as tetanus, botulism, and diphtheria. In the case of diphtheria, equine antitoxin is the only specific treatment available. However, it is only reasonably effective if used during the first 48 hours of the onset of the disease. Trivalent (ABE) antitoxin is used in the treatment of botulism. In the treatment of tetanus, human tetanus immune globulin is preferred, but when it is not available, equine antitoxin is substituted. See **Antitoxin**.

For many years the preferred approach to immunity to infectious disease has been by development of active immunity through the injection of a vaccine. The vaccine may be either an attenuated live infectious agent, or an inactivated or killed product. In either case, protective substances called antibodies are generated in the bloodstream; these are described in the next section. Vaccines for a number of diseases have been available for many years and have assisted in the eradication of some diseases, such as smallpox. As new strains of bacteria and viruses are discovered, additional vaccines becomes available from time to time. See **Vaccines**.

Antibodies. Antigens are excluded from the body by skin and mucous membranes. If these barriers are penetrated, the foreign organism may be ingested by phagocytic cells (monocytes, polymorphs, macrophages) and subsequently destroyed by cytoplasmic enzymes. Some time after a foreign macromolecule has entered the body, induced mechanisms come into play. There are two basic biological manifestations of the immune reaction: (1) Immunity to infectious agents; and (2) specific hypersensitivity. Hypersensitivity, or the heightened response to an agent, can be divided into anaphylactic, allergic, and bacterial. Anaphylaxis, which can be produced by either active or passive sensitization, is a laboratory tool for studying the fundamental nature of hypersensitivity. The amounts of antigen and antibody involved, as well as the nature and source of the antibody, govern the extent of the reaction.

In immunity to infectious agents, some time after a foreign macromolecule has entered the body, induced mechanisms come into play, which result in the synthesis of specially adapted molecules (*antibodies*) capable of combining with the foreign substances which have elicited them. Most macromolecules (proteins, carbohydrates, nucleic acids, etc.) can function as antigens, provided that they are different in structure from autologous macromolecules, i.e., from the macromolecules of the responding organism.

Antibodies are proteins with a molecular weight of 150,000–1,000,000 and with electrophoretic mobility predominantly of gamma globulins. The combination between antigen and antibody results in inhibition of the biological activity of the antigen and leads to increased rate of ingestion (*opsonization*) of the antigen by phagocytic cells. In addition, combination of antigen and antibody results in the activation of a complex chain of interacting constitutive molecules — the *complement system* — leading to

lysis of the cell membranes to which antibody, directed against cellular antigens, is attached.

Biochemical Individuality. This is a unique quality, genetically determined, for each individual and is exhibited with respect to: (1) the composition of blood, tissues, urine, digestive juices, cerebrospinal fluid, etc.; (2) the enzyme levels in tissues and in body fluids, particularly the blood; (3) the pharmacological responses to specific drugs and poisons; (4) the biochemical responses to bacteria, fungi, and other microorganisms; (5) the quantitative needs for specific nutrients — minerals, amino acids, vitamins, etc. — and in a number of other ways, including reactions of taste and smell and the effects of heat, cold, and electricity. Although individual *similarities* are readily apparent at the macro level, each individual must possess a highly distinctive pattern, since the differences between individuals with respect to measurable items in a potentially long list are by no means trifling. Out of these relatively small, but distinct differences has risen the concept of the so-called normal individual, against which high and low levels of response are compared when considering the "chemistry" of a given individual.

Autoimmunity. A very important characteristic of the body's immune system is a capacity to distinguish between *self* and *non-self*. In terms of the immune system, the ability to make such distinctions proceeds at the biochemical level without conscious awareness of the individual. Less than a century ago, the ability of the body to distinguish self from non-self (foreign), at the biochemical level, was considered impossible. Over the years, however, much descriptive information accumulated which, without ample explanation, proved that the body does remember at the biochemical level. Seldom, for example, have medical records shown a second infection with mumps, measles, or smallpox, once an individual survived the first attack. The question, how does the body remember? remained a mystery for many decades until the concept of the immune system was first outlined in a very general way.

When the immune system functions property, which is the normal situation, antibodies to parts of the same body are not produced. But a condition known as *auto-immunity* can sometimes occur. In such circumstances, antibodies and sensitized (antigen-reactive) cells may be produced and directed against "self" antigens. To treat auto-immunity is one of the challenges of modern medicine. This auto-immunity mechanism may trigger some asthmatic paroxysms and is presently being considered as a suspect mechanism by cancer researchers — with considerable study being directed to tumor immunology. Some investigators hypothesize that the body system has the capacity to recognize neoplastic cells and to destroy them, but that in some individuals the process becomes inoperative, allowing the cells to multiply.

The ability of the body to tolerate self-antigens and thus to preclude auto-immunity is known as *immunological tolerance*. As early as 1959, some scientists suggested that the antigen-specific lymphocytes which interact with self-antigens are eliminated during the prenatal state. In recent years, the concept of *suppressor mechanisms* has been well received. In this concept, the immune system, responding to an antigen, in addition to producing antibodies and sensitized cells to combat foreign substances, also initiates various suppressor mechanisms, causing some mediation of the process. Such substances are termed *mediators*. This may explain why, in some clinical situations, an early and strong immune response may be due to deficiencies in the suppressor mechanisms; or, in contrast, a deficient immune response may not be caused by the lack of particular lymphocytes, but rather by over-reactive suppressor mechanisms.

A study of the body's immune system over the years has made possible the preparation of antitoxins and vaccines for preventing and treating many diseases. These studies have assisted in dealing with the problems of allergy and hypersensitivity and in finding partial or effective solutions to problems that arise from malperformance of the immune systems. Further progress is expected in the understanding and treatment of immune-system-related disorders, such as amyloidosis, macroglobulinemia, multiple myeloma, systemic lupus erythematosus, asthma, and various allergies, among others.

ANTIBODY CLASSES. Antibodies are glycoproteins belonging to the immunoglobulin family. The immunoglobulins have a common four-chain structure (two identical light chains and two identical heavy chains) and they can be divided into different classes (and subclasses) according to the isotype of the heavy chain. The heavy chain isotype will confer different structural and functional properties on each antibody class, so that each isotype will occupy a specific site in the body and have a specific role to play in the immune system.

Introduction

The basic structure of all immunoglobulin (Ig) molecules is a four-chain unit consisting of two identical, heavy (H) polypeptide chains and two identical, light (L) polypeptide chains linked by disulfide bonds (Figure 1; Kolar and Capra; and Padlan, refs.). The different polypeptide chains are composed of compact globular domains, the light chain has two domains and the heavy chain has four or five. Each domain is made up of about 110 amino acid residues that share the same three-dimensional structure, a compressed antiparallel β barrel, referred to as the immunoglobulin fold. The amino acid sequence of the amino (*N*)-terminal variable (V) domain of each polypeptide chain varies substantially, while the sequence of the other domains, the constant (C) domains, is more conserved within a given class or subclass.

The whole immunoglobulin molecule has a distorted Y shape with two identical arms (the Fab parts) joined to the stem (the Fc part) by a flexible hinge (Figure 1) [Padlan; and Ollmann-Saphire, et al.: refs.]. The Fab fragments contain the complete light chains paired with the V_H and C_H1 domains of the heavy chains and are responsible for the binding of antigen. The antigen-binding sites, located at the tips of the Fabs, are formed by six hypervariable polypeptide loops, the complementarity determining regions (CDRs): three from V_L and three from V_H. The Fc fragment contains the paired C_H2 and C_H3 (and C_H4) domains from both the heavy chains and is responsible for mediating the effector functions, such as complement activation and interaction with Fc receptors, aiming at the elimination of the antigen–antibody complexes (see Table 2).

There are two types of light chains, kappa (κ) and lambda (λ), which are common to the different immunoglobulin classes, but in a given immunoglobulin molecule both light chains are of the same type [Kolar and Capra, ref.]. The usage of κ and λ varies between species: in rats and mice, about 95% have κ light chains and 5% λ, whereas in humans the figure is closer to 60% κ and 40% λ. However, the human immunoglobulin classes and subclasses can be further differentiated in their usage of κ and λ, ranging from a ratio of $\kappa : \lambda$ of 8.0 (IgG4) to 0.3 (IgD). No functional differences have so far been found between antibodies with κ and those with λ light chains.

Depending on structural differences in the heavy chain constant regions, antibodies are divided into different classes (Table 1 and Figure 1; Kolar and Capra). In mammalian species, five classes–IgA (α), IgD (δ), IgE (ε), IgG (γ) and IgM (μ)–have been detected. Some of these classes can be further subdivided into subclasses. Many species have several subclasses of IgG, including humans, rats and mice, which have four subclasses, while rabbits seem to have only one. IgA exists as 13 subclasses in rabbits, while in humans there are two IgA subclasses and in rats and mice only one. No subclasses of IgD, IgE and IgM have been described so far. In addition, there are genetic variations in antibodies from members of the same species (polymorphism), and these allelic variations, denoted allotypes, represent polymorphic differences in the genes encoding the constant regions. Many allotypic variants have been defined, especially within the human population. It may be of interest to note that it appears that the immunoglobulin subclasses have arisen after speciation and the human subclasses cannot be compared with, for example, the four subclasses of IgG that have been identified in the mouse [Jefferis, ref.].

The hinge region, which shows the greatest variation between the human classes in heavy chain structures, varies in sequence, length, number of disulfide bonds and presence of carbohydrates, and is replaced by an

extra constant domain in IgE and IgM (Figure 1 and Table 2; Kolar and Capra; and Padlan). The Fc parts of human immunoglobulins have the same general structure, but the sequence homology is only about 30% and carbohydrate moieties may confer additional heterogeneity. Furthermore, the classes exist in different molecular forms–monomers (IgG, IgA, IgD, IgE), dimers (IgA) or pentamers (IgM).

The heavy chain isotype will confer different functional properties on each antibody class, so that each isotype will occupy a specific site in the body and have a specific role to play in defending the body against extracellular pathogens and their toxic products. Below, the properties of the human antibody classes are described in more detail.

IgG1–4

Occurrence and Physico-chemical Properties. The IgG class is evenly distributed between the intra- and extravascular pools and is the major immunoglobulin class in normal serum, accounting for 70–75% of the total immunoglobulin population (Table 2). The four subclasses occur in the proportions of 65, 23, 8 and 4%. IgG is a monomeric protein with a sedimentation coefficient of 7S and a molecular weight of about kDa. IgG3 is slightly larger than the other subclasses due to a slightly heavier $\gamma 3$ chain (a longer hinge). IgG is the least glycosylated immunoglobulin class (2–3 versus 7–18%), and the carbohydrate content is the same for all the four subclasses.

Structural Properties. From a structural point of view, IgG is the most well-characterized immunoglobulin class and it is used as a model for the basic four-chain unit described in the literature (Figure 1; and Padlan, ref.). The IgG subclasses display a 95% sequence homology, with the major differences located in the hinge region (Figure 2 and Table 2). IgG3 has (as IgD) a very long (about Å), extended hinge with several more disulfide bonds (not IgD) compared with the other IgG isotypes. Little is known about the three-dimensional structure of the hinge due to its flexible properties. To date, entire structures of IgGs with full-length hinges have been reported only three times [Ollmann-Saphire, et al.:]. Still, the hinge can be regarded as consisting of three parts: a flexible upper region, which allows the Fabs to rotate and to wag, and that also determines the separation of the Fab arms; a middle part that acts as a stiff spacer between the Fabs and Fc containing possible interchain disulfide bonds; and a lower region, which is also flexible and allows Fc to wag. The flexibility of human IgG decreases in the order IgG3 > IgG1 > IgG4 > IgG2. The observed variations in the hinge properties are of great functional importance as they allow the immunoglobulins to cope efficiently with different spacing's and orientations of antigenic epitopes.

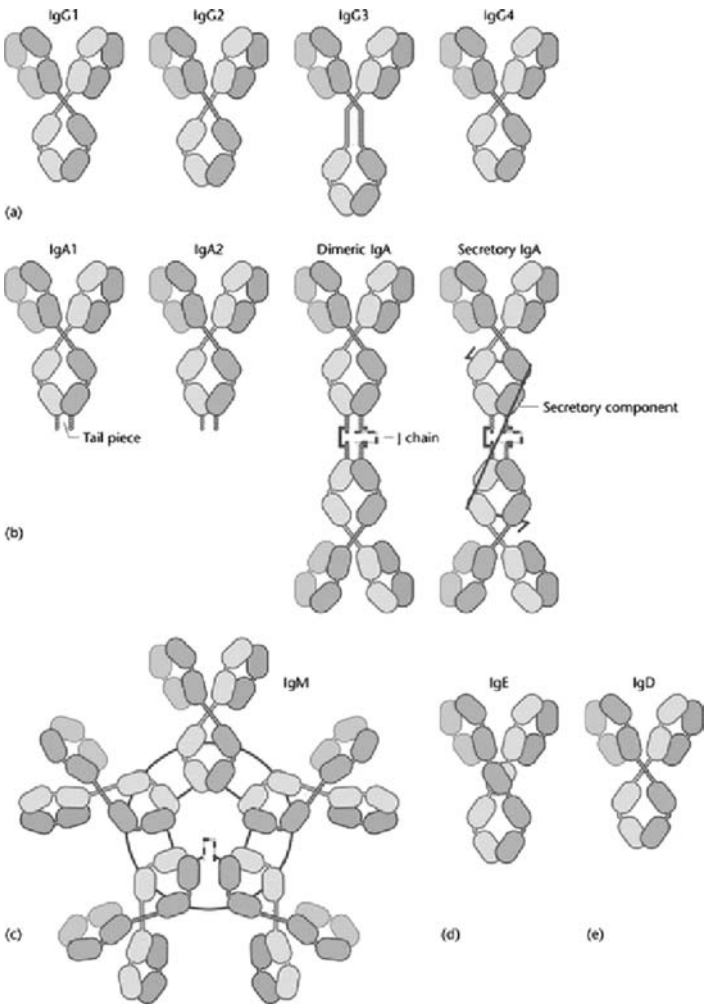

Fig. 2. Polypeptide chain structures of the human antibody classes and subclasses: (**a**) IgG subclasses; (**b**) IgA subclasses, dimeric IgA and secretory IgA; (**c**) IgM; (**d**) IgE and (**e**) IgD.

The overall shape of IgG Fc can be described as resembling a rabbit's head, with the two C_H2 domains protruding upwards from the unit formed by the C_H3 domains [Krapp, et al.:]. The paired C_H3 domains form a compact module. By contrast, the C_H2 domains are not paired, i.e. linked by any protein–protein interactions. Instead, the C_H2 domains interact, but only weakly, through their oligosaccharide chains. The oligosaccharide chains, which fill out a majority of the internal space in between C_H2 domains, are important for maintaining the correct conformation of the domains.

All immunoglobulins contain oligosaccharides at conserved residues in Fc, with each immunoglobulin class possessing a distinct pattern of *N*-linked carbohydrate structures [Rudd and Dwek, ref.]. The structure of these carbohydrates also varies considerably within an immunoglobulin class. The carbohydrate attached to Asn297 on IgG C_H2 consists of a set of about 30 structures based on a mannosyl-chitobiose core. No IgG subclass-dependent oligosaccharide patterns have been observed. In addition, both *N*- and *O*-linked carbohydrate moieties have occasionally been found within the variable regions of IgG where they may affect the binding of antigen.

Functional Properties. IgG is the major antibody class of the secondary response and is usually of higher affinity than IgM, which dominates in the primary response (Table 2). IgG, which is found in the blood and the extracellular fluids, can effectively neutralize toxins, viruses and bacteria, and efficiently opsonize them for phagocytosis, and activate complement via the classical pathway. In addition, maternal IgG can also be transported across the placenta and can consequently provide protection for the fetus.

These unique properties of IgG are thus conferred by the heavy chain isotype. It should, however, be noted that the IgG subclasses also differ with respect to their functional properties. The IgG subclass profile of a specific antibody response varies, as does the range of effector functions that may be activated to neutralize and eliminate the antigens. For example, IgG1 will dominate in an immune response against tetanus toxoid, IgG2 against polysaccharides, IgG3 against rhesus-D and IgG4 against factor VIII. There are three major classes of Fcγ receptors (FcγRI, FcγRII and FcγRIII), and the effector responses mediated via IgG's interaction with these receptors include phagocytosis, endocytosis, antibody-dependent cell-mediated cytotoxicity, the release of mediators of inflammation and the regulation of B-cell activation and antibody production [Burton and Woof, ref.]. The ability of the IgG subclasses to interact with the receptors varies, IgG1 and IgG3 being the most efficient. The FcγRs recognize overlapping, nonidentical binding sites located mainly in the lower hinge region of IgG. The carbohydrates in C_H2 will also indirectly affect the interaction by modulating the conformation of C_H2 [Krapp, et al.:].

IgG1 and IgG3 are efficient complement activators, while IgG2 is effective only at high concentrations, IgG4 is ineffective. The C1q-binding motif (Glu318, Lys320 and Lys322), which is located on C_H2, is present on all the IgG isotypes, but minor differences in the carboxy (*C*)-terminal of C_H2 are believed to be responsible for the observed differences in complement activation. Further, the oligosaccharides on Fc may also modulate this activity.

In contrast to the other Igs, all four IgG subclasses bind staphylococcal protein A and protein G, except for IgG3, which only binds the latter.

Further, antigen-induced conformational changes may occur in the Fc part of IgG (and IgM). However, the relevance of any conformational changes in IgG Fc for the elimination of the complexes is still a matter of debate (compare with the case of IgM).

IgA1–2

Occurrence and Physico-chemical Properties. IgA is the most abundant immunoglobulin class, approximately 60% of all immunoglobulins produced being of the IgA isotype (Table 2; Mestecky and Russel, ref.). However, serum contains relatively low levels of IgA since more than half of the IgA produced is selectively transported into external secretions. Furthermore, the half-life of serum IgA is much shorter than that of IgG. IgA exists in different molecular forms, monomeric (dominates in serum) and dimeric forms (dominate in mucosa), with some traces of even larger polymeric forms. In serum, the IgA1:IgA2 ratio is about 9:1, while the subclasses are more equally distributed in secretions. In addition, cells that produce IgA1 and IgA2 may also display a characteristic tissue distribution. While 90% of the cells in the bone marrow are IgA1 positive, mucosal tissues contain variable proportions of IgA1 and IgA2 cells, and IgA2 cells outnumber IgA1 cells in the large intestine. Both IgA1 and IgA2 have a molecular weight of kDa and a sedimentation rate of 7S, while secretory IgA (sIgA) is larger (kDa and 11 S). IgA2 is more glycosylated than IgA1, but both the isotypes are more glycosylated than IgG.

Structural Properties. In contrast to IgG, the structure of intact IgA is still unknown, but the classes are assumed to share the same overall structure (Figure 2). Still, IgA is the most heterogeneous among the immunoglobulins, and IgA has been found to exist as a T-shaped structure, in contrast to the common Y shape of the other classes. The recent crystal structure of IgA Fc was found to resemble those of the Fcs of IgG and IgE, but had differently located interchain disulfide bonds and external rather than interdomain *N*-linked carbohydrates [Herr, et al.:]. IgA1 and IgA2 differ with respect to 20 amino acids in the heavy chain constant regions, and they also differ in the hinge region where IgA2 lacks a proline-rich sequence of 13 amino acids, present in IgA1 (Table 2). In contrast to IgA2, IgA1 has (as IgD) *O*-linked carbohydrates located mainly within the hinge region. The differences in the hinge confer different susceptibilities to proteases, IgA1 being more vulnerable than IgA2. The hinges of IgA1 and IgA2 are probably, as that of IgG4, less flexible. In contrast to IgA2m(2) and Ig2m(3), the heavy and light chains of the IgA2m(1) allotype are not disulfide linked. Both IgA isotypes (as well as IgM) have an additional 18 amino acid *C*-terminal (tail piece) to the CH3 domain, which enables the formation of polymeric forms (aided by a separate 15-kDa polypeptide chain called the J chain).

When dimeric IgA is secreted into the mucosa, a process mediated by the poly-Ig receptor (pIgR), a portion of the receptor, the secretory component (sc), is proteolytically cleaved and becomes complexed with the dimer (sc is covalently bound to the C_H2 domain of both the molecules in the dimer), yielding the sIgA molecule. The secretory component adds proteolytic resistance to sIgA. The oligosaccharide structures of the IgA subclasses display a high degree of heterogeneity not only in the number

of carbohydrate chains but also in their compositions, IgA2 being more glycosylated than IgA1. As in the case of IgG, both IgA subclasses contain branched biantennary complex-type carbohydrate chains. High-mannose-type carbohydrate moieties have also been detected [Rudd and Dwek, ref.].

Functional Properties. IgA serves as the first line of humoral defense at mucosal surfaces where it neutralizes toxins and viruses and blocks the entry of bacteria across the intestinal epithelium (Table 2). In addition, polymeric IgA internalized by pIgR on epithelial cells may influence intracellular events such as neutralization of viruses within infected cells.

In contrast to IgG, IgA is a poor opsonin and a weak activator of complement. This distinction is not surprising, since IgA operates mainly in mucosa, where complement and effector cells are not normally present, while IgG operates in body tissues where these components are available. These features of IgA are in fact beneficial, as inflammatory reactions likely would affect the most important component of local defense in secretions, the integrity of the mucosal surface. In molecular terms, this inability to bind C1q is not surprising since neither IgA1 nor IgA2 possesses the homologue of the three-residue motif critical for C1q binding to IgG. Further, IgA may induce phagocytosis by binding to its cognate FcγaR expressed on neutrophils, eosinophils and cells of the monocyte/macrophage series. Neither staphylococcal protein A nor protein G is bound by IgA. In contrast to the function of the other immunoglobulin classes, the consequences of the IgA–antigen complexation are more subtle. Thus, IgA has been considered as a noninflammatory isotype capable of inhibiting vigorous reactions mediated by other isotypes or cells.

As in the case of IgG, the IgA subclass profile of an immune response may vary depending on the initiating antigen. For example, in external secretions, antibodies specific for protein antigens are mainly IgA1, while those against bacterial lipopolysaccharides are of the IgA2 subclass.

Further, the functional properties of IgA are (as those of IgG) affected by variations in the oligosaccharide moieties. For example, their ability to activate complement, react with carbohydrate-dependent cell receptors or bind to hepatocytes is markedly affected.

IgM

Occurrence and Physico-chemical Properties. IgM is predominantly found in the intravascular pool where it makes up 5–10% of the total immunoglobulin population (Table 2). The normal serum concentration is 0.5–2 mg mL^{-1}. IgM exists mainly as a pentamer with a molecular weight of kDa and a sedimentation rate of 19S. About 12–15% of the molecule is made up of carbohydrate moieties bound to the μ chains. IgM can also be found as a 7S monomeric part of a transmembrane antigen–receptor complex on B lymphocytes. Furthermore, a minor amount of monomeric IgM can be found in the circulation. The concentration of this 7S IgM is increased in some diseases such as rheumatoid arthritis and systemic lupus erythematosus [Davis and Shulman, ref.]. See also **Rheumatoid Arthritis**.

Structural Properties. The IgM molecule is a star-shaped pentameric polymer of the general four-chain immunoglobulin unit (two heavy μ chains and two light chains of either κ or λ type) with the Fc portions in the middle and the Fab parts pointing outwards (Figure 2c). Interestingly, IgM can adopt a crab-like structure when bound to its antigen (and the subsequent binding of complement is then no longer impaired by steric hindrance). This transition is made possible by the inherent flexibility between the $C_\mu2$ domains and the $C_\mu3$ domains. Crystallographic structure in solution data indicates that IgM can adopt some structural features not found in other isotypes [Corper, et al.:; and Volkov, et al.:].

The four-chain subunits in pentameric IgM are linked by disulfide bonds formed between the respective $C_\mu3$ domains and $C_\mu4$ domains (Cys337, Cys414 and Cys575). In addition, there is an acidic polypeptide, the J chain, which contains eight cysteine residues and links two of the monomers by disulfide bonds in the *C*-terminal part (Cys575) of the μ chains. This 15 kDa polypeptide is supposed to regulate and assist the polymerization of the subunits. B cells lacking the ability to synthesize J chains secrete IgM molecules with a hexameric structure [Randall, et al.:].

Compared to the γ chain, the μ chain has an extra constant domain (130 amino acids) but no hinge region (Table 2). The μ chain also has an additional 20 amino acid "tail"' polypeptide attached to the *C*-terminus of the $C_\mu4$ domain. Moreover, the monomeric 7S IgM functioning as a membrane-bound receptor has a 26 amino acid hydrophobic transmembrane polypeptide and a three amino acid intracellular peptide attached to its *C*-terminal end. Remarkably, nine of the transmembrane amino acid residues are hydrophilic. This amphiphatic property can be beneficial for binding to the other transmembrane proteins, which, together with monomeric IgM, form the multiprotein antigen–receptor complex.

The carbohydrate moieties are *N*-linked to the C_H1 (one), C_H2 (one) and C_H3 (two) domains of the μ chain. They contain mainly branched bi- and triantennary sialylated glycans, but also oligomannose structures. The "tail" piece attached to the C_H4 domain is also glycosylated and contains only oligomannose sugars. The glycosylation of μ chains in secreted monomeric IgM differs from that of the polymeric form, probably due to steric reasons that are a consequence of the state of polymerization [Rudd and Dwek, ref.].

Functional Properties. IgM is the first antibody produced by activated B cells in the primary antibody response (Table 2). The pentameric structure has the potency of binding 10 epitopes. However, due to steric hindrance the valence of IgM varies with the size of the antigen and the epitope density on the antigen. The intrinsic affinity for the individual subunits is mostly lower than that observed for IgG. Still, the multivalency of IgM makes it a potent binder and as such it can efficiently agglutinate and eliminate large particles such as microorganisms. It is also a potent activator of the complement system, making it highly cytolytic. Thus, IgM makes an efficient defense against different infectious agents. IgM can also act as an opsonin, but is not as effective as IgG. Monomeric IgM is the dominating antigen-binding receptor on B lymphocytes. Both in its monomeric and pentameric form, IgM has the ability to react as a destructive autoantibody. It can react with endogenous IgG (rheumatoid factor) or it can act as an antinuclear factor. IgM does not penetrate the placenta. This behavior, together with its ability to react with ABO blood group antigens, gives IgM a beneficial role in protecting the fetus against blood group incompatibility between the fetus and the mother [Davis and Shulman, ref.].

IgE

Occurrence and Physico-chemical Properties. IgE makes up about 0.002% of the total immunoglobulin pool (Table 2). B cells secreting IgE are found in the circulation, skin, lungs and gut. IgE mainly exists bound to receptors on the surface of basophils and mast cells, but also on eosinophils, cutaneous Langerhans cells, dermal and peripheral blood dendritic cells and monocytes. Fifty per cent of the IgE is found in the intravascular space with an exceedingly low quantity present in serum, 17-ng mL$_{-1}$. The amount is elevated in allergic conditions and parasitic infections. Its molecular weight is kDa, with 15–18% carbohydrate and a sedimentation rate of 8S. The catabolic rate of IgE is very high, 89%, and its half-life is 2–3 days [Sutton and Gould, ref.]. See also **Allergy**.

Structural Properties. IgE shares the basic four-chain unit structure of IgG and IgA, but, like IgM, has an extra heavy chain constant domain and no hinge region (Figure 2d and Table 2). There are two intrachain disulfide bonds between the ε chains, one on each side of the $C_\varepsilon2$ domain. IgE can adopt an unusual bent structure upon binding to its Fc receptor. This partial folding takes place in the $C_\varepsilon2 - C_\varepsilon3$ region, resulting in a shortening of the distance (7 nm in the bent configuration and 17.5 nm in the planar mode) between the *N*- and *C*-terminal parts of the molecule [Sutton and Gould; and Wan, et al.: refs.]. IgE has several potential sites that can be glycosylated. On average, there are four *N*-linked oligosaccharide chains found on each IgE molecule. A mixture of oligomannoses are bound to the Asn residues 164 ($C_\varepsilon1$), 275 ($C_\varepsilon2$), 379a ($C_\varepsilon3$) and 401 ($C_\varepsilon3$).

Functional Properties. The concentration of IgE in serum and anatomical places susceptible to invasion of pathogens is small (Table 2). In spite of this, its action through a network of cells and receptors makes it very effective both as a part of the first-line defense mechanism and as a mediator of harmful allergic reactions.

The binding of IgE to antigen results in a range of cellular responses, which in turn lead to physiological and anatomical phenomena, such as inflammation, itching, coughing, bronchoconstriction and mucus secretion, with subsequent elimination of the invading organisms from the body. Allergy is caused by an overproduction of IgE in response to environmental agents like pollen, house dust mites, animal danders, food and insect venoms, leading to disorders like asthma, allergic rhinitis, atopic dermatitis and, in the worst case, an anaphylactic shock [Sutton and Gould, ref.]. See also **Asthma**.

IgE elicits its action through binding to Fc ε receptors present on the surface of mainly mast cells and basophils, but may also bind to receptors on several other cell types. Two types of receptors have been identified: the FcεRI high-affinity receptor and the FcεRII low-affinity receptor, CD23. Crosslinking of receptors through binding of multivalent antigens to adjacent receptor-bound IgE molecules triggers the release of vasoactive amines such as histamine and serotonin, and inflammatory mediators such as leucotrienes and prostaglandins as well as the synthesis of a variety of cytokines initiating an allergic inflammatory response. The asymmetrical bent structure of the IgE-molecule might explain its high affinity (a very slow off rate) for the FcεRI, contributing to its ability to cause a persistent allergic reaction [Wan, et al.:].

IgD

Occurrence and Physico-chemical Properties. IgD does not occur in all species, but it is present in most mammalian and avian species tested and in some fish and xenopus [Preud'homme, et al.:; and Vladutiu, refs.]. It is found mainly as the major membrane-bound receptor on B lymphocytes where it is coexpressed together with 7S IgM. Kinetically, IgD is expressed after IgM, but they have the same specificity when expressed on the same cell. Upon antigen stimulation, IgM is secreted while the expression of IgD is turned off. IgD makes up about 0.25% of the immunoglobulin population and is present in serum only in minor amounts, 0.3–40 $\mu g\,mL_{-1}$ (Table 2); 75% of the IgD is found in the intravascular pool. IgD has a short half-life of 3 days, and a turnover rate of 37% of the intravascular pool per day. Its molecular weight is 180 kDa and its sedimentation rate is 7S [Reth, ref.].

Structural Properties. Like the other immunoglobulins, IgD has the basic four-chain unit structure (Figure 2e). The σ chain has an extended (64 amino acid residues) and flexible hinge region as well as an Fc-part that is less compact compared to the Fc-part of other immunoglobulin classes (Table 2). This structural feature enhances the antigen binding but also makes IgD more susceptible to proteolytic cleavage than the other isotypes [Vladutiu, ref.]. IgD is also rather heat labile. There is a single disulfide bond connecting the two heavy chains. The cell-bound form has a transmembrane portion similar in structure to that found in membrane-bound IgM, but compared to the transmembrane peptide in IgM only five of the residues in the IgD peptide are hydrophilic. Like IgM, IgD is bound to the membrane as a multiprotein complex with an intracellular piece of three amino acids [Reth; and Preud'homme, et al.:].

IgD has a high content of carbohydrates, up to 18%. There are three *N*-linked oligosaccharides. One is found in the $C_\delta 2$ domain (Asn297) and contains a high content of mannose, and two (Asn387 and Asn437) in the $C_\delta 3$ domain. Asn387 contains biantennary structures of complex glycans with fucose and sialic acid found on them. Asn437 also contains biantennary oligosaccharides, but no fucose or sialic acid. The *N*-terminal half of the hinge region contains 5–7 *O*-linked oligosaccharides. The *C*-terminal half of the hinge region is rich in charged residues, making it susceptible to proteolytic degradation [Rudd and Dwek; and Preud'homme, et al..].

Functional Properties. The precise function of IgD still remains to be revealed (Table 2). IgD has been suggested to play a role in B-cell triggering, development of tolerance and in the process of immunological memory. Binding of IgD to IgD receptors on T cells leads to an upregulation of these receptors, implicating an immunoregulatory role for IgD. This augmentation property of IgD has been related to its carbohydrate moieties. IgD might also enhance the protective antibody response of the IgM, IgG and IgA classes. Autoantibodies of IgD type have been described, as antinuclear factors in systemic lupus erythematosus, against insulin in diabetes and against thyroglobulin in Hashimoto disease. IgD antibodies directed against external antigens have also been described in addition to the ability of IgD to induce cytokine production [Blattner and Tucker; and Vladutiu, refs.].

ANTICAKING AGENTS. Some products, particularly food products that contain one or more hygroscopic substances, require the addition of an *anticaking agent* to inhibit formation of aggregates and lumps and thus retain the free-flowing characteristic of the products. Calcium phosphate, for example, is commonly used in instant breakfast drinks and lemonade and other soft-drink mixes.

The general function of an anticaking agent can be described by using silica gel as an example. Generally anticaking agents are available as very small particles (ranging from 2 to 9 micrometers in diameter). A typical application for silica gel is admixture with orange-juice crystals to assure a free-flowing product, avoiding formation of crystal cakes and hard lumps. The very high adsorption properties of the anticaking substance removes moisture that can cause fusion. The billions of extremely fine, inert particles coat and separate each grain of powder (product) to keep it free flowing. Many anticaking agents, including silica gel, also act as dispersants for powdered products. Many food products, when stirred into water, tend to form lumps that are difficult to disperse or dissolve. The agent not only improves flow properties, but also increases speed of dispersion by keeping the food particles separated and permitting water to wet them individually instead of forming lumps. As is true with so many food additive chemicals, anticaking agents serve multiple functions. In addition to acting as an anticaking and dispersing agent, silica gel also can be used as a moisture scavenger and carrier. Some additives, when they are capable of serving several functions, may be called *conditioning agents*.

Anticaking agents commonly used include: calcium carbonate, phosphate, silicate, and stearate; cellulose (microcrystalline); kaolin; magnesium carbonate, hydroxide, oxide, silicate, and stearate; myristates; palmitates; phosphates; silica (silicon dioxide); sodium ferrocyanide; sodium silicoaluminate; and starches.

ANTICANCER DRUGS (The History). Collectively, cancers represent one of the leading causes of death in the western world and have the potential to become the number one killer in the early part of this century. While educational programs aimed at reducing risks from heart disease (the present number one killer) are paying dividends, the identified risk factors for many cancers are less pronounced, making prevention more difficult. Cancer chemotherapy therefore continues to play an increasingly important role in the management of malignancies, either directly or as an adjuvant to surgery and/or radiotherapy. A variety of agents have been clinically approved, often prescribed in the form of combination chemotherapy "cocktails," Although our understanding of the mechanisms of many of these agents has come about only very recently, the history of cancer chemotherapies dates back into the nineteenth century. This overview highlights landmarks in this area, and some of the key players responsible for its evolution. See also **Cancer and Oncology** and **Cancer Research (The History)**.

The Early Beginnings

The origins of documented cancer chemotherapy date back to 1861, when Robert Bentley at Kings College London referred to the local antitumor effect of an extract from the roots of *Podophyllum peltatum*. Indeed, this extract was even listed in the "Materia Medica" list of the first *US Pharmacopoeia*, issued in 1820. In 1881, Podwyssotzki found the active principle of the *Podophyllum* root to be a neutral crystalline substance that was named picropodophyllin, which was associated with an inactive resin-acid named picropodophyllic acid: collectively, these two compounds were referred to as podophyllotoxin. In 1946, the mechanism of tumor suppression was elucidated, when King and Sullivan reported that podophyllotoxin inhibits the formation of the mitotic spindle, thereby holding dividing cells at metaphase. This finding subsequently inspired the design and chemical synthesis of two structural analogues — etoposide and teniposide — that were developed at Sandoz in the late 1960s and early 1970s. Interestingly, the two analogues are also able to inhibit the action of an important DNA regulatory enzyme known as topoisomerase II. Both of these compounds show activity against small-cell lung cancer, testicular cancer, lymphomas and leukaemias, and etoposide is also effective against many brain tumors. See also **Leukaemias**.

Mustard Gases

The history of systematic clinical chemotherapy dates back to the period following World War I, however, and involves the warfare agents collectively known as mustard gases. Krumbhaar's group at the University of Pennsylvania, Department of Research Medicine conducted a study on the effects of mustard gas on soldiers who were killed after exposure to this agent during the war. The results, determined from a total of 75 autopsies, revealed that in addition to other phenomena, extreme depression of leucocyte cell numbers had occurred. Concurrent research conducted at the US Chemical Warfare Service provided additional evidence on the effects of mustard gases. In this clinical study, rabbits injected with doses near to the lethal limit showed a pronounced drop in leucocyte numbers immediately after injection, and damage to bone marrow was also observed. This study served to formally attribute leukopenia to the principal constituent of mustard gas — dichloroethyl sulfide.

Cancers typically divide at a faster rate than healthy tissue, with few exceptions; thus cytotoxins that affect cell division have a more pronounced impact on cancers than on healthy tissues. There are important exceptions to this generalization, however, since the bone marrow tissue, gastrointestinal tract tissue and hair follicles also divide at a much faster rate than other tissues (this in part accounts for the common side effects of cancer chemotherapy). The realization that the observed leucopenia was largely a result of the mustard gases inflicting damage to rapidly dividing cells, and its potential for the control of cancers was then formally pursued following World War II, when the first clinical chemotherapy trials were conducted. Initially, β-chloroethyl sulfides and close analogues β-chloroethyl amines were studied, and by the 1960s dozens of other analogues of mustard gas had been chemically synthesized and evaluated, including prodrug forms developed at ASTA Medica that became activated *in vivo*. This ultimately led to the eventual incorporation of "nitrogen mustards" in established chemotherapy regimens. To this day, the first clinical candidate, and one of the simplest members of this class, mechlorethamine, is still used in the control of non-Hodgkin lymphoma, and structural relatives abound, including cyclophosphamide (employed against leukemia, lymphoma, breast cancer, lung cancer, prostatic cancer and ovarian cancer), chlorambucil (used for treatment of chronic lymphocytic leukemia), and melphalan (approved for multiple myeloma, ovarian cancer and as an adjuvant in primary breast cancer management).

As a result of the findings that natural and synthetic substances alike could exhibit antitumor activity, by 1955 the National Cancer Institute (NCI) (U.S. National Institutes of Health) had established a screening program to test new materials for their effectiveness against a selected panel of cultured tumor cell lines. The screening program is still in existence today (over 60 tumor cell lines are currently used) and has played a significant role in the identification of lead compounds, critical to the development of both rationally designed agents, and those that have resulted from serendipity.

Natural Products

An important source for anticancer agents has traditionally been fermentation products. The clinically effective agent mitomycin C (mutamycin) was discovered at the Kitasato institute in Japan in 1956 from a culture of *Streptomyces caespitosus*. Subsequent work at the Bristol-Myers company (later Bristol-Myers-Squibb) has resulted in many analogues, and the parent structure is still used in combination chemotherapy with other agents despite its toxicity, chiefly myelosuppression. Other notable fermentation products include the structurally related anthracycline antibiotics daunorubicin and doxorubicin, both isolated from *Streptomyces peucetius* in the early 1960s. Although several hundred synthetic analogues of these natural products have been evaluated, only a handful show any additional benefit over the parent structures, which are still used for the management of acute lymphocytic and myelocytic leukemia, despite their cardiotoxic side effects. Plant and marine sources are also rich in compounds exhibiting anticancer activity. Among the earliest examples were vinblastine and vincristine. This study originated from extensive reports that a tea made from the leaves of *Vinca rosea* was effective for the treatment of diabetes mellitus. Further research revealed that when constituents of the material were injected into rats, a number of their cellular blood components were severely decreased. Researchers at Eli Lilly then began investigating this same plant in order to isolate a substance that had shown increase in lifespan of mice injected with leukemia cell lines. In 1965, Gordon H. Svoboda succeeded in isolating vinblastine, and later, related substances, including vincristine. Vincristine was ultimately found to be extremely effective in the clinical treatment of acute leukemia in children, while vinblastine has proved useful against a wide variety of tumors. See also **Alkaloids** and **Kitasato, Shibasaburo (1852–1931)**.

The discovery of vinblastine and vincristine started an extensive search by the NCI for other antitumor agents found in plants and their natural products. Another important antitumor agent, camptothecin owes its origin to serendipity. Seeds of the Chinese plant *Camptotheca acuminata* were originally shipped to the United States in the 1950s via the New Crops Research Branch of the Plant Introduction Station in Maryland, and in 1954 were examined for biological activity. Encouraged by preliminary antitumor activity against carcinoma line 755, workers at the Research Triangle Institute in North Carolina succeeded in the isolation and structural determination of the constituent camptothecin in 1966. The discovery was in fact made by Drs Monroe E. Wall and Mansukh C. Wani, the same scientists who later went on to discover Taxol.

Synthetic Agents

The majority of advances in the field, however, have been made by synthetic chemists working on traditional lead compound modification. Prominent examples include mitotane, ultimately developed as a result of research into the insecticide DDT conducted by Nelson and Woodard; the discovery by Farber of a new class of antimetabolites that led to the development of methotrexate; Heidelberger's inspired design of the commonly used antimetabolite 5-fluorouracil; and the work at the Southern Research Institute that led to the compound, N,N'-bis(2-chloroethyl)-N-nitrosourea, traditionally known as BCNU. As in the case of mitotane, serendipity often plays a role in discovery. A classic example was the drug mitoxantrone, developed originally by Allied Chemical as in ink! An anthracenedione compound developed by Allied was submitted to the NCI for routine chemical screening. The compound showed an unexpectedly high degree of activity in the screen testing procedures. The NCI had previously evaluated many synthetic anthracenediones in their program, but

none of these derivatives showed any antineoplastic activity. Allied thus granted the NCI permission to perform extensive studies on the promising lead compound, who then contracted the Midwest Research Institute to synthesize analogues. Of 47 new compounds synthesized, none showed any improvement in activity. This setback finally led to researchers comparing the structure of the original Allied compound with that of a known antitumor agent adriamycin. Structural modifications were made to the original compound using adriamycin as a superimposable pattern, and the compound 1,4-dihydroxy-5,8-bis[2-[(2-hydroxyethyl)amino]ethyl]amino-9,10-anthraquinone (DHAQ) was developed. DHAQ showed potent antineoplastic activity at one-tenth of the dosage that the original compound required for activity, and ultimately led to clinical use under the name mitoxanthone. Indeed, many advances have typically been made by synthesizing structures closely related to bioactive natural products. Synthetic analogues of camptothecin are currently undergoing clinical trials and one of these, topotecan, is now on the market. In May of 1997, Bristol-Myers-Squibb and Research Triangle Institute entered into a collaborative agreement to explore and develop new synthetic analogues of the camptothecins.

One of the most promising and publicized antitumor agents to be developed in recent years is the natural product paclitaxel (Taxol). This compound was first isolated from the bark of the pacific yew *Taxus brevifolia* during a project sponsored by the US Department of Agriculture and the NCI. The exact mechanism of its cytotoxic action was realized in 1979 when S. B. Horwitz found that Taxol interacts with a cell's microtubules, promoting microtubule assembly and inhibiting tubulin disassembly. Initial concerns for its use in the clinic focused on supply — it was calculated that the bark of 3–6 entire 100-year-old tall trees would be needed to provide enough dose (2 grams) for clinical trials for just one person. Following a challenge to the organic synthesis community, a semisynthetic approach was developed, whereby the main body of the structure, available in seemingly renewable quantities from the needles of the English yew, *Taxus baccata*, was coupled to a synthetic "side chain" to complete the synthesis. In late 1992, the FDA approved Taxol for the treatment of ovarian cancer, and in 1994 it was approved for treatment against breast cancer, becoming one of the most promising anticancer agents to emerge since World War II.

Future Directions

From their humble origins, advances in cancer chemotherapy drug design now progress at a very fast pace. Coupled with our increased understanding of tumor biology and cell signaling pathways, it is thus very likely that advances in cancer chemotherapy will accelerate over the next few decades. At the time of writing, numerous promising research areas are developing momentum, including specific cell cycle inhibitors, antihormones, angiogenesis inhibitors, and anti-gene approaches. As we refine our understanding of the genetic links to cancers, it is also likely that emphasis may shift from cancer chemotherapies to cancer chemopreventatives.

ANTICATHODE. In an x-ray tube, the target on which the electron beam is focused and from which the x-rays are radiated.

ANTICLINE. A folded structure involving bedded rocks in which the strata are arched upward so that the beds bend downward on either side See Fig. 1. These downward-bending beds constitute the limbs of the fold.

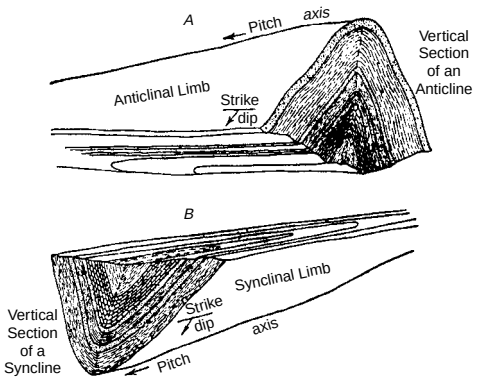

Fig. 1. Parts of folds. (*Willis, U.S. Geological Survey*.)

The angle that the beds on the limbs of the fold make with the horizontal is spoken of as the dip. The term dip is also used to indicate the inclination of bedding in other structures.

Anticlinal arches may be broad and gentle or sharp with a steep dip, symmetrical or asymmetrical, or may be complicated by minor folds on the limbs. Anticlinal folds may be of sufficient magnitude to be measured in miles (kilometers), involving great thicknesses of sediments, or they may be so small as to be measured in inches (centimeters).

The direction of prolongation of the fold is termed the axis of the fold, and if not exactly horizontal the angle of inclination of the top bed of the anticline is called the pitch. Plunge is used as a synonym for pitch by some geologists.

ANTICLINORIUM. A composite anticlinal structure of folded beds is called an anticlinorium; a composite synclinal structure is called a synclinorium. The latter term, however, should be applied only to the compressed sedimentary filling of a geosyncline.

ANTICOAGULANTS. These are substances that prevent coagulation of the blood. For blood investigations made outside the body, sodium or potassium citrates, oxalates, and fluorides are sometimes used. For blood that is to be used for transfusions, sodium citrate is used.

Organic anticoagulants are used in vivo in the treatment of numerous conditions where blood coagulation can be dangerous, as in cerebral thrombosis and coronary heart disease, among others which will be described later. The main anticoagulants used are heparin and coumarin compounds, such as warfarin.

Heparin. [CAS: 9005-49-6] A complex organic acid (mucopolysaccharide) present in mammalian tissues and a strong inhibitor of blood coagulation. Although the precise formula and structure of heparin are uncertain, it has been suggested that the formula for sodium heparinate, generally the form of the drug used in anticoagulant therapy, is $(C_{12}H_{16}N_2Na_3)_{20}$ with a molecular weight of about 12,000. The commercial drug is derived from animal livers or lungs.

Heparin is considered a hazardous drug. Heparin may be the leading cause of drug-related deaths in hospitalized patients who are relatively well (Porter and Jick, 1978). It has been reported (Bell, et al., 1976) that some patients who receive continuously infused intravenous heparin develop *thrombocytopenia* (condition where the platelet count is less than 100,000 per cubic millimeter). Some authorities believe that the risk of thrombocytopenia associated with porcine heparin may be less than the risk associated with heparin of bovine origin.

Heparin, in addition to inhibiting reactions that lead to blood clotting, also inhibits the formation of fibrin clots, both in vitro and in vivo. Heparin acts at multiple sites in the normal coagulation system. Small amounts of heparin in combination with antithrombin III (heparin cofactor) can prevent the development of a hyper-coagulable state by

inactivating activated factor X, preventing the conversion of prothrombin to thrombin. Once a hyper-coagulable state exists, larger doses of heparin, in combination with antithrombin II, can inhibit the coagulation process by inactivating thrombin and earlier clotting intermediates, thus preventing the conversion of fibrinogen to fibrin. Heparin also prevents the formation of a stable fibrin clot by inhibiting the activation of the fibrin, stabilizing factor. The half-life of intravenously administered heparin is about 90 minutes.

Coumarin. [CAS: 91-64-5] Oral anticoagulants can be prepared from compounds with coumarin as a base. Coumarin has been known for well over a century and, in addition to its use pharmaceutically, it is also an excellent odor-enhancing agent. However, because of its toxicity, it is not permitted in food products in the United States (Food and Drug Administration). One commercial drug is 3-(alpha-acetonyl-4-nitrobenzyl)-4-hydroxycoumarin. This drug reduces the concentration of prothrombin in the blood and increases the prothrombin time by inhibiting the formation of prothrombin in the liver. The drug also interferes with the production of factors VII, IX, and X, so that their concentration in the blood is lowered during therapy. The inhibition of prothrombin involves interference with the action of vitamin K, and it has been postulated that the drug competes with vitamin K for an enzyme essential for prothrombin synthesis.

Another commercial drug is bis-hydroxy-coumarin, $C_{19}H_{12}O_6$. The actions of this drug are similar to those just described.

Warfarin. [CAS: 81-81-2] This compound is also of the coumarin family. The formula is 3-(alpha-acetonylbenzyl)-4-hydroxycoumarin. In addition to use in anticoagulant therapy in medicine, the compound also has been used as a major ingredient in rodenticides, where the objective is to induce bleeding and, when used in heavy doses, is thus lethal. The compound can be prepared by the condensation of benzylidene-acetone and 4-hydroxycoumarin.

The anticoagulant action of warfarin is through interference of the gamma-carboxylation of glutamic acid residues in the polypeptide chains of several of the vitamin K-dependent factors. The carboxylation reaction is required for the calcium-binding activity of the K-dependent factors. Because of the reserve of pro-coagulant proteins in the liver, usually several days are required to effect anticoagulation with warfarin.

Warfarin antagonists include vitamin K, barbiturates, glutethimide, rifampin, and cholestyramine. Warfarin potentiators include phenylbutazone, oxyphenbutazone, anabolic steroids, clofibrate, aspirin, hepatotoxins, disulfiram, and metronidazole. In patients undergoing anticoagulation therapy with warfarin, it has been found that cimetidine (used in therapy of duodenal ulcer) may increase anticoagulant blood levels and consequently prolong the prothrombin time.

Anticoagulation Therapy

Prior to administration of anticoagulant drugs, patients must be carefully evaluated. Anticoagulant drugs are to be avoided if any of the following conditions prevail: a history of abnormal bleeding, recent corticosteroid therapy, recent intra-ocular or intracranial bleeding, recent pericarditis, and recent peptic ulcer or esophageal bleeding. A history of the individual's use of antiplatelet agents, such as aspirin, dipyridamole, phenylbutazone, and indomethacin, should be obtained and evaluated. Anticoagulant drugs should be administered with particular care during pregnancy. Heparin does not anticoagulate the fetus because it does not cross the placenta. Warfarin, on the other hand, anticoagulates both the mother and the fetus. Problems may arise from the administration of warfarin during pregnancy, particularly during the first trimester.

The bile sequestrant cholestyramine is frequently used in the treatment of familial hypercholesterolemia. This drug not only binds cholesterol, but also a number of other drugs, including anticoagulants.

Deep Vein Thrombosis and Pulmonary Embolism. Prompt administration of intravenous heparin is indicated in the treatment of this condition. Heparin is fast-acting, prevents further thrombus formation, and when used in therapeutic doses, also prevents the release of serotonin and thromboxane A_2 from platelets that adhere to thrombi that embolize to the lungs. The size of the dose required varies with a number of patient conditions. Several authorities are convinced that the continuous (pump-driven) infusion method is superior to intermittent injections.

Heparin is usually administered for a period ranging from 7 to 10 days. Frequently, during the last half of this period of heparin therapy, oral anticoagulation will be commenced with warfarin. The time during which oral anticoagulation administration should be continued may be three months or longer after clinical evidence that the venous thrombosis has subsided; and for one year after pulmonary embolism.

Cerebral Thrombosis. Among the specific modes of treatment that have been used in anticoagulation therapy. Many authorities suggest the use of anticoagulants for an evolving stroke in an effort to arrest the propagation of thrombus. In this procedure, a lumbar puncture is usually prepared first. If there is a presence of red blood cells in the spinal fluid, this infers a hemorrhagic infarction, in which case anticoagulants are withheld for a minimum of 48 hours. If the fluid is clear, heparin can be administered by continuous intravenous drip.

Cerebral Transient Ischemic Attack (TIA). Aspirin, as a platelet-inhibiting agent, has been found effective in the medical management of TIA. As studied by the Joint Committee for Stroke Facilities in the late 1970s, the results of anticoagulant therapy for TIA were reported as vague, but possibly this is due to poorly planned tests. However, anticoagulant therapy is considered a proper mode of treatment for persons who cannot tolerate aspirin, with warfarin the drug of choice. Oral anticoagulants are not given to persons with gastrointestinal ulcerations, severe hypertension, bleeding tendencies, or renal or hepatic failure.

Coronary Heart Disease. Long-term preventive anticoagulation with warfarin and similar drugs in patients with coronary artery disease has decreased in popularity during the last few years because evidence collected over a long period of time has not shown, in a convincing way, that the therapy is of value. As of the late 1980s, the therapy of choice included the use of platelet-inhibiting drugs, notably acetylsalicylic acid (aspirin), sulfinpyrazone, and dipyridamole.

Prevention of Thromboembolism. Anticoagulation for prevention of thromboembolism is not used to the extent that it was once employed in the 1950s. Some professionals have reexamined the data of that period, however, and have concluded that anticoagulant therapy does have value, but their observations have not been widely accepted.

In present times, because of early mobilization and shorter stays in hospital, venous thrombosis in the legs and resulting pulmonary embolism has declined to a large degree. In persons with acute myocardial infarction, prophylactic low-dose heparin has reduced the incidence of venous thrombosis in the legs. It is considered as a reasonable alternative to warfarin in selected patients. Preventive anticoagulation may be indicated in some cases to prevent strokes due to left ventricular mitral thrombi embolizing in the brain.

Prosthetic Valve Endocarditis. Anticoagulants are sometimes used in the overall treatment of PVE even though there are risks of intracerebral hemorrhage or hemorrhagic infarction. Countering this risk, however, is the risk of major thromboembolic complications involving the central nervous system that may occur in the absence of continued anticoagulant therapy.

Anticoagulant therapy is also sometimes used in cases of congestive heart failure and in the treatment of polycythemia vera (elevation of the packed cell volume or the hemoglobin level) where not contraindicated.

Massive Venous Occlusion. This may be described as a surgical emergency. Immediately after diagnosis, intravenous heparinization is started and continued during the thrombectomy.

Mini-Dose Heparin. Small subcutaneous doses of heparin have been found to be effective in high-risk post-surgical patients and in patients with acute myocardial infarction. The preventive treatment is commenced a few hours before an operative procedure and continued postoperatively for 4 to 5 days. As the result of a study in 1975, low-dose heparin prophylaxis in high-risk patients who undergo abdomino-thoracic surgery has become a widely accepted practice. However, preventive anticoagulant therapy, to date, has been unsatisfactory and controversial in the instances of hip surgery or prostatectomy.

ANTICOINCIDENCE CIRCUIT. A circuit with two input terminals which delivers an output pulse if one input terminal receives a pulse, but delivers no output pulse if pulses are received by both input terminals simultaneously or within an assignable time interval.

ANTICOINCIDENCE COUNTER. An arrangement of counters and associated circuits that will record a count if and only if an ionizing particle passes through certain of the counters but not through the others.

ANTICYCLONE. An atmospheric anticyclonic circulation, a closed circulation. The wind in an anticyclone is in the clockwise direction in the Northern Hemisphere and counterclockwise in the Southern Hemisphere.

With respect to the relative direction of its rotation, it is the opposite of a cyclone. Because anticyclonic circulation and relative high atmospheric pressure usually coexist, the terms anticyclone and high are used interchangeably in common practice. See also **Atmosphere (Earth)**.

ANTIDOTE. An agent that inhibits or counteracts the action of a poison. There is a wide variety of poisons, such as the *corrosives* (strong acids and alkalis) that cause local destruction of tissues; irritants that produce congestion of the organ they contact; the neurotoxins that affect the nerves or some of the basic processes within the cell; hemotoxins; hepatotoxins, and nephrotoxins. Consequently, the list of effective antidotes is long and reasonably complex, and usually much less lifesaving than making immediate efforts to have the poison victim vomit and thus expel as much of the poison as may be possible. Unless the appropriate antidote is selected, administration can be harmful rather than helpful. To illustrate this, if a sleep-producing drug, such as opium or morphine, has been taken in overdose, it is best to keep the patient awake by giving strong coffee. In contrast, in the instance of strychnine poisoning, no stimulants should be given and the patient should be kept as quiet as possible. In every type of poisoning, immediate medical aid is essential. Most local health departments have lists of antidotes for common poisons.

ANTIFERROELECTRIC. Certain crystals, such as tungstic oxide WO_3, ammonium dihydrogen phosphate $(NH_4)H_2PO_4$, sodium niobate $NaNbO_3$, and disilver trihydrogen paraperiodate $Ag_2H_3IO_6$ have been shown to exhibit spontaneous microscopic polarization similar to that in ferroelectrics, except that different types of ions are polarized in different directions, so that the megascopic spontaneous polarization is small, or even vanishing. These materials are described as being antiferroelectric. Strictly the term is applied only to substances in which the net spontaneous polarization is zero; materials in which the polarizations of the individual ions cancel only in part are often referred to as *quasi-ferroelectrics* or as *ferrielectrics*. The relation of antiferroelectrics to ferroelectrics is similar to that of antiferromagnetics to ferromagnetics. See **Antiferromagnetism**; and **Ferromagnetism**.

ANTIFERROMAGNETISM. The observed susceptibility curves of certain substances suggest that the system has gone into a state analogous to the ferromagnetic state, but with neighboring spins antiparallel, instead of parallel. See Fig. 1. That is, such substances exhibit a paramagnetism (low positive susceptibility) that varies with temperature in a manner similar to ferromagnetism, exhibiting a Curie point. Their resulting superlattices have been observed by neutron diffraction. The interaction giving preference to the antiparallel arrangement is believed to be an exchange force, similar to that invoked in the Heisenberg theory of ferromagnetism, but opposite in sign. Evidence from face-centered crystals has suggested the importance of super-exchange between next-nearest neighbors, through the anions. The alignment of the ions can be removed by heating the crystal, and the temperature at which the ordered spin arrangement breaks down is called the *Néel temperature*.

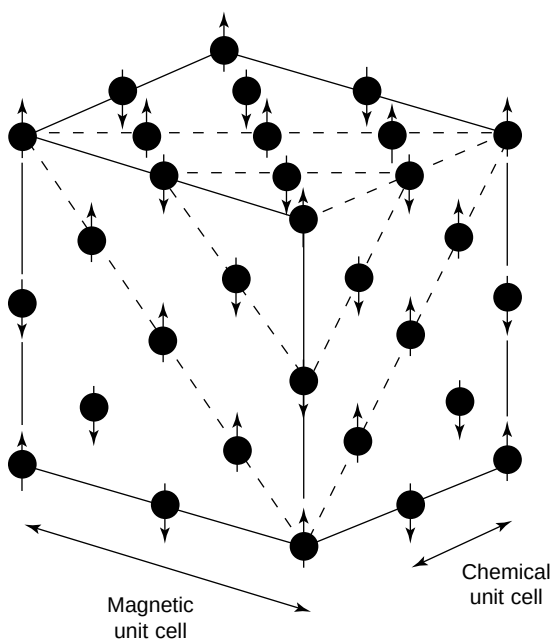

Fig. 1. Antiferromagnetic state spin structure of manganese oxide as determined by Shull, Strauser, and Woolan.

ANTIFOAMING (DEFOAMING) AGENTS. See **Defoaming Agents; and Food Additives**.

ANTIFOULING AGENTS. Various chemical substances added to paints and coating to combat mildew and crustaceous formations, such as barnacles on the hull of a ship. In the past, large quantities of mercury compounds have been used in this manner. With growing environmental concern over possible mercury pollution, manufacturers have been turning to other, sometimes less efficacious compounds. Research continues to find compounds of a less toxic, but equally effective power of the mercury compounds. Bis(tributyltin) fluoride has been used on ship bottoms. See also **Mercury**; and **Paints and Coatings**.

ANTIFREEZE AGENTS. A substance that lowers the freezing point (essentially of water). At one time, sodium chloride and magnesium chloride were widely used, but their extremely corrosive properties made them a liability in automotive and industrial cooling systems. Methyl alcohol, which requires about 27% by volume to protect against freezing to 0 °F (−17.8 °C), has a tendency to evaporate rapidly at operating temperatures and, coupled with its flammability and low boiling point of 147 °F (64.9 °C) limits its practical use in cooling systems. Many years ago, alcohols were replaced by glycol derivatives, which are relatively noncorrosive, nonflammable, have very low evaporation rates, and are effective heat-exchange media. A concentration of about 35% ethylene or propylene glycol antifreeze provides protection against freezing to 0 °F (17.8 °C). Because of their overall properties, it is now common practice to retain the antifreeze concentrations in cooling systems the year around.

Antifreeze agents are also used in fuels where severe environmental conditions are encountered. For example, a mixture of methyl alcohol, isopropyl alcohol, TM "Drygas," and sometimes proprietary substances are used to inhibit the formation of ice from water vapor in hydrocarbon fuels. It is added directly to the gasoline. These additives are toxic and flammable.

See also **Coolant**.

ANTIFUNGAL AGENTS. Antifungal agents are used to treat fungal infections ranging in severity from superficial to life-threatening. Current agents available to treat serious, invasive fungal infections are effective but have limitations. New classes are currently being developed to improve treatment options for patients with infections refractory to current therapies.

Modes of Action of Antifungal Agents

Fungi cause an increasing number of invasive infections in seriously ill or immunocompromised patients. Currently, physicians use three major classes of prescription therapies to treat serious fungal infections: (1) amphotericin B, a polyene; (2) azoles, including ketoconazole, fluconazole and itraconazole; and (3) the allylamine terbinafine. All three impact ergosterol, a major component of fungal cell plasma membranes. Amphotericin B binds to ergosterol, forming a channel in the membrane that allows leakage of intracellular contents, leading to cell death. Azoles and terbinafine block two steps in the biosynthesis of ergosterol: demethylation of lanosterol to yield ergosterol (azoles); and conversion of squalene to squalene epoxide (allylamines). See also **Fungal Infections (in Humans)**.

In theory, any essential biological process could be the target of an antifungal agent; however, an ideal target is more than simply an essential process. Because both fungi and the host are eukaryotes, fungal-specific targets are preferred because these are more likely than highly conserved molecules to provide distinguishing structural features that can be exploited to interfere with the fungal process without harming the host. Ergosterol is such a fungal-specific sterol; human cells contain cholesterol not ergosterol. Azoles have a greater affinity for the fungal demethylase that synthesizes ergosterol than they do for the human homologue responsible for the synthesis of cholesterol, contributing in part to the improved safety profile of newer azoles. Another factor in fungal therapy is the endpoint of growth arrest. Eukaryotic cells possess several mechanisms for arresting cell growth in the presence of different kinds of cell damage. Such arrest mechanisms protect the cell by allowing time for repair or recovery from insult, such as exposure to an antifungal agent, before the cell cycle proceeds. Compounds targeting processes that result in growth arrest without leading to cell death are termed fungistatic; the azole class is generally considered to be fungistatic. Fungicidal agents like amphotericin B result in cell death.

Other agents used in treatments of some mycoses are griseofulvin (Figure 1) and 5-fluorocytosine (Figure 2), which define two other antifungal targets. Griseofulvin binds to tubulin, a component of microtubules, such as those of the mitotic spindle. Griseofulvin binding stabilizes microtubules and interrupts cell division. Possibly as a consequence of this mode of action, griseofulvin has been associated with tumor formation in long-term animal studies. 5-Fluorocytosine (5-FC) is converted to the toxic 5-fluorouracil (5-FU) and 5-fluorodeoxyuracil (5-FdU) after uptake by fungal cells. Incorporation of 5-FU into ribonucleic acid (RNA) and 5-FdU into DNA causes misreading of the corresponding nucleic acid, leading to synthesis of aberrant proteins. Therapeutic use of 5-FC can be complicated by formation of 5-FU in the host gastrointestinal tract and is associated with bone marrow toxicity. Additionally, fungi can develop

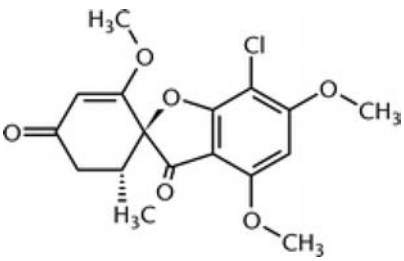

Fig. 1. Griseofulvin.

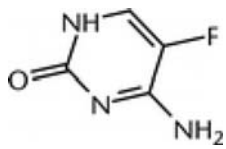

Fig. 2. 5-Fluorocytosine.

resistance to 5-FC through a decrease in activity of cytosine deaminase, the fungal enzyme that converts 5-FC to 5-FU. Thus, to overcome the potential for resistance, 5-FC is generally only used in combination with other agents, such as amphotericin B. Use of griseofulvin and 5-FC as single agents has been supplanted in large part by azole therapies.

Previous investigational antifungal agents under investigation have defined other targets. Nikkomycin (Fig. 3), inhibits synthesis of the cell wall component chitin, not found in the host. Pradimicin (Fig. 4), binds to mannoproteins found in the fungal cell wall. Uptake of nikkomycin by fungal cells can be complicated by the presence of peptides in the circulatory system and so its development was halted; pradimicin use was associated with side effects during clinical trials and has not been developed for that reason. It is possible that other agents directed against these targets could be successful. Additional fungal processes targeted by agents that have been actively studied include: (1) synthesis of β-1,3-glucan, another component of fungal cell wall; (2) synthesis of inositol phosphoryl ceramide, a lipid found in fungal membranes but not in the host; and (3) components of the elongation phase of protein biosynthesis.

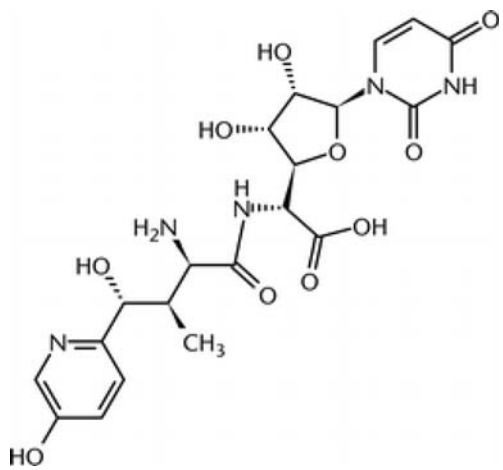

Fig. 3. Nikkomycin Z.

With the advent of genomic sequencing and genome-wide survey methods, additional fungal-specific processes may be identified and targeted. Mycota Biosciences recently reported the identification of 900 essential genes in the pathogen *Candida albicans*, leading to the speculation that there are numerous additional processes that could be the targets of novel classes of antifungal agents beyond the handful currently known and exploited.

Clinical Applications of Antifungal Therapy

Mycoses can range from superficial cutaneous infections to deep-seated invasive infections. Cutaneous or subcutaneous infections are not life-threatening but contribute to morbidity. Such infections affect a significant

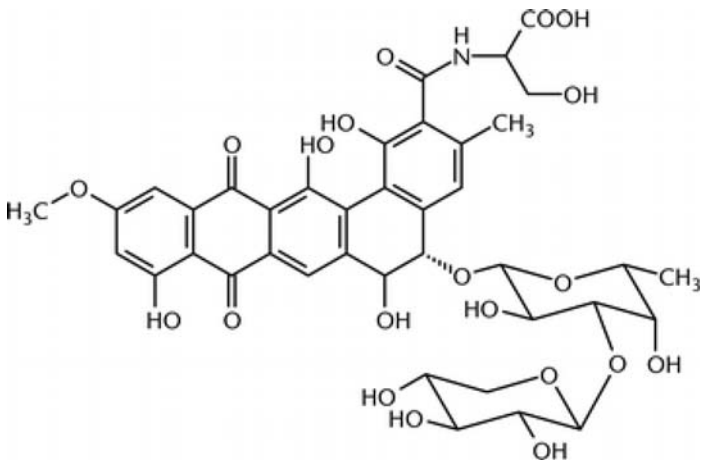

Fig. 4. Pradimicin.

fraction of the population, currently requiring therapy extending over many months to cure. Much more serious are systemic mycoses, which are life-threatening invasive fungal infections. Patients with compromised immunity are at risk from such deep-seated infections. The course of a mycotic infection depends in large part on the immune status of the patient, as in a relatively healthy individual the immune system is a first line of defense against infection. Patients with compromised immune systems, such as those with advanced acquired immune deficiency syndrome (AIDS), cancer patients undergoing chemotherapy, patients with organ transplants requiring immunosuppressive therapy, patients with acute leukemia and neutropenic patients (those with significantly reduced neutrophil count), are at increased risk of fungal invasion. See also **Acquired Immune Deficiency Syndrome (AIDS)**; and **Mycoses**.

Estimates of the proportion of patients affected by these diseases vary for different sites and different populations of patients at risk. *Candida* infections are the fourth most common cause of hospital-acquired disseminated infections. Furthermore, *C. albicans* and non-*albicans Candida* spp. are isolated from patients in many hospital settings [Rangel-Frausto, et al.:]. *C. albicans*, which can invade immunocompromised patients to cause disseminated candidiasis, is a commensal organism commonly found in the human oral cavity and gastrointestinal tract. Candidiasis is the most common systemic fungal infection encountered today. The most common causative agents of infections in bone marrow transplant and neutropenic patients are *Candida* spp. and *Aspergillus* spp. Oropharyngeal candidiasis, cryptococcal meningitis (caused by *Cryptococcus neoformans*) or pneumonia caused by *Pneumocystis carinii* are often seen in patients with AIDS.

Amphotericin B is the first-line therapy for aspergillosis, mucormycosis (due to *Mucor racemosus*) and most serious invasive mycoses. Fluconazole and/or amphotericin B are used to treat candidiasis, coccidioidomycosis (due largely to *Coccidioides immitis*), cryptococcosis (due to *Cryptococcus neoformans*); itraconazole and/or amphotericin B are used to treat infections caused by *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis* or *Sporothrix schenckii* (summarized by Andriole, 1998).

One predictor useful for selection of therapy is the susceptibility of the organism to the therapeutic agent. Susceptibility to an agent is measured by its minimum inhibitory concentration (MIC), the minimal concentration of the agent required to inhibit growth in culture. MIC measures of susceptibility are termed *in vitro* measures to distinguish them from *in vivo* measures of susceptibility performed in an animal model. MIC measurements can be problematic because many factors contribute to culture susceptibility, including the growth medium used, the time allowed for growth, the inoculum density, the growth state and the means used to measure growth. This variation became especially difficult with the introduction of azole agents because azoles often do not produce a sharp endpoint between complete inhibition and growth but rather lead to a gradual decline in culture growth.

Disagreements of several orders of magnitude in MIC measures were reported from different laboratories during early characterization of azoles. This prompted the National Committee for Clinical Laboratory Standards (NCCLS) to establish a subcommittee to define a standard method for determining *in vitro* susceptibility to azoles and other antifungal agents. The goal was to find a method that would allow MIC measures made in different laboratories to be compared directly, and also to allow the definition of breakpoints — concentrations above which an organism was deemed to be resistant to a particular therapy [Rex, et al.:]. The NCCLS protocol established for *Candida* spp. and *Cryptococcus neoformans* (Staff: National Committee for Clinical Laboratory Standards) and a protocol for filamentous fungi, such as *Aspergillus* spp., has been reviewed.

It is frequently difficult to achieve a therapeutic cure for a systemic infection. The success of a course of therapy is often dependent on patient factors, in particular the patient's immune system, making predictions from *in vitro* tests of susceptibility difficult. Disseminated infections can often be improved by removing the source of infection, such as an indwelling catheter used for extended therapy or parenteral nutrition. Other risk factors include use of broad-spectrum antibiotics or glucocorticoid hormones, and discontinuing these can also improve patient outcome.

Amphotericin B

Amphotericin B is a member of the polyene class of antifungals and was first identified from an extract of *Streptomyces nodosus* by Gold and coworkers in the 1950s. Amphotericin B (Fig. 5**a**) is an amphoteric molecule with a "greasy" hydrophobic polyene face and a hydrophilic surface containing multiple hydroxyl groups. Polyenes bind to ergosterol in the fungal membrane forming a channel in the membrane with the hydrophilic surface facing the interior of the channel. This permits leakage of intracellular components, leading to fungal death. Amphotericin B also binds to cholesterol in human membranes, although with lower affinity than it does to ergosterol. It has also been associated with oxidative damage to fungal cells. An agent capable of killing the fungal pathogen is well suited to clearing an infection in a patient lacking a fully functional immune system.

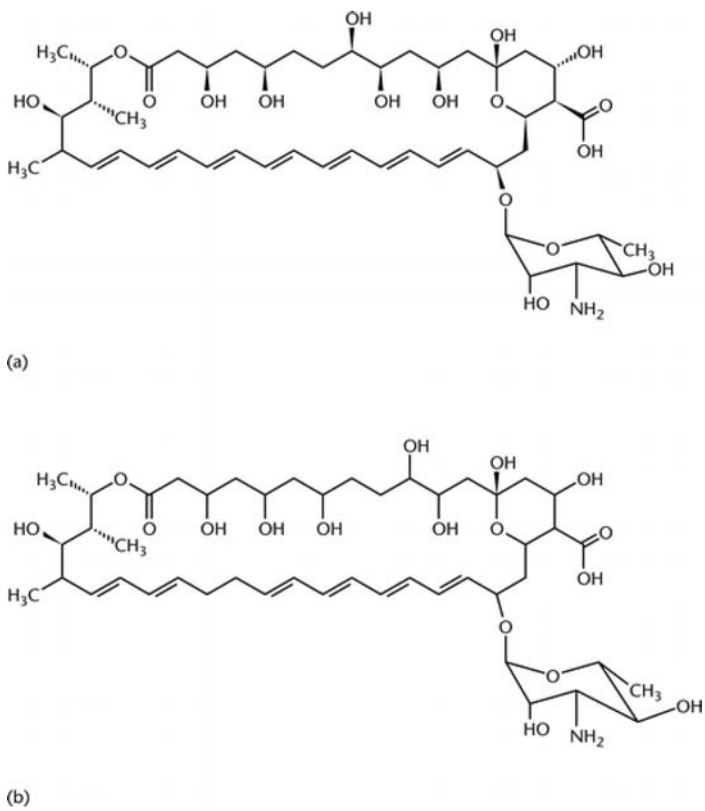

Fig. 5. Polyenes: (**a**) amphotericin B; (**b**) nystatin.

Most fungi contain ergosterol, giving amphotericin B a broad spectrum of activity. Because most pathogenic fungi are susceptible to amphotericin B, this treatment has been one of the first lines of defense in the treatment of systemic mycoses since it was introduced in the 1960s. Amphotericin B is now recommended for treatment of serious invasive infections, including disseminated aspergillosis, candidiasis, blastomycosis, cryptococcosis, coccidioidomycosis, histoplasmosis, mucormycosis and sporotrichosis. Empiric therapy with amphotericin B is recommended for

neutropenic patients with persistent fever that is unresponsive to antibiotics, with the anticipation that such a fever could be of fungal origin. Clinical isolates with acquired resistance to amphotericin B are rare; species intrinsically less susceptible to amphotericin B include *Candida lusitaniae*, *Trichosporon* spp. and *Fusarium* spp. See also **Aspergillosis**; **Blastomycosis**; **Candidiasis**; **Coccidioidomycosis**; **Cryptococcosis**; **Histoplasmosis**; **Mucormycosis**; and **Sporotrichosis**.

Amphotericin B is poorly soluble in water and has limited oral absorption; it is therefore delivered by intravenous infusion as a suspension with deoxycholate. Unfortunately infusion-related adverse effects (IRAEs), such as fever, chills and hypotension, limit amphotericin B dosage in a majority of patients receiving therapy. A more serious limitation is nephrotoxicity, which is associated with more than half of patients treated with amphotericin B. Because of these associated risks, amphotericin B is often used as a first-line defense against a serious infection until neutropenia can be resolved or other risk factors reduced, thereby allowing different agents to be used to control the infection. Because there are other treatments available for less serious conditions, the use of amphotericin B is not recommended for patients with thrush, vaginal candidiasis or oesophageal candidiasis in nonneutropenic patients (those with normal neutrophil counts). Administration of amphotericin B at doses below its MIC can increase fungal cell permeability, thus improving the activity of other agents if administered concurrently, as shown with a variety of *in vitro* studies.

Lipid Formulations of Amphotericin B

Significant work has been dedicated towards improving the safety profile of amphotericin B. The use of liposomes to deliver it is seen as a means of increasing therapeutic potential by focused delivery and lower nephrotoxicity. Liposomes are vesicles with an aqueous core surrounded by a phospholipid bilayer. Amphotericin B is dissolved in the lipid bilayer and the vesicle is introduced into the bloodstream. It has been suggested that endocytosis by monocytes or association with circulating lipoproteins transport liposomes to sites of infection. Amphotericin B is released from the liposome at the site of the infection through the action of phospholipases able to digest the lipid vesicle. Phospholipases are released by activated smooth muscle and vascular endothelial cells and by some fungal cells, providing an effective mechanism for targeting the action of amphotericin B at the source of the infection.

Three lipid formulations of amphotericin B have been approved for clinical use. These are amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD) and liposomal amphotericin B (L-AmB). Clinical studies of these formulations have generally been limited to compassionate use or open-label noncomparative studies; Wong-Beringer, et al., have compared these three formulations: vesicle size, surface charge and rigidity affect circulation and clearance, which in turn affects tissue distribution. Patient factors, such as the extent of neutropenia and the degree of infection, and the infecting organism itself also contribute to therapeutic outcome.

ABLC was approved in 1995, initially for treatment of aspergillosis in patients refractory to, or intolerant of, conventional amphotericin B treatment, and it has now been expanded for use against all invasive mycoses in such patients. ABLC is a complex of amphotericin B and two lipids, dimyristoylphosphatidylcholine and dimyristylphosphatidylglycerol, yielding a 33% molar composition of amphotericin B. This formulation produces a relatively large, ribbon-like structure. ABLC is rapidly cleared by the reticuloendothelial system, leading to higher concentrations in liver and spleen. Clinical studies suggest ABLC is as effective as amphotericin B in clearing fungal infections. The IRAE rate is 30–50%, somewhat less than is seen with amphotericin B. ABLC is also less nephrotoxic than amphotericin B).

ABCD was approved in 1996 for treatment of aspergillosis in patients refractory or intolerant of conventional amphotericin B. It is a 1:1 molar complex of amphotericin B and cholesteryl sulfate and forms a disc-like structure. The drug is rapidly cleared from circulation and has relatively low accumulation in the kidney, perhaps accounting for its reduced nephrotoxicity. The IRAE rate is above 50%, comparable to conventional amphotericin B. ABCD is effective in treating patients with aspergillar infections refractory or intolerant to amphotericin B.

L-AmB is a liposome formulated from three lipids (hydrogenated phosphatidylcholine: cholesterol: distearoylphosphatidylglycerol in 2:1:0.8 molar ratio) combined with amphotericin B at approximately a 10% molar content. L-AmB was approved in the USA in 1997 for indications that include aspergillosis, candidiasis and/or cryptococcosis in patients refractory or intolerant to conventional amphotericin B, and also for empiric use in febrile neutropenic patients. Studies comparing L-AmB to conventional amphotericin B showed improved clinical response rates for L-AmB and fewer dose-limiting symptoms.

The consensus of clinical studies of lipid formulations is that all three have a use in reducing the dose-limiting toxicity often associated with conventional amphotericin B treatment [Wong-Beringer, et al.; Williams and Kearns]; however, there are few studies that allow the three to be compared directly. The cost of lipid formulations is 10–30 times higher than conventional amphotericin B therapy, leading to the recommendation that these drugs be reserved for patients who do not respond to conventional amphotericin B [Williams and Kearns].

The success of lipid formulations of amphotericin B has increased interest in extending this to other polyenes, such as nystatin (Fig. 5**b**). Nystatin is not absorbed orally, and parenteral administration has associated toxicities that limit its use to topical applications. Nystatin is used to treat fungal infections of the mouth, throat, gastrointestinal tract, skin, and vagina. By chemically binding to the cell membranes of fungal organisms, this medication causes the cell contents to leak out, which kills the infecting fungi.

Azoles

The azole class of antifungal agents was discovered in the late 1960s. The imidazole agents, miconazole and clotrimazole, were introduced for clinical use in the early 1970s, followed by ketoconazole, an orally active imidazole introduced in 1981 (Fig. 6). These agents interfere with the biosynthesis of ergosterol, an important component of fungal plasma membrane, by inhibiting the enzyme C14 demethylase, which converts lanosterol to ergosterol. Imidazoles have also been shown to interfere with mitochondrial respiration. Ketoconazole is efficacious towards mucocutaneous candidiasis and is still used to treat superficial fungal infections, such as onychomycoses and ringworm.

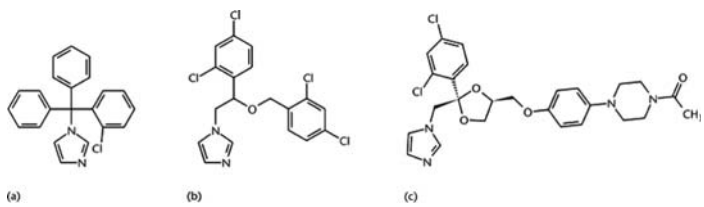

Fig. 6. Imidazoles: (**a**) clotrimazole; (**b**) miconazole; (**c**) ketoconazole.

Triazoles constitute the second generation of azoles (Fig. 7). The name of the class derives from the number of nitrogen atoms in the azole ring — two nitrogens in the case of imidazoles and three nitrogens in the case of triazoles. The first triazoles, fluconazole and itraconazole, were introduced in the early 1990s and have found widespread acceptance in the treatment of candidiasis, in large part due to an improved safety profile compared to alternatives. In addition, fluconazole is available in both oral and parenteral formulations and has good bioavailability. Over 15 million patients were treated with fluconazole in the first 5 years it was available.

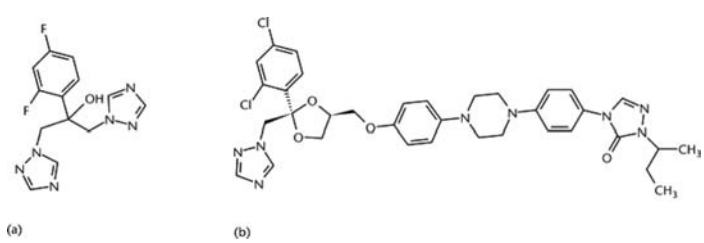

Fig. 7. Trizoles: (**a**) fluconazole; (**b**) itraconazole.

Weaknesses of fluconazole include its limited activity against *Aspergillus* and, like other azoles, a mechanism that tends to be fungistatic rather than fungicidal. Novel azoles such as voriconazole, posaconazole and ravuconazole have undergone clinical evaluation (Fig. 8), and are currently in use. Voriconazole is used to treat infections caused by yeast or other

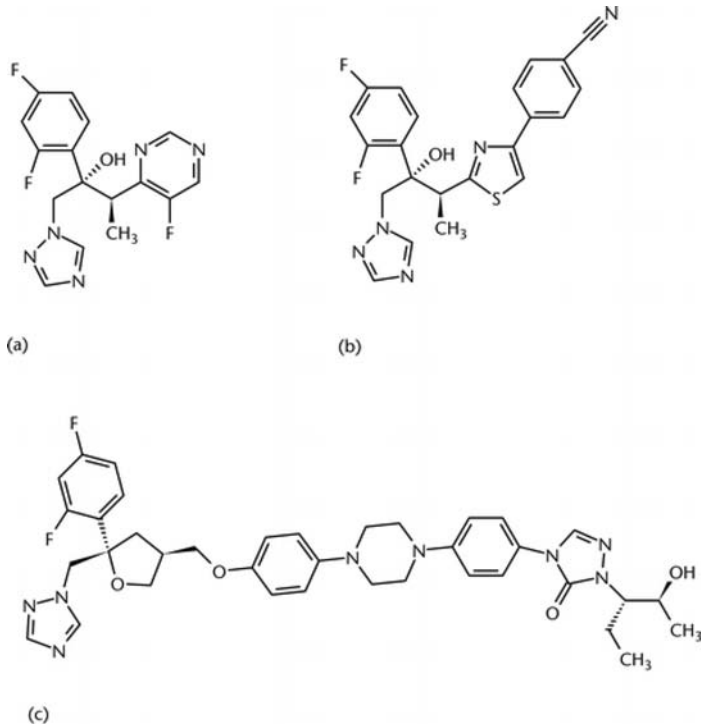

Fig. 8. Investigational azoles: (**a**) voriconazole; (**b**) ravuconazole; (**c**) posaconazole.

types of fungus. Posaconazole (marketed as Noxafil) is a prescription medicine used in patients, 13 years and older; with weak immune systems to prevent serious *Candida* and *Aspergillus* fungal infections. Ravuconazole is currently in Phase II clinical trials. Unfortunately, the drug has not advanced as of yet to Phase III Trials. Ravuconazole is active against *Candida* spp., *Cryptococcus neoformans*, *Aspergillus fumigatus*, dermatophytes and dematiaceous fungi.

Fluconazole is the agent of choice for the treatment of oropharyngeal candidiasis in AIDS patients, a condition that frequently recurs, leading to the need for extended therapy/prophylaxis. One complication of long-term use of a fungistatic agent is the replacement of susceptible strains and species with resistant organisms. Isolates of *C. albicans* resistant to ketoconazole were reported within a few years of its introduction, and azole resistance can be a problem. Inhibition of the sensitive organism can provide a niche for recolonization by a resistant strain or species, or resistant organisms within the original population can outgrow sensitive organisms inhibited by the azole therapy.

The three major routes to azole resistance are: (1) increasing activity of efflux mechanisms used by the fungi to remove intracellular toxins; (2) changes in the azole target, C14 demethylase; and (3) ancillary mechanisms, such as changes in other steps in ergosterol biosynthesis. Only the first two mechanisms are commonly found in clinical isolates.

Fungi contain a number of efflux pumps and facilitator molecules that rid the cell of toxins, including azoles. These efflux molecules have broad specificities, tending to transport any of several agents rather than one particular chemical compound. Work by the Sanglard laboratory has shown that overexpression of an efflux pump CDR1 or the facilitator MDR1 is associated with decreased sensitivity to azoles in clinical isolates (see Vanden Bossche, et al.: ref.). The names of the genes encoding these efflux systems indicate the nature of these molecules: CDR indicates *c*andida *d*rug *r*esistance and MDR1 indicates *m*ultiple *d*rug *r*esistance. The PDR5 pump (*p*leiotropic *d*rug *r*esistance) in the yeast *Saccharomyces cerevisiae* is also associated with resistance to azoles. Vanden Bossche and coworkers have shown that overexpression of PDR5 pumps in the yeast *S. cerevisiae* confers decreased susceptibility to terbinafine (Figure 9) as well as to azoles.

A second route to azole resistance involves changes in the target of azoles, the C14 demethylase enzyme. Either overproduction of the native enzyme or mutations that reduce azole binding but still permit catalytic function can decrease susceptibility of fungi to azoles. Finally, changes in other biological processes can result in azole resistance. Alterations

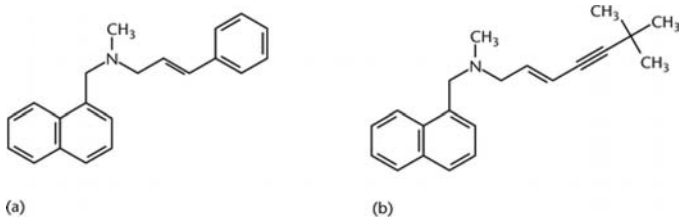

Fig. 9. Allylamines: (**a**) naftifine; (**b**) terbinafine.

in mitochondrial function or in another component of the ergosterol biosynthetic pathway, encoded by *ERG3* in *S. cerevisiae*, can also result in resistance to azoles.

There are probably several aspects to the mechanism of growth inhibition by azoles. Azoles inhibit the production of ergosterol by inhibiting C14 demethylase. This inhibition causes the build up of 14-α-methyl sterols, which are normally converted into ergosterol by C14 demethylase. The presence of high levels of 14-α-methyl sterols in the cell can be toxic; thus inhibition of C14 demethylase both depletes the cell of an important membrane component and causes the accumulation of a toxic byproduct.

Terbinafine

Naftifine (Figure 9), the first antifungal member of the allylamine class, was discovered in 1974. Allylamines are reversible noncompetitive inhibitors of squalene epoxidase, the enzyme that works together with (2,3)-oxidosqualene cyclase to complete the cyclization of squalene to lanosterol, a precursor to ergosterol. Interference with squalene epoxidase results in depletion of ergosterol and accumulation of squalene, both of which affect fungal membrane structure and function.

Naftifine is an effective topical agent active against dermatophytes, such as *Trichophyton mentagrophytes* and *Microsporum canis*, and other fungi, such as *Sporothrix schenckii*, which cause superficial infections. Terbinafine, the next generation allylamine (Figure 9), was introduced in 1991. Terbinafine is approved for the treatment of superficial skin and nail infections caused by dermatophytes. It is effective *in vitro* against a broad range of fungal species; however, pharmocokinetic limitations currently restrict its use to cutaneous infections. Despite this focused application, terbinafine has been widely used by over 11 million patients in the first 8 years it has been available [Ryder, ref.]. It is well tolerated and results in a cure rate of over 80%. Interestingly, there is a consistent failure to clear infection in a subpopulation of patients. This is not due to reinfection by resistant organisms but may reflect host-related factors, especially as many of these patients have a family history of onychomycosis [Bradley, et al.:].

Efforts to increase the utility of terbinafine have included studies of drug combinations with terbinafine and amphotericin or terbinafine and azoles. Such studies reveal synergy resulting in enhanced activity of the combination compared with the individual components. Of interest is enhanced activity of a combination of azole and terbinafine against azole-resistant isolates, which may allow control of this class of pathogens without requiring the use of amphotericin B.

Emerging Agents: Echinocandins and Sordarins

The echinocandin class of antifungals was discovered in the 1970s and is currently represented by the three investigational agents: caspofungin (formerly MK-0991), VER-002 (formerly LY303366) and FK463 (Fig. 10). Echinocandins are lipopeptides with lipid chains attached to a cyclic peptide center. These molecules are not orally absorbed and so are limited to an intravenous formulation. An aerosol formulation for *Pneumocystis carinii* pneumonia is under evaluation as well. Current clinical studies reveal few dose-limiting complications, the primary one being abdominal discomfort.

Echinocandins inhibit the biosynthesis of β-1,3-glucan, an important component of fungal cell walls. Loss of glucan leads to weakened cell walls and cell lysis; thus these agents have the potential to be fungicidal. This class will extend safe and effective antifungal therapy to a target other than ergosterol. The cell wall is a structure not found in the host. Moreover, host cells lack glucan synthase, although proteins with weak homology to glucan synthase can be identified in mammalian cells. Glucan is an important component of fungal cell walls and echinocandins are active against numerous fungal species, including *Candida* and *Aspergillus* spp.

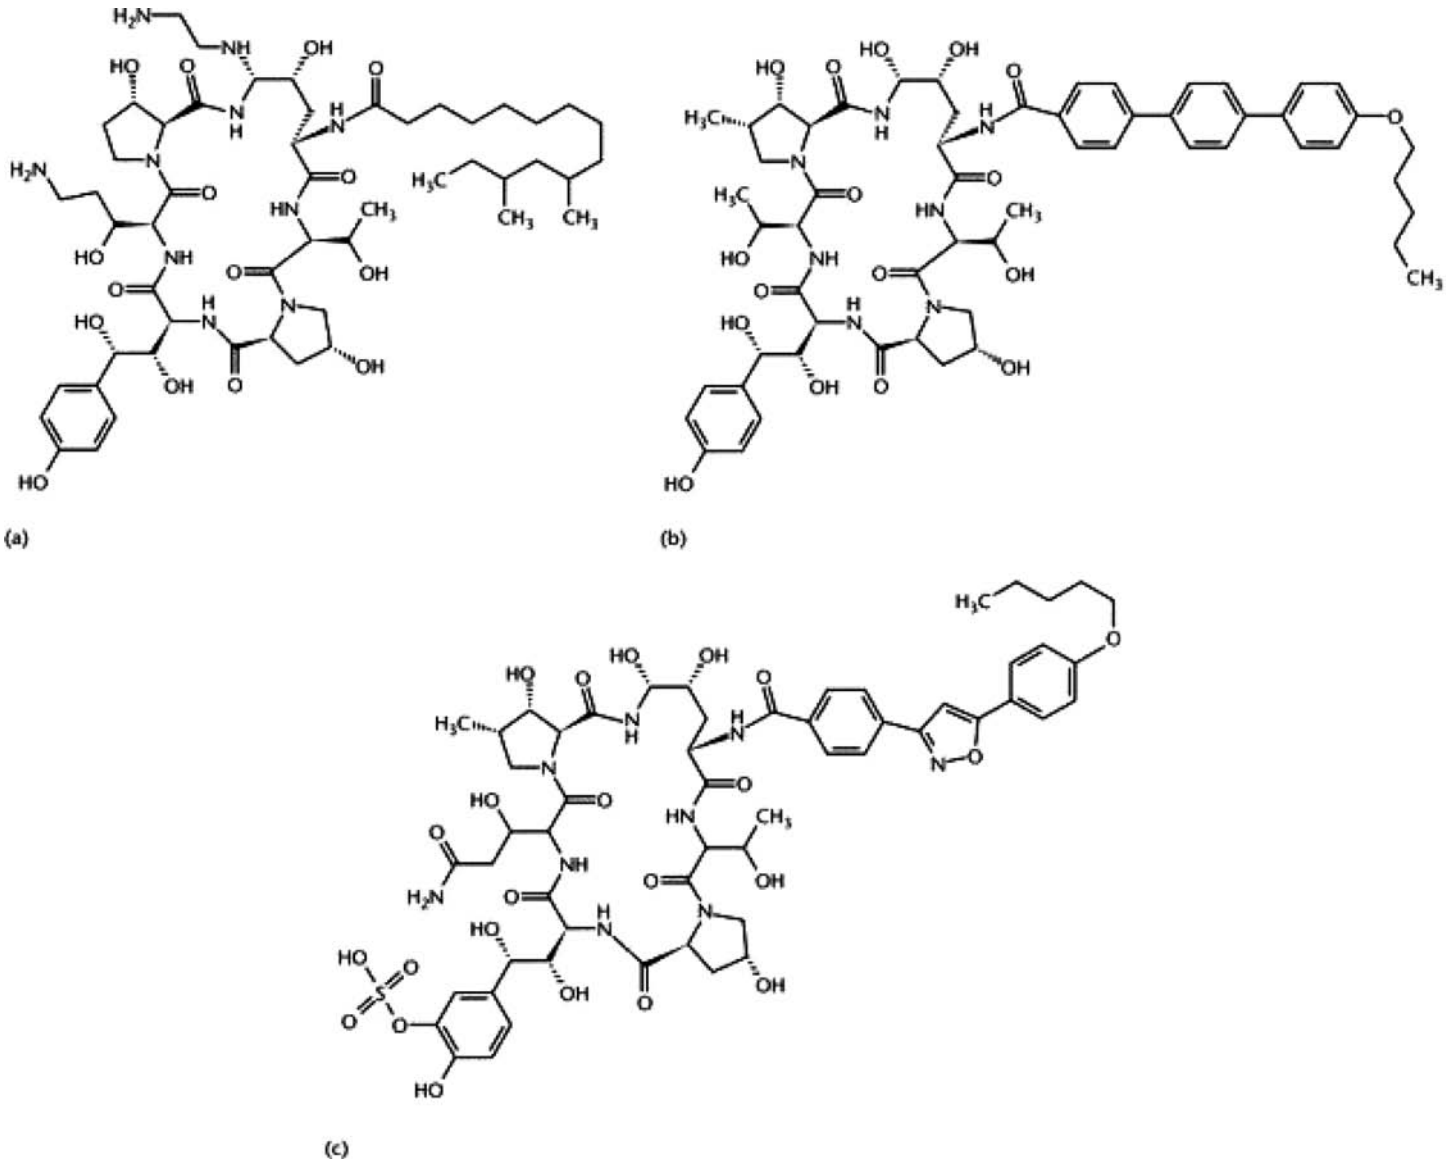

Fig. 10. Candins: (**a**) caspofungin; (**b**) VER-002; (**c**) FK463.

as well as *P. carinii*. While *Cryptococcus neoformans* and *Trichosporon* spp. are less sensitive to this class, echinocandins in combination with amphotericin B are synergistic against *Cryptococcus neoformans*.

One complication of *in vitro* measures of susceptibility to echinocandins against filamentous fungi such as *Aspergillus* is the concentration range resulting in impaired growth without achieving growth inhibition. At concentrations above the MIC, echinocandins completely inhibit growth. At concentrations between the MIC and the MEC (minimal effective concentration), echinocandins reduce filament growth, leading to microcolonies of stunted, abnormal cells. At concentrations below the MEC, cells are not affected by echinocandins and the normal hyphal mat develops. The MEC is a better predictor of *in vivo* outcome than the MIC [Kurtz, et al.:] and reflects the utility of identifying an optimal measure of activity for classes of chemical agents.

Antifungal sordarins (Fig. 11) were isolated in the 1990s and are still at an early stage of development. Sordarins interfere with protein synthesis through specific interaction with components of the translation machinery. Isolation of *Saccharomyces cerevisiae* strains resistant to sordarins demonstrates that the target is elongation factor 2 (EF-2) and the ribosomal P-protein stalk where EF-2 binds during its active step. Early sordarins had an unusual spectrum of activity, with a thousand-fold difference in MICs towards, for example, *Candida albicans* and non-*albicans* species, such as *C. krusei* and *C. parapsilosis*. These sordarins do not inhibit human protein biosynthesis [Dominguez, et al.:]. More recent derivatives have started to close these gaps in the antifungal spectrum. If the safety profile of the class holds, sordarins may yield another novel class of antifungal agents for future therapy.

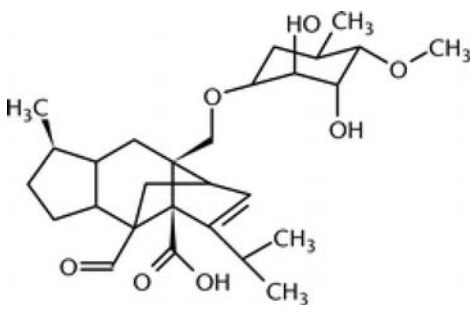

Fig. 11. Sordarin.

Conclusions

The need for agents to treat serious fungal infections has increased significantly over the last half-century, and discovery efforts have paralleled this growing need. Agents currently available for the treatment of serious deep-seated fungal infections target a key component of the fungal membrane, ergosterol. Amphotericin B, the gold standard, binds to ergosterol, thereby interfering with the membrane barrier and leading to cell death. Amphotericin B is widely used to treat serious life-threatening infections

but is limited by associated nephrotoxicity and infusion-related adverse events. Azoles target the C14 demethylase required to synthesize ergosterol. Azoles are safer and more water-soluble than amphotericin B but have a fungistatic mechanism; a further complication of azole use is the incidence of azole-resistant fungal isolates. Recent improvements in antifungal therapy are: (1) within class (development of new azoles), and (2) in formulation (lipid formulations of amphotericin B). Additionally, the echinocandin class of cell wall inhibitors represents both a novel mode of action and a new chemical class of agent. The Enchinocandin caspofungin offers a therapeutic antifungal option that differs from those currently available. Other classes are under study, including sordarins, fungal-selective inhibitors of protein biosynthesis. There is a need for novel and effective antifungal agents in order to address the increases in patients at risk owing to immunoinsufficiency and other factors and the increasing incidence of azole-resistant fungal isolates. Current therapies are not fully adequate for the task.

ANTIGEN. The adaptive immune system is an extremely efficient defense mechanism found in its most advanced form in higher vertebrates. It provides the means to generate rapid, highly specific and often protective responses against the myriad of pathogens that inhabit the world in which we live. For the immune system to mount a response against any microorganism it must first be able to recognize it. It is here that the adaptive immune system distinguishes itself from any other system in the body, being equipped with the ability to recognize a variety of molecular species that form the constituents of the microbe. This article will discuss the underlying principles of immune recognition, and the nature of its molecular targets. Such targets are commonly referred to as "antigens."

The term antigen represents a functional annotation that is generally used in the context of adaptive or acquired immunity. Substances or, more specifically, molecules that can be recognized by one or more constituents of an acquired immune response are referred to as antigens. Given that the immune system has evolved to recognize all molecular species foreign to the host, in principle antigens encompass a broad spectrum covering all classes of organic molecules, from the simplest of chemical compounds to the most complex of macromolecules. See also **Immune System and Immunology**.

The property of antigenicity is, however, operationally distinct from that of immunogenicity. While antigenicity refers to recognition by the effector components of an immune response, immunogenicity denotes the ability to elicit such a response. As a result, although all molecules which are immunogenic also possess the property of antigenicity, the reverse is not necessarily true. For example, many small molecules possess the property of antigenicity but are incapable, by themselves, of inducing a specific immune response. These are commonly referred to as haptens. Haptens are rendered immunogenic only upon chemical conjugation to larger proteins, which function as carriers. Thus, while antigenicity represents an intrinsic property of the molecule, immunogenicity characterizes a condition that is influenced by a number of additional factors involved in the total biological system.

Types of Antigens

As noted above, the adaptive immune system can recognize a wide variety of molecular species, ranging from a few hundred daltons in molecular mass to structurally complex macromolecules. Neither does the chemical nature of the entity pose a restriction, as targets for immune recognition can include small organic molecules such as dinitrophenol, simple and complex sugars, lipids, proteins and even nucleic acids. While all of these may be characterized as antigens there are, nevertheless, subtle distinctions specified by the constituents of the immune system.

The adaptive immune system is now generally accepted to be composed of two effector arms: humoral immunity, the arm derived from the antibody-producing B lymphocytes, and cell-mediated immunity, comprising immune-effector responses derived from T lymphocytes. Substances that are recognized by antibody (or B cells) are called *B-cell antigens*, whereas those recognized by T lymphocytes are known as *T-cell antigens*. Recognition of antigen by T and B lymphocytes is performed by cell surface antigen receptors. These are associated in the lymphocyte membrane with signal-transducing proteins, which together serve to activate the lymphocyte in response to binding specific antigen. The antigen receptors of T and B lymphocytes are termed T-cell receptor (TCR) and B-cell receptor (BCR), respectively. After activation by antigen, B lymphocytes secrete a soluble form of their receptors (commonly termed antibody), the term BCR being normally reserved for the membrane-bound, signal-transducing form only. See also **Lymphocytes**.

Fundamental differences in the way B- and T-lymphocyte antigen receptors recognize an antigen determine which molecular features are recognized. B lymphocytes recognize antigens in soluble form and, therefore, are able to target molecular species of wide-ranging size, structural and chemical heterogeneity. Thus, for example, antibodies against a variety of small molecules such as phosphorylated amino acids, steroids, etc. have been successfully obtained, and it is equally feasible to generate antibodies against more complex chemical species, such as chemical polymers, branched sugars, oligomeric proteins and DNA. Furthermore, B-cell or antibody recognition is targeted against the surface topology provided by the antigen and is therefore independent of the nature of the underlying structural units that contribute to it. As a result, humoral responses to protein antigens can include antibodies directed against linear segments of sequence presented in either an extended conformation or in any one of the numerous possible secondary structural configurations at the surface of the antigen. In addition, antibodies can be obtained that recognize surfaces generated by noncontiguous segments juxtaposed as a consequence of either tertiary or quaternary structural folding of the native protein (Fig. 1).

A good example of the heterogeneous recognition potential of humoral immunity can be had from looking at the antibody specificities produced in response to infection by a pathogenic agent. A bacterial infection yields individual antibodies directed against a host of molecules that represent the chemical constituents of the organism. These include capsular polysaccharides, glycolipids, lipoproteins, low molecular weight constituents of the cell wall, membrane-bound and intracellular proteins, small polypeptides and, occasionally, lipids and nucleic acid.

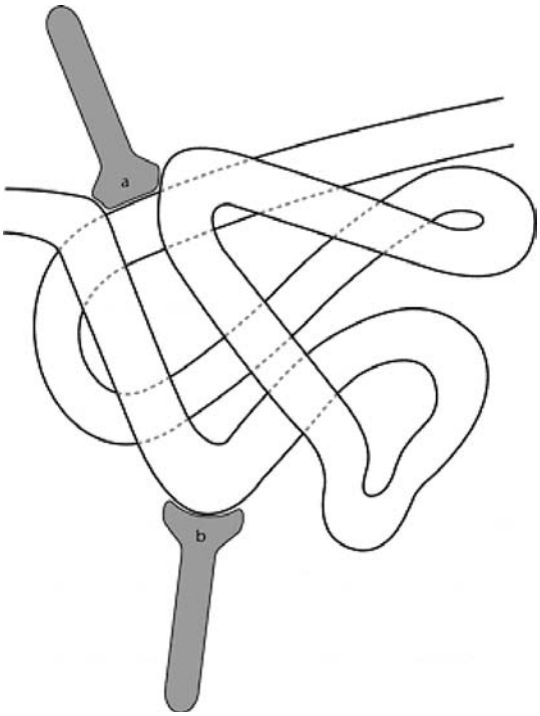

Fig. 1. Antibody binding to a protein antigen. The figure shows a cartoon of a folded protein (black) with antibodies (red) bound to selected epitopes on it. Note that, while antibody a binds an epitope composed of 'noncontiguous' protein segments, antibody b recognizes a contiguous epitope.

In stark contrast to the broad canvas that B-cell antigens represent, recognition by T lymphocytes is principally restricted to polypeptide fragments that are usually derived from proteolytic degradation (also called *antigen processing*) of native proteins. Furthermore, unlike B lymphocytes which recognize soluble antigen, T-cell antigens are targeted only when associated with specific molecules on the surface of an appropriate cell. Thus T-cell antigenicity restricts itself to a single class of molecules, namely small peptides without dramatic structural variation and where the only true element of diversity permitted is at the level of the primary amino acid sequence.

Immune Recognition

The function of the adaptive immune system can be divided into two interrelated activities — recognition and response. The former defines the property of antigenicity, whereas an ability to invoke the latter describes the quality of immunogenicity. Regardless of qualitative distinctions in the recognition potential of B and T lymphocytes there is, nevertheless, a common feature relevant to recognition of larger, more complex antigens. Neither subset of immunocytes interact with, or recognize, the entire antigen molecule. Rather, lymphocytes individually recognize discrete sites on macromolecules. Such sites are called *antigenic determinants* or *epitopes*. Thus, antigens may also be defined as those molecules which possess within their structure recognition-competent domains for either T or B lymphocytes. See also **Epitopes**.

The hallmark of the adaptive immune system is not only the wide array of chemical entities that it can potentially recognize, but also the specificity of such individual recognition. Thus antibodies generated against a given protein, particularly in the later stages of the response, will not cross-react with another, even if they are closely related. Thus recognition of individual epitopes on an antigen by either B or T lymphocytes is of a highly specific nature. The basis for such exquisite specificity derives from the fact that immune recognition is dependent upon binding of antigen to antigen receptors on the surface of either B or T lymphocytes. If the antigen also happens to be immunogenic (e.g. protein or hapten conjugated to a carrier), then such a recognition results in activation of that lymphocyte, eventually leading to an effector immune response.

It is noteworthy that both the specificity of individual recognition and the wide range of antigens recognized stem from the requirement of receptor-mediated interactions. The antigen receptors on T and B lymphocytes are distinct from any other class of receptor in that the ligand-binding site displays a high degree of variability from one cell to another. Such variability derives from the fact that the antigen-combining site (or paratope) of both kinds of receptor is generated by rearrangement of multiple gene segments where each segment is randomly selected from one of many members of individual gene families. Nondirected imprecision at the site of joining of the gene segments, as well as variable options of subunit pairing further add to the diversity of the antigen-combining sites generated. Whereas the principle of 'allelic exclusion' ensures that a given T or B lymphocyte will only bear identical receptors all expressing a common paratope, these are nevertheless distinct from those borne by its cohorts. As a result, while recognition by individual lymphocytes is extremely specific, the B- and T-lymphocyte pools collectively define a broad repertoire of antigen specificities. A fundamental distinction, however, remains between antigen receptors present on T lymphocytes and that borne on B lymphocytes. While the TCR always remains cell associated, B lymphocytes are empowered with the ability to secrete modified versions of their receptor as soluble antibody.

Antigen Recognition by B Lymphocytes

It has been noted earlier that BCRs recognize soluble antigen, which implies that antigens are generally recognized in the native form. This becomes particularly relevant for structurally complex macromolecules such as proteins and branched polysaccharides, where the topology of the molecular surface constitutes the epitopic repertoire available for B-cell (or antibody) recognition (Fig. 1). Proteins, for example, are normally folded into a three-dimensional structure such that the hydrophobic domains are buried within the interior, whereas the hydrophilic domains remain exposed on the surface. In addition, secondary structural elements such as β turns also contribute to surface topology by protruding out from the protein surface, thereby facilitating binding by B cells bearing the appropriate receptor. Consequently, given the virtually limitless repertoire of B-cell specificities, it is generally believed that the entire accessible surface of a protein constitutes an antigenic continuum. This notion has spurred the generation of a variety of predictive algorithms that seek to identify surface-accessible domains on proteins whose primary amino acid sequence, but not the three-dimensional structure, is known, as potential approaches to localize B-cell epitopes on proteins. Identification has been attempted on the basis of anticipated biophysical properties such as local hydrophilicity, domain flexibility (or mobility), secondary structural motifs, etc. Thus, for example, any extended stretch of primary amino acid sequence which is composed predominantly of hydrophilic residues is expected to be present on the surface of a fully folded protein — thereby being available for recognition by B cells. Similarly, B-cell epitopes have also been predicted on flexible domains of proteins and segments with pronounced secondary structural motifs, such as β turns and either hydrophilic or amphipathic α helices. It must be mentioned, however, that such attempts yielded only limited success when predicted epitopes on a variety of protein antigens were compared with those experimentally determined by fine analysis of polyclonal antibodies produced against the same protein in an appropriate host. This further underscores the distinction between the potential antigenicity of a polypeptide segment and its functional immunogenicity.

Recognition of an antigen (or epitope) either by an antibody or its corresponding BCR follows the established norms of all protein–protein interactions. Recognition principally implies a binding interaction between the paratope of antibody (or BCR) and epitope, which is achieved only when two necessary preconditions are met: (1) There must be topological complementarity between the interacting paratope and epitope surfaces. (2) There must be a sufficient number of short range, noncovalent interactions (hydrogen bonding, Van der Waals interactions, salt-bridging, etc.) between the two contact surfaces, so as to cumulatively contribute favorably to the overall free energy of binding. In general, it has been found that the free energy of binding in an antigen–antibody interaction ranges between 18 and 25 kcal mol^{-1}, with a contact surface area between 600 and 900 $Å^2$.

In the literature, B-cell antigens are frequently described as either T-dependent or T-independent. This characterization is used to distinguish between antigens that induce a humoral response only in the presence of T-cell help (T-dependent), and those that do not require assistance from T-helper cells to elicit antibodies (T-independent). T-independent antigens have been further subclassified as type I if they are directly mitogenic for

B cells and type II if they are nonmitogenic. Type I antigens frequently represent components of bacterial cell walls, the best known of which is lipopolysaccharide (LPS). Type II antigens; on the other hand, represent polymeric compounds presenting repeating units of the same antigenic determinant (e.g. polysaccharides). It is believed that binding of such antigens results, by virtue of their multivalency, in extensive crosslinking of the BCR, leading to cellular activation and proliferation without a requirement for T-cell help.

T-dependent antigens are molecules with either a mono- or limited valency of individual epitopes. Such antigens are unable to induce BCR crosslinking and, consequently, require assistance from T-helper cells to stimulate B-cell proliferation and differentiation. Most protein antigens fall under this category. The assignment of the terms T-dependent or T-independent, therefore, essentially define properties related to immunogenicity. It may perhaps be more appropriate then, to describe such molecules as T-dependent or T-independent B-cell immunogens.

Antigen Recognition by T Lymphocytes

Unlike B cells, the antigen receptor on T cells does not recognize native antigen, but only peptide fragments derived from the processing of larger proteins. Furthermore, recognition only occurs when the peptide fragment is presented on the surface of an appropriate antigen-presenting cell (APC), and in association with a member of the family of transmembrane proteins called the *major histocompatibility complex* (MHC) molecules. Thus, antigen recognition by T lymphocytes involves the formation of a trimolecular complex between the TCR, antigenic peptide and a self-MHC molecule. Another distinction between the two arms of adaptive immunity is that while B-cell (or antibody) recognition is solely directed against the antigenic determinant, T-cell recognition requires simultaneous contact between the TCR paratope and both the residues presented by the antigenic peptide and those provided by regions of the MHC molecule adjacent to the buried peptide. In other words, the overall structure bound by the TCR effectively represents a topological surface that is a composite of contributions from the nonself antigenic peptide and the self-MHC molecule (Fig. 2).

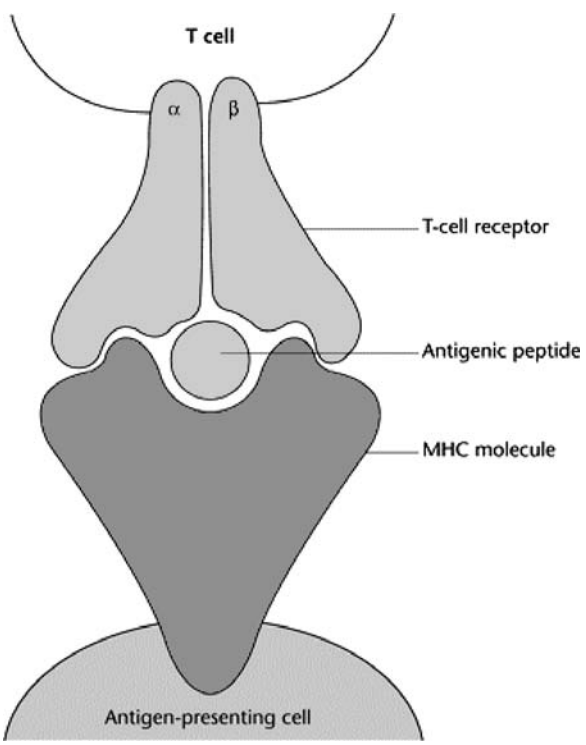

Fig. 2. TCR recognition of a peptide–MHC complex, showing the interaction between an α β TCR heterodimer and a peptide presented by an MHC molecule. Note that the TCR contact is with surfaces provided by both the antigenic peptide and neighboring regions of the MHC molecule.

Although the TCR alone is capable of binding peptide–MHC complexes the affinity for such interactions is low (K_d between 10^{-4} and 10^{-7} mol L^{-1}). As a result, binding of a T cell to an APC or target cell cannot depend on the affinity of this interaction alone. This is further compounded by the fact that, in normal circumstances, the frequency of both cells presenting a particular antigen and T lymphocytes with the appropriate receptor for binding to this peptide–MHC complex are low. Indeed a series of elegant studies have shown that antigen recognition by T lymphocytes does not constitute a direct receptor–ligand interaction, but represents a multistep process guided by assistance from accessory molecules. Adhesion molecules on the surface of both T lymphocytes and APCs act first to ensure a contact between the two cell types. Once cell-to-cell contact is made, the TCR then scans the APC membrane for peptide–MHC complexes that it can bind to. Binding then initiates a complex series of molecular events that eventually lead to proliferation and differentiation of the participant T lymphocyte into effector cells. In the event that the interacting APC does not express an appropriate peptide–MHC complex that can be recognized by the TCR, the cell-to-cell contact weakens and the T lymphocyte dissociates to continue its search for the right partner. It is clear, therefore, that antigen recognition by T lymphocytes represents a process that is far more complex and involved than that by B lymphocytes.

Depending on whether the antigenic peptide is presented in association with a self-MHC class I or class II molecule, it can serve as a target for recognition by either the CD8+ or CD4+ subset of T lymphocytes, respectively. Extracellular antigens or microbes that are taken up by APCs via receptor-mediated endocytosis, phagocytosis or pinocytosis are targeted to the lysosomes, where the protein components are degraded by lysosomal proteases. A select proportion of the fragments thus generated — those which have the requisite sequence — bind to the MHC class II molecule. Such peptide–MHC complexes are subsequently transported to the cell surface to await recognition by a CD4+ T lymphocyte bearing the appropriate TCR.

MHC class I molecules, on the other hand, present peptides derived largely from endogenously synthesized proteins. Endogenous antigens, such as those produced by a virus replicating within an infected cell, are degraded by the proteasome complex in the cytoplasm. Select peptide fragments are then transported to the endoplasmic reticulum where they bind to newly synthesized MHC class I molecules, before being transported to the cell surface for interaction with appropriate CD8+ T cells.

Crystal structure studies of peptides bound to MHC class I and class II molecules have revealed that the peptide usually is bound — in both cases — in an extended conformation with one face buried within the cleft of the MHC molecule, and the other exposed for TCR binding. Thus, for any peptide to possess T-cell antigenicity it must necessarily contain two distinct interaction sites. One site is required for binding to the MHC molecule, and the antigen residues involved in this interaction are called *agretopic residues*. The other site interacts with the TCR and the residues which comprise this site are known as *epitopic residues*. While a given MHC allele can bind a variety of different peptides, the specificity of immune recognition is defined by the stringency imposed by the TCR. In this connection, the low affinity of TCR for the peptide–MHC complex serves as an important check since any variation in peptide sequence will result in an interaction that is of too low an affinity to be biologically relevant.

As in the case of B-cell recognition, attempts have also been made to predict — *a priori* — the locations of T-cell epitopes on protein antigens. While one such approach relied on the identification of specific motifs within the primary amino acid sequence, another predicted on the basis of segments capable of forming amphipathic alpha-helices in solution. Both of these approaches, however, have met with limited success — the reasons for which have become apparent since the elucidation of crystal structures of MHC–peptide complexes. As already alluded to earlier, these latter studies have revealed that the peptide is bound in an extended confirmation. A complicating factor in the prediction of T-cell epitopes is that it requires prediction of two distinct binding sites — one for MHC and the other for the TCR. This is further compounded by the diversity of MHC alleles, each with its own range of peptide specificities. Attempts are underway, in many laboratories, to delineate sequence motifs for binding to the various alleles of MHC class I and class II proteins.

In addition to the conventional T lymphocytes expressing a TCR composed of α and β subunits, there is also a small population of T cells with a receptor made up of γ and δ subunits. This subset of T lymphocytes appears to violate the established norms of T-cell recognition — namely,

that all T cells are self-MHC restricted and recognize peptide antigens displayed in the cleft of the self-MHC molecule. Indeed $\gamma\delta$ T cells appear far more promiscuous in the type of antigens that they recognize and, in this respect, resemble B lymphocytes. For example, a $\gamma\delta$ T-cell clone has been derived that can bind directly to a herpes virus protein without requiring processing and presentation together with MHC. Again like B lymphocytes, antigen specificity of $\gamma\delta$ T cells does not appear to be restricted solely to polypeptide antigens. Activated $\gamma\delta$ T cells induced in response to a mycobacterial infection have been shown to bind some bacterial antigens that are protease resistant. One of these antigens has recently been identified to be isopentyl pyrophosphate. Thus, though many more details on this subpopulation remain to be elucidated, $\gamma\delta$ T cells appear to represent yet another (possibly more ancient) dimension to the cognitive armamentarium of the adaptive immune system.

It becomes obvious then, that the adaptive immune system is endowed with the enormous capability to recognize virtually any molecular species that it encounters. This ability, coupled with a "learning" process that imparts a self versus nonself discriminatory capacity, enables it to mount a selective effector response against only those antigens that are foreign to the host. Nevertheless, immune responses against self antigens that are either altered in form (e.g. denatured proteins) or over expressed (as occurs in some tumor cells) are also sometimes produced. While in general such responses are beneficial, constituting a surveillance machinery for cellular aberrations within the host, there are instances where a breakdown in self-tolerance leads to autoimmune responses with pathological consequences.

Antigenic Competition

Our understanding of the recognition repertoire of the adaptive immune system logically leads us to expect that virtually any antigen it encounters can be recognized and, subsequently, responded to. While this is undoubtedly true in principle, in practice, however, factors relating to immunogenicity often complicate the issue. For instance, it is not uncommon to find that immunization of a host with a complex mixture of diverse antigens — such as that represented by a microorganism — leads to an unequal immune response against the individual constituents of the mixture. This is largely dictated by variables in intrinsic immunogenicity between the antigenic components. Thus, for example, antibody responses to the T-independent antigen constituents would remain muted, primarily due to the absence of T-helper cell involvement — a factor critical for the amplification and differentiation of responder B cells. Even among the T-dependent antigens, the proportion of immune-effector responses directed against each will depend on their immunogenicity at the T-cell level, which can vary markedly from one antigen to another. As already discussed, T-helper cell antigenicity and immunogenicity requires proteolytic degradation of the target protein within the lysosome of APCs, and binding of the peptide fragments generated to MHC class II molecules. It can be envisaged, therefore, that T-cell immunogenicity, as defined by the ability to activate specific T cells and induce their proliferation, would then depend on the affinity of peptide binding to the MHC molecule because this would determine the number of MHC–peptide complexes available on the APC surface for TCR interaction. In addition to affinity, the concentration of peptide fragments generated within lysosomes will also determine the number of MHC–peptide complexes produced. This, in turn, will depend on the processing efficiency of the antigen, and the number of antigen molecules present in the original mixture (or microorganism). Finally, it must be remembered that a multitude of proteins are simultaneously being proteolysed in the lysosome. These include, apart from the antigen in question, other constituents of the antigen mixture, ligands endocytosed by unrelated receptors on the APC surface, and self proteins of membrane origin. As a result, immunogenicity at the T-cell level is the outcome of an intensely competitive process in which antigenic peptides in the lysosomes compete not only among each other, but also with those derived from unrelated proteins — including self proteins — for binding to a limited number of available MHC class II molecules. It is the degree of success achieved in this process that will ultimately determine immunogenicity, not only at the level of T-helper cells, but also at the level of humoral immunity for T-dependent antigens. See also **Vaccination**; and **Vaccines**.

It may be pertinent to emphasize here that neither antigen receptors nor the MHC molecules possess the inherent capacity to distinguish between epitopes derived from self and nonself antigens. Indeed, immune recognition (or binding) is an unprejudiced process governed by conventional physicochemical rules. Discrimination is enforced at the level of response, where "self recognition" leads to tolerance either by deletion or inactivation of autoreactive lymphocytes. The discriminatory capacity is further enhanced by cellular components of the underlying innate immune system. In response to foreign antigens, particularly those derived from infectious agents, these cells produce a variety of chemical messengers which are now being commonly referred to as "danger signals." These molecules act on the lymphocytes, potentiating their ability to generate effector responses.

The phenomenon of "selective" immunodominance is even more pronounced when the immunogenicities of individual epitopes on multideterminant antigens such as proteins are compared. The common finding here has been that not all B- and T-cell epitopes present on a protein antigen are equally immunogenic. While some remain cryptic, a "hierarchy" of immunodominance is frequently observed against those determinants which display functional immunogenicity. Selective and hierarchical immunodominance for T-cell responses can easily be rationalized as the outcome of quantitative differences in loading of individual peptides onto MHC, resulting from the competitive processes described above. In such instances, competition would also include that among the various peptide fragments derived from the same antigen.

Selective and hierarchical immunodominance in T-dependent humoral responses has, however, proved more difficult to rationalize, particularly since B cells (or antibodies) directly bind their respective epitopes without taking recourse to accessory mechanisms. A variety of explanations has been put forward, of which the most prominent one proposes that the aetiology of selective recognition resides in the fact that antigen supplies become limiting soon after administration in the host. This is presumably due to proteolytic degradation. It is argued that a limiting antigen availability will restrict B-cell recognition to only those paratope–epitope fits that are of a high enough affinity, thereby restricting the spectrum of antibody specificities produced. More recent studies, however, suggest that it is not limiting antigen supply but rather a limiting frequency of antigen-primed T-helper cells that drives competitive selection, at least in a primary humoral response. These studies have demonstrated that while the early stage of a primary humoral response is indeed consistent with expectations in that all accessible domains of antigen are recognized, competitive selection is enforced during the subsequent stages of response maturation. Survival of an antigen-activated B cell continually depends on its ability to recruit T-cell help. Consequently, a limiting population of antigen-primed T-helper cells in an early primary response acts to enforce a competition between the numerous early activated B-cell clonotypes, or clonal subsets with distinct BCRs, for survival. The efficiency with which an antigen-activated B cell can recruit T-cell help is known to be directly related to the facility of antigen binding (either in terms of affinity or kinetics) by its BCR. This influences by defining the amount of antigen endocytosed by the BCR, subsequent to its processing and presentation of appropriate fragments as complexes with MHC for TCR recognition. As a result, those early activated B-cell clonotypes with favorable antigen-binding properties selectively engage the antigen-primed T-cell population, thereby denying it to the less competent clones, resulting in their elimination.

Antigen-binding characteristics of the BCR have also been shown to be critical in events downstream of the selection process by defining the quantum of T-cell help that a positively selected clonotype can recruit. This, in turn, will regulate the extent to which that particular cell can proliferate and eventually differentiate into antibody-secreting plasma cells. Collectively, these results provide a reasonable rationale for the observed phenomenon of selective and hierarchical immunodominance in humoral responses to T-dependent antigens.

In view of the enormous effort and energy that goes into equipping the adaptive immune system with a virtually unlimited recognition potential, why then does it restrict itself in its responses towards either multiple antigens or multiple determinants on a given antigen? The reason for this is not known. However, one may speculate that — in a situation where the total pool size must always remain constant — unrestricted proliferation of a given clonotype will always be at the expense of other, unrelated, cohorts. This could well lead to a 'dent' in the overall recognition repertoire. Yet another probable cause may stem from the need to minimize the possibility of generating autoimmune reactivities. Nondiscriminatory responses to a

spectrum of determinants may increase the likelihood of generating effector responses that cross-react with one or more self antigens. Nevertheless, regardless of what the true explanation might be, it is abundantly clear that the adaptive immune system is virtually limitless in its potential but — at the same time — highly disciplined in its behavior.

ANTIHISTAMINE. A synthetic substance essentially structurally analogous to histamine, the presence of which in minute amounts prevents or counteracts the action of excess histamine formed in body tissues. See also **Histamine**. Antihistamines are usually complex amines of various types. They find a number of medical uses.

In immediate hypersensitivity situations (reaction between antigen and antibody as encountered in hay fever, hives (urticaria), allergic (extrinsic) asthma, bites, drug injections, among others), antihistamines can be part of the effective therapy. Although widely used, antihistamines and steroids are not always the drugs of choice. In atopic dermatitis (chronic skin disorder), antihistamines may assist in breaking the itch-scratch cycle, particularly in persons whose sleep may be interrupted by pruritus. Antihistamine compounds for urticaria are also effective for atopic dermatitis therapy. Frequently, shifting from one antihistamine to another is effective and helps to reduce side effects of the drugs. Antihistamines are sometimes effective in the treatment of autoerythrocyte purpura, a rare disease. Antihistamines are also used in connection with mild penicillin reactions, and in cases of penicillin desensitization procedures. Certain antihistamines find application to control mild Parkinsonism.

Some antihistamines are particularly effective in alleviating the onset of motion sickness. Some antihistamines have been found helpful in relieving persistent, unproductive coughs that frequently accompany bronchitis or coughs associated with allergy. They are used in connection with perennial and seasonal allergic rhinitis.

Most antihistamines have anticholinergic (drying) and sedative side effects, sometimes producing marked drowsiness and reduction of mental alertness and thus should not be used by persons who operate machinery, drive vehicles, or otherwise must react quickly. Because of their similar structure, antihistamines appear to compete with histamine for cell receptor sites. Although conventional antihistaminic drugs, such as mepyramine, block the allergic and smooth muscle effects caused by histamine, the structure of these drugs is not sufficiently similar to histamine to inhibit histamine-stimulated gastric acid secretion. However, during the last few years, so-called histamine-blocking drugs have been developed which appear to be effective. It has been found that such compounds must contain the imidazole ring of histamine, with their potency enhanced by extension of the side chain. Among these new drugs are metiamide and cimetidine.

Some drugs in the antihistamine series play markedly different roles. Hydroxyzine hydrochloride and hydroxyzine pamoate have been used in the total management of anxiety, tension, and psychomotor agitation in conditions of emotional stress, usually requiring a combined approach of psychotherapy and chemotherapy. Hydroxyzine has been found to be particularly useful for making the disturbed patient more amenable to psychotherapy in long-term treatment of the psychoneurotic and the psychotic. The drug is not used as the only treatment of psychosis or of clearly demonstrated cases of depression. Hydroxyzine has also been found useful in alleviating the manifestations of anxiety and tension in acute emotional problems and in such situations as preparation for dental procedures. Hydroxyzine therapy has been used in treatment of chronic alcoholism where anxiety withdrawal symptoms or delirium tremens may be present. Hydroxyzine may potentiate narcotics and barbiturates.

Most conventional antihistamines are available for both oral and intravenous or intramuscular administration. In serious cases of urticaria (hives), for example, the injection rather than oral route is most effective. The major excretion route for most antihistamines is hepatic (liver), occurring within 4 to 15 hours.

In addition to the side effects previously mentioned, some antihistamines may cause neutropenia (neutrophil count in the blood is less than 1800 per cubic millimeter). Some antihistamines also may cause a modification of normal platelets in the blood.

Some of the more commonly used antihistamine compounds are listed below:

Ethanolamines:
- Diphenhydramine hydrochloride (Benadryl®)
- Dimenhydrinate (Dramamine®)

Ethylenediamines:
- Tripelennamine hydrochloride (Pyribenzamine®)

Alkylamines:
- Chlorpheniramine maleate (Chlor-Trimeton®)

Piperazines:
- Cyclizine hydrochloride (Marezine®)

Phenothiazines:
- Promethazine hydrochloride (Phenergan®)

Others:
- Cyproheptadine hydrochloride (Periactin®)
- Hydroxyzine hydrochloride (Atarax®)
- Hydroxyzine pamoate (Vistaril®)

ANTIHUNTING CIRCUIT. A stabilizing or equalizing circuit used in a closed-loop feedback system to modify the response of the system in order that self-oscillations may be prevented.

An *anti-hunting transformer* is sometimes used in D.C. feedback systems as a stabilizing network. The primary of this transformer is

in series with the load connected to the system. The secondary of the transformer has a voltage proportional to the derivative of the primary current, and is thus an appropriate signal to be fed back into some other part of the loop to prevent self-oscillations.

ANTIKNOCK AGENTS. Any of a number of organic compounds that increase the octane number of a gasoline when added in low percentages by reducing knock, especially in high-compression engines. Knock is caused by spontaneous oxidation reactions in the cylinder head, resulting in loss of power and characteristic ignition noise. Branched-chain hydrocarbon gasolines ameliorate this problem, and antiknock additives virtually eliminate it. Tetraethyllead, the most effective of these, has been used for many years, but its contribution to air pollution has almost eliminated its use in automotive fuels. Lead-free gasolines are now used in conjunction with catalytic converters. The antiknock agents used in them are nometallic compounds such as methyl-*tert*-butyl ether (MTBE) or a mixture of methanol and *tert*-butyl alcohol.

ANTILLES CURRENT. An ocean current, the northern branch of the north equatorial current flowing along the northern side of the Great Antilles carrying water that is identical with that of the Sargasso Sea. The Antilles current eventually joins the Florida current (after the latter emerges from the Straits of Florida) to form the Gulf Stream. See also **Ocean Currents**.

ANTIMATTER. Matter that consists of antiparticles. One of the great discoveries of modern physics was that for every type of elementary entity of matter and radiation (particle), there exists a corresponding conjugate type of entity (an antiparticle). In the antiparticle, certain of the particle-defining properties are identical (*conjugation invariant*), and others are reversed in sign (*conjugation reversing*). The reversed sign in a conjugation-reversing property allows one to maintain a conservation law for that property in the dramatic processes of *pair creation* and *pair annihilation* in which an antiparticle is observed to appear and disappear together with the particle to which it is conjugate. In those cases where all the conjugation-reversing properties occur with zero values, the antiparticle is identical with the particle. The progressive recognition of the existence of antiparticles was initiated by Dirac's relativistic antielectron theory in 1931, and by Anderson's independent experimental discovery of the antielectron (positron) in 1932.

Particles and (antiparticles) include: Electron (positron); Proton (antiproton); Electron neutrino (antielectron neutrino); Muon neutrino (antimuon neutrino); Neutron (antineutron); Positive pion (negative pion), etc.

The principle of charge conjugation symmetry states that if each particle in a given system is replaced by its corresponding antiparticle, then an observer will be unable to tell the difference. For example, if in a hydrogen atom, the proton is replaced by an antiproton and the electron is replaced by a positron, then this antimatter atom, if observed by persons also made of antimatter, will behave exactly like an ordinary atom. In an antimatter universe, the laws of nature could not be distinguished from the laws of an ordinary matter universe. However, it turns out that there are certain types of reactions where this rule does not hold, and these are just the types of reactions where conservation of parity breaks down. For an explanation of this, see long footnote in early portion of entry on **Particles (Subatomic)**. Also see list of related entries at end of aforementioned entry.

ANTIMER. See **Amino Acids**.

ANTIMETABOLITES. These substances fall into the general class of cytotoxic chemicals, i.e., agents that damage cells to which they are applied. Antimetabolites are so similar to normal enzymatic substrate molecules or metabolites as to gain entry into the cellular machinery of intermediary metabolism, but once there they differ enough to cause enzymatic inhibition. If incorporated into protein, nucleic acids, or coenzymes, for example, they will diminish the biological worth of those substances. Spectacular agents of this sort include the antifolic acids, such as aminopterin and amethopterin, various other vitamin analogs, and analogs of the naturally occurring purines, pyrimidines, nucleosides, and amino acids. Effective action against the integrity of the cell appears to be exerted at a number of points of intermediary metabolism in these multifarious antimetabolites. Of particular interest with many of them is an interference in normal nucleic acid metabolism. 5-Fluoro-2′-deoxyuridine, for example, acts to inhibit the synthesis of thymidylate, a necessary precursor of DNA, and the related 5-bromo-2′-deoxyuridine is actually incorporated into new DNA in the place of thymidine. Both of these agents increase the frequency of chromosomal disturbances. Various other base analogs, if incorporated into DNA, can lead to gene mutation by alteration of the normal sequence of nucleotides during replication through incorrect base pairing. 2-Aminopurine is an example of such a mutagen. 8-Azaguanine can be incorporated into ribonucleic acids, which are thus rendered defective. Among the actions of 6-mercaptopurine is an interference in the biochemical activity of coenzyme A, with resultant mitochondrial damage. Such amino acid analogs as b-fluorophenylalanine can effectively halt cellular activities by being incorporated into new proteins, which thereupon fail to attain their proper enzymatic or other functions.

Advantage is taken of the properties of antimetabolites in chemotherapy. In cancer chemotherapy, several antimetabolites are used. These include methotrexate, 6-mercaptopurine, 6-thioguanine, 5-fluorouracil, and cystine arabinoside. In the chemotherapy of metastatic breast cancer, 5-fluorouracil and methotrexate, in combination with cyclophosphamide, have been used. Antimetabolites, sometimes along with corticosteroids, are used in the therapy of various autoimmune diseases, such as thrombocytenic purpura, thyroiditis, Goodpasture's syndrome, among others.

Metabolites are implicated as agents that produce marrow aplasia as found in leukemia.

ANTIMICROBIAL AGENTS (Foods). Frequently substances are added to food products or applied to the surface of some foods while in transit or storage for the purpose of inhibiting the growth of certain destructive microorganisms. Such organisms affect a large percentage of fresh fruits and vegetables, as well as meat that has been cut and packaged. In addition to spoilage of the foods themselves, inadvertent consumption of certain molds can cause human disease. See also **Foodborne Diseases**.

Antimicrobials for foods act against microorganisms by (1) adversely affecting the cellular membranes of the destructive molds, yeasts, bacteria, etc.; (2) by interfering with the genetic mechanisms of the offending microorganisms; and (3) by interfering with cellular membranes of the microorganisms. The chemicals used for such agents function against the microorganisms not unlike the actions of antibiotics and other antimicrobial drugs in preventing or arresting microbially caused infections in humans and other animals.

For several years, the use of antimicrobial agents in connection with food products has been strictly regulated in the United States and most of the other developed countries. Consequently, this is a field that is subject to constant change. This is evidenced by continuing controversy concerning, for example, the use of nitrates and nitrites and, more recently, the use of sulfur dioxide and sulfites. In the United States, the best source for current regulations is the Food and Drug Administration, Washington, DC.

The principal antimicrobial agents still permitted, in most countries, for use in foods are benzoic acid and sodium benzoate; the parabens; sorbic acid and sorbates; propionic acid and propionates; acetic acid and acetates; nitrates and nitrites; sulfur dioxide and sulfites; diethyl pyrocarbonate; epoxides; hydrogen peroxide; and phosphates. These agents are not used uniformly — some are applied to the food products near point of sale or consumption; others are introduced directly into the products during processing; still others are used only in connection with controlling microorganisms that may collect in the processing equipment. For the latter purpose, inasmuch as the equipment is thoroughly washed after control chemicals are used, many stronger and toxic (to humans in high concentrations) can be used, including hypochlorites and strong detergents. Because the need to maintain food processing equipment in ultra-clean condition at all times, microbial decontamination is practiced on a shift or daily basis. To alleviate many of the problems and loss of time required by such cleaning operations, much food processing equipment has been designed for cleaning in place (CIP), where the cleaning is essentially automatic and does not require disassembly and re-assembly of critical

parts. Antimicrobial agents are also used in the packaging and wrapping of a number of food products, notably in connection with certain fruits and vegetables. Numerous studies have been made and, consequently, regulations established concerning the possible migration of such control chemicals from the packaging materials to the consumable product. Also, very powerful antimicrobial agents are permitted and used for special purposes, such as fumigating grain elevators and bulk food storage warehouses, where the objective is not simply that of killing microorganisms, but also to kill insects, rodents, and the like. See article on **Grain Storage Insects**.

Although food irradiation has been proved effective and could ultimately significantly alter the need for antimicrobial chemical agents, there remain a number of regulatory as well as consumer acceptance questions that require further resolution.

Benzoic Acid and Sodium Benzoate. These compounds are most active against yeasts and are less effective against molds. They are best suited for foods with a natural or adjusted pH below 4.5. The average dosage in foods ranges between 0.05–0.1% (weight), depending upon product. Benzoic acid occurs naturally in cinnamon, ripe cloves, cranberries, greengage plums, and prunes. See also **Benzoic Acid**. For a number of years the sodium salt has been preferred over the acid by food processors.

Common applications for these compounds include carbonated and noncarbonated beverages, but excluding beers and wines because of their action against yeasts. They are also used in salted margarine, jams, jellies, and preserves, pie fillings, salads and salad dressings, pickles, relishes, and other condiments, as well as olives and sauerkraut. In terms of human metabolism of these substances, some authorities have suggested that benzoate is conjugated with glycine to produce hippuric acid, which is excreted, possibly accounting for 65–95% of benzoate ingested. It has been postulated that the remainder is detoxified by conjugation with glycuronic acid.

Parabens. These compounds include the methyl, ethyl, propyl, and butyl esters of para-hydroxybenzoic acid. In the United States and a number of other countries, the methyl and propyl esters are preferred, while European food processors favor the ethyl and butyl esters. The parabens were first described in 1924 as having antimicrobial activity and initially were used in cosmetic and pharmaceutical products.

The parabens are most effective against molds and yeasts, but less active against bacteria, particularly gram-negative bacteria. The antimicrobial activity of the parabens is directly related to the molecular chain length (methyl is weakest; butyl is strongest). However, the solubility of these compounds is in inverse relationship with chain length. These characteristics give rise to the use of two or more esters in combination and sometimes in combination with entirely different antimicrobial agents, such as sodium benzoate. Below a pH of 7, the parabens are only weakly effective.

The parabens are used in carbonated beverages and other soft drinks, including cider. In lieu of pasteurizing or using Millipore filtration, some brewers use the parabens for controlling secondary yeast formation. Because of their activity against yeasts, they are not used in bread and rolls, but they find use in other bakery products, such as pie crusts, certain pastries, icings, toppings, fillings, and cakes. The parabens are particularly effective in preserving fruit cakes. Usage also includes creams and pastes, fruit products, flavor extracts, pickles and olives, and artificially sweetened jams, jellies, and preserves. Average dosage ranges from 0.03–0.6% (weight).

Sorbic Acid and Sorbates. Sorbic acid and its potassium and sodium salts are effective against molds, but less effective against bacteria. These compounds may be incorporated directly into the food product, but they are frequently applied by spraying, dipping, or coating. The compounds are effective up to a pH of about 6.5. This is higher than propionates and sodium benzoate, but not so high as the parabens. Metabolism in humans parallels that of other fatty acids.

Because sorbates affect yeasts, the compounds are not directly useful in yeast-raised goods. Sorbates are particularly favored for use in chocolate syrups. They can be used in wine production in conjunction with sulfur dioxide against bacteria and are effective in inhibiting development of unwanted yeasts. They are also used in artificially sweetened jellies, jams, and preserves; in pickles and related products; in nonsalted margarines; in dried and smoked fish products; in semimoist pet foods; in dry sausage castings; in fruit-filled toaster pastries; and in cheese and cheese products. In the latter products, the agents usually are applied by dipping or spraying. Wrappers also may be impregnated with sorbates.

Propionic Acid and Propionates. The antimicrobial properties of propionic acid and its calcium and sodium salts were first noted in 1913. Today, the calcium and sodium salts are most commonly used. These compounds are more active against molds than sodium benzoate, but have little if any activity against yeasts. The propionates are well known for their effectiveness against *Bacillus messentericus*, a "rope"—forming microorganism. These compounds are effective up to a pH of 5 or slightly higher. Metabolism in the human body parallels that of other fatty acids.

An early application for the propionates was that of dipping cheddar cheese in an 8% propionic acid solution. This increased mold-free life by 4 to 5 times more than when no preservative was added. For pasteurized process cheese and cheese products, propionates can be added before or with emulsifying salts. Research has indicated that propionate-treated parchment wrappers provide protection for butter.

Use of propionates in breads can extend mold-free life by 8 days or more. Propionates are favored by bakers because of their effectiveness against ropy mold in breads up to pH levels of 6. For cakes and unleavened bakery goods, the sodium salt is usually preferred; for bread, the calcium salt is favored. This additive also contributes to the mineral enrichment of the product.

Acetic Acid and Acetates. Acetic acid (pure and as vinegar) and calcium, potassium, and sodium acetates, as well as sodium diacetate, serve as antimicrobial agents. In the United States, vinegar can contain no less than 4 grams of acetic acid per 100 milliliters of product. Acetic acid and calcium acetate are most effective against yeasts and bacteria, and to a lesser extent, molds. The diacetate is effective against both rope and mold in bread. It is interesting to note that the antimicrobial effectiveness of acetic acid and its salts is increased as the pH is lowered.

Optimal pH range varies with products and target microorganisms, but generally falls between 3.5 and 5.5. These agents are particularly effective against *Salmonella aertrycke*. *Staphylococcus aureus*, *Phytomonas phaseoli*, *Bacillus cereus*, *B. mesetericut*. *Saccharomyces cerevisiae*, and *Aspergillus niger*.

Unfortunately, to be effective against microorganisms in bakery products, acetic acid concentrations must be so high that an overly sour taste is imparted to the products. Sodium diacetate, however, can be used in small concentrations in bread and rolls to control rope and molds. Traditional concentrations of the acetate are 0.4 part to 100 parts of flour. During recent years, the propionates have largely displaced sodium diacetate for this use.

Vinegar or acetic acid is used in a number of products as much for its sour taste as for its antimicrobial properties. Such products include catsup, mayonnaise, pickles, salad dressing, and various condiment sauces. These agents also have been used to a lesser extent in malt syrups and concentrates, cheeses, and in the treatment of parchment wrappers for products, such as butter, to inhibit mold.

Nitrates and Nitrites. For many decades, sodium nitrate and nitrite, and potassium nitrate and nitrite have been used to cure, preserve, and provide a characteristic flavor to such meats as bacon, corned beef, frankfurters, ham, and various sausages. This tradition continued into the late 1980s, but was seriously threatened in the mid- and late 1970s. Some researchers reported that N-nitrosopyrolidine (NPyr) formed in bacon upon application of heat during preparation for consumption. It was observed that there was a greater concentration of the NPyr in adipose tissue than in the lean portion. A connection was proposed that involved serious implications of the ultimate carcinogenic risk involved in meat treated with the nitrates and nitrites. Numerous tests proceeded. One of the main factors learned during this period was how little knowledge food scientists had concerning the fate of the nitrates and nitrites. Although the precursors of the nitrosamines formed under certain conditions of cooking were known, the mechanism of formation was unknown.

Sulfur Dioxide and Sulfites. The use of sulfur dioxide gas and with it the production of sulfites differ somewhat from the other antimicrobial agents thus far described. Historical records show that burning sulfur to produce sulfur dioxide (SO_2 gas) dates back to the ancient Egyptians and Romans who used it in connection with wine making. See **Sulfur**. Action by sulfur dioxide is accomplished in the gaseous phase. The effect of SO_2 is markedly determined by concentration and pH conditions of the target product. Research has demonstrated that most bacteria are inhibited by

HSO_3^- at concentrations of 200 parts per million (ppm) or less. With few exceptions, yeasts are also similarly inhibited. There are, however, some strains of molds that are considerably more resistant. The sulfite salts tend to be unstable and oxidize during long periods of storage, thus decreasing the availability of SO_2. This process is aggravated by the presence of moisture.

The most effective range for optimal microbial inhibition with sulfites is a pH of 2.5 to 3. It has been found that from 2 to 4 times greater concentrations of SO_2 are needed to inhibit the growth of microorganisms at a pH of 3.5 than at a pH of 2.5. It also has been demonstrated that, at a pH of 7, SO_2 has little if any effect on yeasts and molds, even at concentrations up to 1000 ppm. The inhibitory effects against bacteria are also considerably less when pH rises above 3.5. Some researchers believe that at higher pH levels, penetration of cell walls is much more difficult.

Because residual levels of sulfites in excess of 500 ppm impart a noticeable taste to food substances, this fact, regardless of any regulations toward limiting concentration, requires SO_2 levels to be controlled.

The use of SO_2 for preserving fruit juices, syrups, concentrates, and purees is particularly attractive in regions with warm climates and where products must be stored in bulk prior to processing. In these situations, the SO_2 concentration will range between 350 and 600 ppm. High sugar concentrations require higher levels of SO_2. For optimal effectiveness, the pH of some products has to be reduced.

It is a common practice to expose many fruits to SO_2 prior to dehydration. The SO_2 also extends storage life of raw fruit prior to dehydration. The optimal temperature for exposure to the gas is from 43 to 49 °C. Unlike fruit, vegetables are usually dipped in solutions of neutral sulfites and bisulfites.

Many countries do not allow use of SO_2 or sulfite salts on meats, fish, processed meat and fish products, or fresh fruits and vegetables. Where permitted, sulfite is helpful in eliminating "black spot" formation in shrimp. End-use application of sulfite related compounds as, for example, to prevent discoloration of leafy vegetables on salad bars, is now subject to regulation in the United States.

A major use of sulfites is in wine making. It is used for sanitizing equipment and, prior to fermenting, the grape *musts* have to be treated with sulfites to inhibit the growth of any natural microbial flora present. This is done prior to the addition of pure cultures of the appropriate wine-making yeasts. While fermenting SO_2 also can function as an anti-oxidant, clarifier, and dissolving agent. Sulfur dioxide is often used after fermentation to prevent undesirable post-fermentation alterations by various microorganisms. Levels of SO_2 during fermentation range from 50 to 100 ppm, depending upon condition of the grapes, temperature, pH, and sugar concentration. The wine industry uses sulfur dioxide dissolved in water, vaporized SO2, and sulfite salts. An SO_2 level of 50–75 ppm assists the prevention of bacterial spoilage during the bulk storage of wine after fermentation.

Antibiotics. Much attention has been given to the use of antibiotics in food-associated applications since the introduction of penicillin in the 1940s. Their use has been limited. The use of antibiotics in animal foodstuffs continues to remain a topic of controversy in many countries; in other countries they have been banned. Antibiotics carry into the meat produced and further into human diets, thus possibly reducing their effectiveness in the treatment of human diseases.

Diethyl Pyrocarbonate. The preservative qualities of this compound were not recognized until the late 1930s and research on the compound continues to date. Also called pyrocarbonic acid diethyl ester, the compound is extremely effective against yeasts. It is also active against bacteria, such as *Lactobacillus pastorianus*, and various molds. The substance is generally used in still wines, fermented malt beverages, and non-carbonated soft drinks, as well as fruit-based beverages. Regulations on its use vary from one country to the next. Effective inhibition by diethyl pyrocarbonate is largely confined to acid products of low microorganism count. Some researchers point out that the pH should be less than 4 and that the microorganism count should not exceed 500 per milliliter. Some authorities observe that because of its rapid hydrolysis, no toxicity or residue problems should occur in products where the compound is permitted.

Epoxides. Two compounds are included in this category of antimicrobials. One is the gas, *ethylene oxide*; the other, *propylene oxide*, a colorless liquid with a boiling point of 35 °C. Ethylene is highly reactive and must be used carefully and only with proper equipment. Somewhat less hazardous from an explosion standpoint, propylene oxide also has an explosive range of 2–22%. Consequently, these materials are usually mixed with inert substances, such as carbon dioxide or organic diluents.

Ethylene oxide is a universal antimicrobial in that it is lethal to all microorganisms. However, it is not universal from the standpoint of application. Propylene oxide is considered a broad-range microbiocide. In practically all aspects, propylene oxide is a considerably less effective agent, requiring longer exposures and greater concentrations because of its low penetrating power. However, propylene oxide is less toxic to humans.

The use of these gases (propylene oxide is volatilized) has been called "cold sterilization" and is frequently useful in sterilizing a number of low-moisture ingredients that end up on high-moisture foods. This prior sterilization lessens the total load on later thermal processing. The ability of these gases to kill microorganisms in low-moisture foods is an outstanding advantage. At the same time, macro-organisms also are killed. The gases find application in connection with spices, starches, nut meats, dried prunes, and glacé fruit. They are not used on peanuts (groundnuts).

Hydrogen Peroxide. Although usually regarded as a bleaching and oxidizing agent, this compound, H_2O_2, can be an effective antimicrobial and can be particularly useful in sterilizing processing equipment and packaging materials, notably prior to the aseptic packaging process. Regulations regarding the use of hydrogen peroxide vary from one country to the next.

Phosphates. The various phosphates are an effective multipurpose food additive chemical and functions other than their antimicrobial properties are usually given the greatest stress. The antimicrobial properties of the phosphates have been investigated over the years and are reasonably well documented.

This topic is discussed in detail in the "Foods and Food Production Encyclopedia," (D.M. and G.D. CONSIDINE, Eds.), Van Nostrand Reinhold, NY, 1982

ANTIMONY. [CAS: 7440-36-0] Chemical element, symbol Sb, at. no. 51, at. wt. 121.75, periodic table group 15, mp 630.5 °C, bp 1950 °C, sp gr 6.62 (vacuum-distilled solid at 20 °C) and 6.73 (single crystal). Naturally occurring isotopes are ^{121}Sb and ^{123}Sb. Antimony metal is a lustrous, silvery, blue-white solid, extremely brittle, and exhibiting a scale-like or flaky crystalline texture. The metal is easy to pulverize. The pure metal has a hardness of 3.0–3.3 on the Mohs scale and 55 on the Brinell scale. Of the more common metals, antimony is the poorest conductor (4.5 on a scale of 100 for copper). From careful studies, it has been observed that Sb contracts upon solidification rather than expanding. The element was first described by Th "olden (Valentine) in 1450.

There are two natural isotopes, ^{121}Sb and ^{123}Sb; and ten radioactive isotopes, ^{116}Sb through ^{120}Sb, ^{122}Sb, and ^{124}Sb through ^{127}Sb. ^{124}Sb is used as a radiation source in industrial instruments for the measurement of flow of slurries and interface measurements in pipelines. See also **Radioactivity**.

First ionization potential 8.64 eV; second 16.5 eV; third 25.3 eV; fourth 44.1 eV; fifth 56 eV. Oxidation potentials $Sb + H_2O \rightarrow SbO^+ + 2H^+ + 3e^-$, −0.212 V,

$$2\ SbO^+ + 3\ H_2O \longrightarrow Sb_2O_5 + 6\ H^+ + 4\ e^-,$$

-0.581 V, $Sb + 4OH^- \rightarrow SbO_2^- + 2H_2O + 3e^-$, 0.66 V. Other important physical properties of antimony are given under **Chemical Elements**.

Antimony exists in a number of allotropic forms. Gray or metallic antimony, density 6.79 g/per cm^3, is the stable form, forming rhombohedral crystals. Its vapor is that of Sb_4 up to 800 °C, where dissociation to Sb_2 commences. Yellow antimony, Sb_4, density 5.3 g/cm^3 is less stable than yellow arsenic. It is produced by oxidation of stibine (see below) at very low temperatures, above which it is unstable. It changes even in the dark to black antimony at -90 °C (in the light at -180 °C). Black antimony, produced most readily by cooling antimony vapor or oxidizing stibine at 40 °C, density 5.3, is metastable with respect to the gray form. It is also more reactive, igniting in air at room temperatures or above. Explosive antimony is produced by rapid electrodeposition of antimony from its halides. When heated or scratched, it undergoes an exothermic transformation to gray antimony. Its structure is amorphous, and differs somewhat from that of gray antimony.

Antimony is used in alloys, with lead for storage battery plates, with lead and tin in type metals and body solders, with tin and copper in bearing or antifriction metals. Antimony occurs chiefly as the sulfide (stibnite, Sb_2S_3) which is produced mainly in China, only small amounts in Mexico and Bolivia. Stibnite is (1) melted and reduced to antimony by iron metal and separated from fused ferrous sulfide (See also **Stibnite**); (2) roasted in air, and sublimed antimonous oxide collected and reduced by heating to fusion with carbon and sodium carbonate.

Antimony is also leached from tetrahedryte ore and recovered by electrowinning.

Antimony is scarcely tarnished in dry air but oxidizes slowly in moist air; burns at a red heat in air or oxygen with incandescence forming antimonous oxide; it is insoluble in HCl and is converted by HNO_3 into antimonous oxide or antimonic oxide, depending upon the concentration of acid; by chlorine into trichloride or pentachloride, by NaOH solution into antimonite.

Stibine. SbH_3, is formed by hydrolysis of some metal antimonides or reduction (with hydrogen produced by addition of zinc and HCl) of antimony compounds, as in the Gutzeit test. It is decomposed by aqueous bases, in contrast with arsine. It reacts with metals at higher temperatures to give the antimonides. The antimonides of elements of group 1a, 2a, and 3a usually are stoichiometric, with antimony trivalent. With other metals, the binary compounds are essentially intermetallic, with such exceptions as the nickel series, Ni_2Sb_3, NiSb, Ni_5Sb_2 and Ni_4Sb.

Trihalides. SbF_3, $SbCl_3$, $SbBr_3$, and SbI_3, are solids, and have pyramidal structures. Except for the fluoride, which is not hydrolyzed, they undergo partial hydrolysis only (in contrast with the phosphorus trihalides) on contact with water to yield insoluble oxyhalides, either of composition SbOX or varying somewhat from this composition to give such compounds as $Sb_4O_5Cl_2$. The antimony pentahalides, SbF_5 and $SbCl_5$ can be prepared, but the pentabromide exists only in double compounds, known as bromoantimonates, those for monovalent metals being of the type $MSbBr_6$, plus water of hydration, and yielding $SbBr_6^-$ ions. $SbCl_6^-$ and SbF_6^- ions are also known. Mixture of antimony(III) chloride, $SbCl_3$, in HCl solution with antimony(V) chloride, $SbCl_5$, in equimolar proportions yields a dark-colored solution. While antimony(IV) chloride cannot be isolated from it, compounds such as cesium antimony(IV) chloride, Cs_2SbCl_6 are formed by addition of cesium chloride, CsCl, and they are isomorphous with similar compounds of lead, tin, and other metals. However, tetravalent antimony should be paramagnetic because of the unpaired electron, whereas compounds of $SbCl_6^{2-}$ are diamagnetic. Therefore it may be that these compounds contain equimolar mixtures of $SbCl_6^-$ and $SbCl_6^{-3}$. The existence of these higher halide complexes with tin (and bismuth), but not with phosphorus or arsenic, may be due to steric considerations.

Antimony(III) oxide. Sb_2O_3 or Sb_4O_6, is formed by melting antimony in air, or from the hydroxide $Sb(OH)_3$. The Sb_2O_3 of commerce is produced from the oxidation of stibnite ore. Antimony is below arsenic in the periodic table, and $Sb(OH)_3$ is more definitely amphiprotic than $As(OH)_3$, forming not only antimony(III) salts and antimonites (containing the ion SbO_2^- or $Sb(OH)_4^-$), but also basic salts, especially the antimonyl salts, containing the ion SbO^+. Antimony(V) oxide, formed by oxidation of the metal with HNO_3, is less soluble in H_2O than As_2O_5. Antimonic acid cannot be obtained by hydration, and the product resulting upon hydrolysis of pentahalides has a variable H_2O content. The salts of the acid, the antimonates, are of the type $M^ISb(OH)_6$, as Pauling showed to be necessary to conform to accepted ionic radius ratios. Although the strength of antimonic acid has not been accurately determined, it appears to be comparable to acetic acid.

Antimony(IV) oxide. Obtained by heating in air the trioxide or the hydrated pentoxide.

There is a marked structural difference between the phosphates and the antimonates. Thus sodium pyroantimonate, $Na_2H_2Sb_2O_7{\cdot}5H_2O$ contains the ion $Sb(OH)_6^-$ rather than $Sb_2O_7^{4-}$, and the magnesium compound (hydrated) which has a 12:1 ratio of oxygen to antimony, and would thus be a hexahydroxyantimonate, has the (X-ray determined) structure $[Mg(H_2O)_6][Sb(OH)_6]_2$.

Sulfides. Sb_2S_3 and Sb_2S_5, which may be obtained from the elements or by precipitation, respectively, of Sb(III) and Sb(V) solutions with H_2S. The Sb_2S_3 dissolves in alkaline solutions to form thioantimonites, containing the ion SbS_3^{3-}, or $Sb(SH)_6^-$, while Sb_2S_5 forms the thioantimonates, containing SbS_4^{3-}. The latter is probably present as $[SbS_2(SH)_{21}(OH)_2]^{3-}$ or $[SbS_4(H_2O)_2]^{3-}$.

In alloys, antimony is easily detected by its formation of a white solid upon treatment with concentrated HNO_3 and subsequent separation from tin, which is the only other metal thus forming a white solid.

Both trivalent and pentavalent antimony form several organic antimony compounds. Some of these include methylstibine CH_3SbH_2 and the substitution product, methyldichlorostibine CH_3SbCl_2; phenylstibine $C_6H_5SbH_2$ and the substitution product, phenyldichlorostibine $C_6H_5SbCl_2$; methylantimony tetrachloride CH_3SbCl_4; phenylantimony tetrachloride $C_6H_5SbCl_4$; sodium methylantimonate $Na[CH_3Sb(OH)_5]$; sodium trifluoromethyl antimonate $Na[(CF_3)_3Sb(OH)_3]$; triethylstibine sulfide $(C_2H_5)_3SbS$; tetraphenylstibonium tetraphenylborate $[(C_6H_5)_4Sb][B(C_6H_5)_4]$; stibiobenzene $C_6H_5Sb{=}SbC_6H_5$ and lithium hexaphenylantimonate $LiSb(C_6H_5)_6$.

Uses. Representative alloys containing antimony are described in the Table 1.

TABLE 1. ANTIMONY CONTENT OF REPRESENTATIVE ANTIMONY-CONTAINING ALLOYS

Hard lead	Up to 12% Sb
Antimony reduces mp of Pb and hardens resulting alloy. Alloy has better abrasion resistance than chemical Pb at temperatures below 140 °C. Alloy is age-hardenable.	
Tin-lead solders	Up to 1% Sb
Type metals	3–19% Sb
These Pb-base alloys also contain from 3–9% Sn.	
Lead-base diecasting alloys:	
[a]ASTM No. 4	14–16% Sb
ASTM No. 5	9.25–10.75% Sb
Bearing alloy	15% Sb
CT metal	12.5% Sb
Tin-free alloy	10% Sb
Babbitt (bearing) metals:	
[b]SAE 10	4–5% Sb
SAE 11	6–7.5% Sb
SAE 12	7–8.5% Sb
SAE 13	9.25–10.25% Sb
SAE 14	14–16% Sb
SAE 15	14.5–16% Sb
Britannia metal	5% Sb
This alloy also contains 93% Sn and 2% Cu. Very useful for spinning utensils.	
Pewter	Up to 7% Sb
Pewter also contains up to 20% Pb and 4% Cu with the remainder made up by Sn.	

[a] American Society for Testing and Materials
[b] Society of Automative Engineers

Metallic antimony is an effective pearlitizing agent for producing pearlitic cast iron. The principal use of antimony, however, is in the form of the oxide. Its major application is as a flame retardant for plastics and textiles. Other applications of importance are in glass, pigments, and catalysts.

Toxicity. The threshold limit value of antimony and its compounds is 0.5 milligram/cubic meter (as Sb). Antimony and its compounds used under conditions giving rise to dust, fume, and vapor should be carried out under proper ventilation. In handling antimony and its compounds, appropriate hygienic practices and good housekeeping should be observed. Stibine, SbH3, requires extreme caution in handling because it is very toxic. When using antimony and its compounds, reducing conditions, which may give rise to the undesired formation of stibine, must be avoided.

ANTINODES (or Loops). The points, lines, or surfaces in a standing wave system where some characteristic of the wave field has maximum amplitude.

ANT *(Insecta, Hymenoptera).* Social insects of varied structure and habits. They may be distinguished from the related bees and wasps by the form of the slender petiole, which connects thorax and abdomen; in the ants it is expanded above and looks wedge-like in profile. Ants have been known to exist on earth for some 30 to 40 million years. Evidence of their early existence is found in historic fossil Baltic amber. The average ant is about one-sixteenth inch in length, but the large Texas ant may measure up to one inch or more. Stages in the development of the ant are egg, larva, pupa, and adult. Most ants are omnivorous and wingless. There are over 5000 species of ants. Among varieties found in the United States are the army ants, carpenter ants, the leaf cutters, the dairyman, the garden (common ant), honeydew, and mound-building ants.

A sampling of ant types and habits would include: the voracious Argentine ant, which steals eggs and ants from other nests, making the captive ants their slaves; the honey-pot ant, which stores extra honey in its flexible body to furnish food for the young; the Legionaries ants, which travel in single file to steal and store other insects for food, live in wet areas mostly under foliage, and are nearly blind; the garden ant, which builds small mounds of sand in gardens or on walkways (brown in color, and with a good-natured temperament); the Texas ant, known as the fungus grower in the ant world, which builds mounds up to 12 inches (0.3 meter) in diameter, and chews leaves into a mulch for the growth of fungus that then becomes its food; the harvest ant or seed collector, one of the largest of the ants, which stores small seeds of various kinds in its mound and whose bite is painful; the carpenter ant, which drills tunnels in rotting wood; the sugar ant, which is extremely small, very light-brown in coloration, harmless, and excessively fond of sweets; the tree ant of India (*Olcophylla smaragdina*), which uses its larvae as a means of sewing leaves together to make a nest; Brazil's terrible ant, which is fully 1 inch (1.5 centimeters) long, and produces a vicious sting.

It has been determined that the behavior habits of ants are strictly acquired naturally, as in the case of the honeybee, and that no intelligence in the normal interpretation of the word is required. Ants recognize excitement and unusual conditions, however, and relay this information to other ants by stroking them with their antennae, pecking them on the head or thorax: if a danger signal is required, the ant will open its jaws wide, or it may hold its abdomen high and run about wildly. Ants are also known to leave scent trails by pressing their stomach close to the ground. Although the scent persists for just a short time, the scent trail is refreshed by other ants repeating the same procedure.

Texas Leaf-Cutting Ant (*Atta Texana*, Buckley). Native to southern and eastern Texas (and western Louisiana), this species of ant prefers loamy soil that is adequately drained. Some nests range from 10 to 20 feet (3 to 6 meters) in depth, incorporating numerous craters, but not rising very high above ground level. Such nests are the habitat of many thousands of ants. The worker ants of this species range from $\frac{1}{16}$ to $\frac{1}{2}$ inch (1.5 to 12 millimeters) in length, they are light-brown in color, and have hardened bodies equipped with many spines on the head and thorax. Food for these ants is prepared by the workers who macerate freshly cut leaves, which subsequently promotes the growth of a fungus used as food. In addition to serious pests in the garden, the ants attack field crops and, in particular, they are damaging to young pine seedlings and thus must be eradicated in areas of reforestation. Poisoned bait that the ants can carry back to their nest is effective. Argentine bait has been successful. This includes tartaric acid crystals, benzoate of soda, and sodium arsenite. These materials are boiled, along with sugar, and then mixed with honey. The resulting syrup is used as bait for ants that like sweet foods, such as the Argentine ant. The bait does not work, however, with the Pharaoh ant, the southern fire ant, or the tiny thief ant. A similar bait for protein-loving ants is prepared from thallous sulfate, groundnut (peanut), butter, and German sweet chocolate. Both of these concoctions are quite poisonous and must be prepared and used with extreme caution, marking all containers as *poison*. Placing insecticides in the normal pathways of travel of ants also is effective. Pouring liquid carbon bisulfide directly into nest openings also can be effective.

Imported Fire Ant (*Solenopsis saevissima richteri*, Forel). Native to South America, the fire ant invaded the United States at Mobile, Alabama in 1918. Since then, it has spread into more than 130 million acres (52 million hectares) in Alabama, Arkansas, Florida, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, and Texas. This is a small, aggressive insect that produces a painful, burning sting. When disturbed, the ant is quick to attack both people and domestic animals. Each colony of imported fire ants builds a hard-crusted nest, or mound, sometimes 3 feet (1 meter) high and nearly 3 feet (1 meter) across. In some areas, there may be as many as 50 mounds per acre (125 per hectare), making it difficult to operate mowers and other machinery in pastures and fields, as well as lawns and park grounds. See Fig. 1.

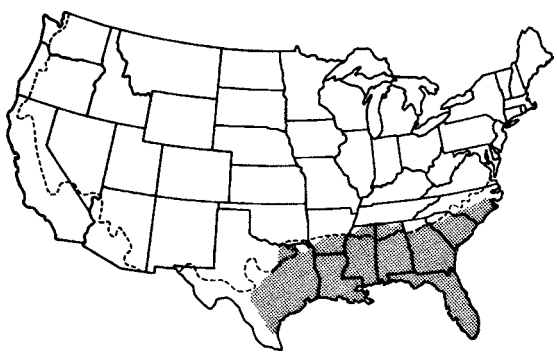

Fig. 1. Areas of infestation of the imported fire ant in the southeastern United States as of 1990. Migration of the ants commenced in a comparatively small strip of land along the southern borders of Louisiana and Mississippi. The infested area spread southwesterly to include part of Texas and northeasterly to include nearly all of Alabama, Georgia, Florida, and South Carolina. Entomologists forecast the spread ultimately will include nearly all of central and south Texas, southern Arizona, and north along the western half of California, Oregon, and Washington. A meticulous survey of over 29,000 physicians in the affected areas (conducted in 1989) identified 32 deaths attributed to anaphylaxis caused by fire-ant stings. The patients who died ranged from 16 months to 65 years of age and usually had been stung fewer than five times. Anaphylaxis may occur hours after a sting. Seizures and mononeuritis also have been reported after fire-ant stings. (Map: *USDA*.)

The damage from the pest is difficult to measure in economic terms. The stings cause blisters that require as long as 10 days to heal. If the blisters break, infection may develop. Some people have been hospitalized; a few have died, primarily from allergic reaction to the stings. Some farm workers may refuse to work on land where these ants are numerous for fear of being stung while clearing clogged mower blades, handling crops, and performing other agricultural tasks.

Imported fire ants look like ordinary house and garden ants. They are from $\frac{1}{8}$- to $\frac{1}{4}$-inch (3 to 6 millimeters) long and reddish-brown or dark brown to black in color. A single mature mound contains a queen ant, several thousand winged males and females (future queens), and up to 100,000 workers. The winged forms leave the mound, most frequently in May and June, and mate in flight. Afterward, the queens land and

break off their wings. They dig shallow burrows in the soil and begin to lay eggs that start new colonies. Winds and air currents may carry the new queens 12 or more miles (22+ kilometers) during mating flights. They prefer to build their "homes" in open, sunny areas. Thus, the most valuable land on farms and in suburbs is often the most likely to be infested.

Cooperative programs between federal, state, county, and local governments have been established to make continuous surveys and to provide controls over the pest. Quarantines may be established to prevent further widespreading of the insect.

Medical Implications of Fire-Ant Stings. The human resistance to the effects of fire-ant stings ranges widely. Some persons develop extreme sensitivity (anaphylaxis) to a single sting. In relatively infrequent cases, seizures and mononeuritis have been reported after fire-ant stings.

Investigators have found that the venom of the fire ant is quite different from that of wasps, bees, and hornets, which are aqueous solutions containing proteins. Fire-ant venom, in contrast, contains up to 95% alkaloids, with only a small aqueous fraction of soluble proteins. Researchers have found that almost 100% of the fire-ant venom contains 2,6-di-substituted piperidines that have hemolytic, antibacterial, insecticidal, and cytotoxic properties. However, the very small quantity of proteins present in the venom induce allergic responses in some individuals.

As reported by R.D. DeShazo (University of South Alabama College of Medicine), B.T. Butcher (Arthritis Foundation, Atlanta, Georgia), and W.A. Banks (USDA, Gainesville, Florida), "Since the natural history of sensitivity to imported fire ant stings is unknown, the indications for immunotherapy to prevent the recurrence of sting-related anaphylaxis are unclear. Studies of anaphylaxis in response the stings of other insects, such as honeybees and yellow jackets, have established that the production of IgE (antibody responses) after stings is common and often transient. Moreover, there are differences between adults and children in the clinical manifestation of anaphylaxis, the probability of serious reactions after subsequent stings, and the duration of sensitization. This information is useful in selecting patients who would benefit from immunotherapy with honeybee and yellow-jacket venom. Unfortunately, similar information is not available for imported fire-ant venom."

Fire-ant stings produce at least three types of local reactions: (1) a wheal-and-flare reaction; (2) a sterile pustule; and (3) a large local reaction. The wheal-and-flare reaction usually resolves in about a half-hour to an hour and evolves into a fully developed sterile pustule at the site of the sting within 24 hours. The epidermis covering the pustule sloughs off over a period of 48 to 72 hours. Healing occurs at the base of the lesion, where it is covered with new epidermis. No treatment has been found to prevent or resolve pustules. If there are several pustules and they become excoriated (i.e., if they are worn off the skin) and then superinfected, pyoderma and even sepsis can result, a condition of specific concern to diabetics. Much more detail is provided in the DeShazo, Butcher, and Banks reference listed.

Early, rather effective control chemicals such as the pesticide heptachlor and later mirex were used in attempts to eradicate the fire-ant mounds. These substances were banned because of their carcinogenicity. Drenching individual ant mounds with diazinon or injecting mounds with chlorpyrifos (under pressure) are less effective, because adjacent areas soon become infested from the perimeter. In recent years, there have been numerous reports of how fire ants are attracted to an electrical field. They have eaten through electrical lines, causing power outages. Incidentally, the Texas site for the Super Conducting Supercollider was infested with fire ants. The cause of the electrical field attraction of the insects has not been explained.

Cornfield Ant (*Lasius alienus*, Förster). The cooperation between ant and aphid is mentioned in the entry on **Aphid**. The corn root aphid (*Anuraphis maidiradicis*, Forbes) and the cornfield ant provide an excellent example of this cooperation and thus, indirectly, the cornfield ant contributes in a major way to the damage wrought on corn by the corn root aphid. Whenever the food producer notices half-grown corn (maize) that is not doing very well, as indicated by sluggish growth and yellow- or red-tinged leaves, it will be noted that, at the base of the plant, there will be numerous blue-green aphids and a great activity of small brown cornfield ants milling about between the corn roots (which they tunnel) and a number of anthills near the plant. During the winter season, aphid eggs are collected by the ants and stored in their nests during the cold weather. The eggs are frequently moved about to assure they are obtaining the best exposure to temperature and humidity. In early spring, the aphid eggs commence to hatch. At this time, the ants carefully carry the tiny eggs to the roots of nearby smartweed plants or other grasses suitable for aphid feeding. After 2 to 3 weeks of this feeding process, the full mature aphid females commence to give birth to live female young. In turn, these females mature and give birth to others in 2 weeks or less. Reproduction is by parthenogenesis (development of the egg without fertilization). Throughout the summer, the ants care for the welfare of the aphids. Distribution of the aphids in a corn (maize) field, for example, depends almost totally upon the actions of the ants. The reward to the ant is the honeydew, a sticky sweet exudation from the anal opening of the aphid. The honeydew comprises a major part of the ant's diet. It has been observed that ants have moved over 150 feet (50 meters) from a grass meadow to a cornfield, moving their own young as well as large numbers of aphids, which the ants then turn out to pasture on young corn roots.

Thief Ant (*Solenopsis molesta*, Say). A common household pest, the thief ant prefers protein foods to sweet foods, and sometimes damages grain seed when germinating.

ANTIOXIDANT. Usually an organic compound added to various types of materials, such as rubber, natural fats and oils, food products, gasoline, and lubricating oils, for the purposes of retarding oxidation and associated deterioration, rancidity, gum formation, reduction in shelf life, etc.

Rubber antioxidants are commonly of an aromatic amine type, such as dibeta-naphthyl-para-phenylenediamine and phenyl-beta-naphthylamine. Usually, only a small fraction of a percent affords adequate protection. Some antioxidants are substitute phenolic compounds (butylated hydroxyanisole, di-tert-butyl-para-cresol, and propyl gallate).

When used in foods, antioxidants are highly regulated to extremely small percentages in most countries — down to the low fractions of one percent. Composition of the substrate, processing conditions, impurities, and desired shelf life are among the most important factors in selecting the best antioxidant system for a given food product. The desirable features of antioxidants may be summarized as (1) effectiveness at low concentrations; (2) compatibility with the substrate; (3) nontoxic to consumers; (4) stability in terms of conditions encountered in processing and storage, including temperature, radiation, pH, etc.; (5) non-volatility and non-extractability under the conditions of use; (6) ease and safety in handling; (7) freedom from off-flavors, off-odors, and off-colors that might be imparted to the food products; and (8) cost effectiveness.

Mechanism of Oxidative Degradation. It could appear that inasmuch as oxidative degradation occurs in a variety of organic materials that are dissimilar in appearance and have entirely different applications and different properties, with degradation producing different effects, the oxidation mechanism itself might be different. Current knowledge indicates, however, that the mechanism of oxidative degradation is the same for all organic substances. They appear to degrade by the same free-radical mechanism.

Common examples of food oxidative degradation include products that contain oils and fats. For example, some antioxidants have made it possible to store groundnuts (peanuts) and other nuts, maize (corn) products, and bakery and cereal products on the shelf for periods well in excess of the four months that was considered the traditional limiting period prior to the appearance of such additives. Other examples of food products that tend to become rancid by way of oxidation include various meat-flavored stuffing mixes, cake mixes, unbaked cheesecake mix, and essentially all foods that incorporate lipids. The stability of natural fats and oils present in raw materials varies over a wide range and hence the amount of antioxidant required must be tailored to each product situation.

Enzymatic "browning" is another example of oxidative degradation. The enzymes in fruits and vegetables cause apples, apricots, and potatoes, among others, to darken when they are exposed to air after being cut, bruised, or allowed to over-mature. Some antioxidants can prevent or delay enzymatic browning much in the same manner as dipping freshly cut fruits in lemon, orange, or pineapple juice. Limonene and ascorbic acid naturally present in these juices serve as antioxidants. Oxidative changes may affect carbohydrate, protein, and fat substances, the primary building blocks of foodstuffs, but generally the oxidative rancidity problem results mainly from the *autoxidative* degradation of fatty (glyceridic) components.

Some authorities describe oxidation as a free radical, chain-type reaction. At usual processing temperatures and more slowly at room temperature, organic free radicals ($R\bullet$) are formed. These react with oxygen to form peroxy radicals ($ROO\bullet$), which can abstract a hydrogen atom from the affected substance to form a hydroperoxide (ROOH) and another organic free radical. The cycle repeats itself with the addition of oxygen to the new free radical. The unstable hydroperoxides left along with the substance are the major source of degradation. Under the influence of heat, light, and any metals if present, the hydroperoxides decompose to form carbonyl groups. When this happens, the organic molecule breaks and splits off another organic free radical. Ultimately, this type of degradation can lead to rancidity and color deterioration in oils and fats.

An antioxidant ties up the peroxy radicals so that they are incapable of propagating the reaction chain or to decompose the hydroperoxides in such a manner that carbonyl groups and additional free radicals are not formed. The former, which are called *chain-breaking antioxidants*, *free-radical scavengers*, or *inhibitors*, are usually hindered phenols or amines. The latter, called *peroxide decomposers*, are generally sulfur compounds or organophosphites. A number of antioxidants useful in rubber and plastics, for example, are not suited to food products because of their toxicity.

A mixture of two antioxidants often will display synergism. Probably the most generally effective mixtures of antioxidants are those in which one compound functions as a decomposer of peroxides (sulfides, thiodipropionate) and the other as an inhibitor of free radicals (hindered phenols, amines). Although the latter retards the formation of reaction chains, some hydroperoxide is nevertheless formed. If this hydroperoxide then reacts with a decomposer of peroxides, instead of decomposing into free radicals, the two antioxidants act together to complement each other. Moreover, the peroxide decomposer may itself be subject to oxidation by peroxy radicals, and its efficiency will therefore be increased in the presence of an inhibitor of free radicals. In the case of phenolsulfide mixtures, the sulfide (peroxide decomposer) also continuously regenerates the phenol (radical scavenger) to accentuate the synergistic nature of the mixture. Metal chelators or deactivators, such as citric and phosphoric acids, of pro-oxidant metals (iron, copper, nickel, tin), ultraviolet-light absorbers (carbon black, substitute benzophenones, benzotriazoles, and salicylates), and antiozonants (substituted phenylenediamines) also develop synergistic effects with antioxidants.

Applications of Antioxidants. The use of antioxidants in foods, pharmaceuticals, and animal feeds (direct feed additives), as well as their use in food-contact surfaces (indirect additives) is closely regulated by the governments of several countries. Antioxidants are approved only after extensive extraction, toxicological, and feeding studies. The list is relatively limited. Although antioxidants have been used for several decades and some occur naturally in food substances, intensive research in continuing, partly accelerated by the growing use of unsaturated oils in numerous food products.

Butylated hydroxyanisole (BHA) was first used in food products in 1940. This continues as one of the commonly used antioxidants, sometimes in combination with butylated hydroxytoluene (BHT), propyl gallate, citric, or phosphoric acids, to obtain a synergistic effect. In foodcontact surfaces, BHT has been used by itself or in combination with thiodipropionates and/or phosphoric acids, to obtain a synergistic effect. Well over $50 million of antioxidants are produced per year commercially in the United States alone.

The value of antioxidant protection by way of natural food sources has been pointed out in the literature with considerable frequency. Among the components of soy flour known to have some antioxidant properties are isoflavones and phospholipids. Amino acids and peptides in soybean flour also possess some antioxidant activity. There also may be some antioxidant impact from aromatic amines and sulfhydryl compounds.

Rosemary and sage have been shown to have effective antioxidant properties. The extracts in the past have been of strong odor and bitter taste and thus unsuited for use in most food products. However, solvent extraction procedures have been developed to produce purified antioxidants from rosemary and sage.

For many years, in connection with certain food products, a barrier to freeze-drying has been the problems associated with the storage stability of foods that are susceptible to lipid oxidation. In order for such foods to have a reasonable shelf life and acceptable flavor characteristics, protective additives, which retard oxidation, are often added before dehydration. Such antioxidants must carry through the process and not be lost because of volatilization. For these applications, BHA, BHT, and tert-butylhydroquinone (TBHQ) have been found quite effective.

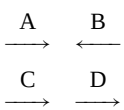
ANTIPARALLEL. Having opposite senses. Thus the vectors A and B are antiparallel, while the vectors C and D are parallel.



ANTIPARASITIC AGENTS, ANTIPROTOZOALS. Diseases caused by protozoa affect more people than those brought on by any other biological cause. There are over 60,000 species of protozoa, of which some 10,000 are parasitic. In humans, protozoa chiefly infect the gastrointestinal tract, vagina, urethra, blood, and blood-forming organs. Malaria is the most widespread of the protozoan diseases, and is responsible for the greatest number of deaths due to infection. Although protozoan diseases occur throughout the world, they impact most severely on people of tropical areas where there is widespread malnutrition, minimal health education, and poor sanitation. Fatal protozoal infections are occurring to an increased extent in the more developed countries among immunosuppressed individuals, especially those with AIDS. Domesticated and wild animals are also extensively affected and can harbor and propagate infectious protozoa. Protozoan diseases of poultry and ruminants deprive large numbers of people, especially in Africa, of much needed food.

The word protozoa is derived from the Greek *protos* and *zoon*, meaning first and animal, respectively. Protozoa are a highly varied group of one-celled animals that reproduce by both sexual and asexual means. Given suitable conditions, ie, host susceptibility and lack of immunity, their numbers can increase by the tens of thousands in the course of one day. They are eukaryotic (having a well-defined nucleus), are surrounded by a membrane through which nutrients can pass, and their cytoplasm contains organelles that enable them to generate energy, digest nutrients, respire, grow, and reproduce. Protozoa are capable of motility and propel themselves by means of cilia, flagella, or pseudopods. Accurate differentiation and identification of infective protozoa facilitates the choice of treatment, but is frequently a difficult task.

Progress in finding new chemotherapeutic agents to combat protozoal disease has been slow. The urgency of the problem has been dramatized by the realization that AIDS patients usually die from opportunistic

diseases, many of which are protozoan in origin. There are no satisfactory treatments for many of the protozoal diseases; where there are proven drugs available, parasites in many parts of the world are developing resistance to them. This resistance has necessitated the continual design, synthesis, and testing of new classes of prophylactic and therapeutic agents. Despite the alarming view by a World Health Organization spokesman the war against tropical diseases is being lost, only a modest proportion of the world's research resources is being devoted to devising new treatments. Unfortunately, most pharmaceutical firms do not anticipate adequate financial reward from solving the health problems of developing countries.

ANTIPARTICLES. One of the great discoveries of modern physics is that for every type of elementary entity of matter and radiation (particle), there exists a corresponding conjugate type of entity (antiparticle). In the antiparticle, certain of the particle-defining properties are identical (*conjugation-invariant*) and others are reversed in sign (*conjugation-reversing*). The reversed sign in a conjugation-reversing property allows one to maintain a conservation law for that property in the dramatic processes of *pair creation* and *pair annihilation* in which an antiparticle is observed to appear and disappear together with the particle to which it is conjugate. In those cases where all the conjugation-reversing properties occur with zero values, the antiparticle is identical with the particle. The progressive recognition of the existence of antiparticles was initiated by Dirac's relativistic antielectron theory in 1931, and by Anderson's independent experimental discovery of the antielectron (the positron) in 1932. See also **Particles (Subatomic)**.

ANTIPODAL CELLS. The three usually small cells which occur in the embryo sac of angiosperms at the end most distant from the micropyle. No known function has been ascribed to them.

ANTIPODE. With respect to any given point, the opposite point is known as the antipode. In terms of a sphere, Y would be the antipode of X of a line XY drawn through the center of the sphere and intersecting the two opposite surfaces. Antipodes often refer to regions rather than specific localized areas. Thus, the British Isles are approximately antipodal with Australia and New Zealand.

ANTIPROTON. An elementary particle having a mass equal to that of the proton, differing from the proton only in the sign of its charge, which is negative, and a magnetic moment oppositely directed with respect to its spin. Positive identification of the antiproton was first made at the University of California. In 1959 Segre and Chamberlain received the Nobel Prize in physics for this discovery. Protons that had been accelerated to an energy of 6200 MeV in the bevatron, the proton synchrotron of the University of California Radiation Laboratory at Berkeley, were allowed to collide with a copper target. Negatively charged particles coming out in a forward direction from this collision were selected and separated in momentum by a focusing and analyzing magnet system to provide a beam of negative particles of known momentum. After a time of flight of about one-tenth of a microsecond, this beam may be expected to consist mainly of negative pions and muons, with some negative kaons (mass about 965 electron masses) and possibly negative protons. These particles were then distinguished both by measurement of their time of flight from the target (since particles of different mass have different velocities for given momentum) and by means of a device measuring the velocity of each particle passing through by the angle of its Cerenkov radiation. In this way the presence of negative particles with protonic mass (within about 10%) and distinct from the known kaons and hyperons was established. Their rate of production for the momentum and direction of this experiment was about one negative proton for every 50,000 negative pions with the same momentum and direction.

Antiprotons were first captured (1987) by researchers working with the Low-Energy Antiproton Ring (LEAR), which is a part of the large European Laboratory for Particle Physics (CERN) located in Geneva, Switzerland. The team of scientists made up from physicists of the University of Washington and the University of Mainz (West Germany) captured antiprotons from a high-energy accelerator and stored them for several minutes in an electromagnetic ion trap. The scientists forecast that with improvements in the trapping process it will facilitate the precise measurement of the inertial mass of the antiproton. They plan to ascertain the mass from the frequency of the circular motion of the antiprotons around the magnetic field lines in the trap (cyclotron resonance frequency). This will require slowing down the axial motion in the trap from the kiloelectron volt energies of the present equipment to a maximum of approximately 5×10^{-4} eV, i.e., the thermal energy associated with the ambient temperature of 4.2 K. To make the most meaningful measurement, there should be just one antiproton cooled to 4.2 K and the trapping time should be at least one day, compared with the minutes of the first experiment. Much greater vacuum and cryogenic cooling with helium is planned for future experiments. The scientists envision a number of interesting uses for trapped antiprotons: — determination of the gravitational constant of an antiproton; and possible use of large numbers of antiprotons as an energy source for space and military applications, although the scientists in the late 20th Century admitted that the idea of collecting antiprotons in macroscopic quantities stretched the imagination. See also Particles **(Subatomic)**; and **Proton**.

ANTIPYRETIC. Any physical agent or drug that lowers the temperature of the body. Among antipyretics used are aspirin, antipyrine, acetanilid, and phenacetin. See also **Analgesics**.

ANTIRESONANCE (or Parallel Impedance). In general, a condition of maximum impedance, as results when two or more impeders are connected in parallel, under such conditions that (for resistance-less impeders), Z approaches infinity when $\omega_1^2 = 1/LC$.

ANTISOLAR POINT. The point on the celestial sphere that lies directly opposite the sun from the observer, i.e., on the line from the sun through the observer. See also **Celestial Sphere and Astronomical Triangle**.

ANTISTOKES LINES. When all the molecules are in the normal state, the transitions caused by exciting radiation are those in which the scattered or fluorescent light is of the same or lower frequency than the incident light (Stokes Lines). However if some of the atoms or molecules are in states other than normal, lines of frequencies higher than that of the incident light (Antistokes Lines) may result. See **Raman Spectrometry**.

ANTISYMMETRIC. In mathematics, a term used to denote a function that is transformed into its negative when the variables of the function are interchanged in pairs. In physical science, the term antisymmetric is applied to any physical system in which each point has properties opposite to those of a point symmetrically located with respect to it, e.g., an electric dipole is antisymmetric in its charge distribution. See **Symmetric**.

ANTITOXIN. (1) A substance made and elaborated in the body to neutralize a specific bacterial, plant, or animal toxin; (2) one of the class of specific antibodies. See also **Antibody**.

The history of the development of antitoxins in combating bacterial infection dates back to the early beginnings of organized bacteriology. Behring was the first to show that animals that were immune to diphtheria contained, in their serum, factors which were capable of neutralizing the poisonous effect of the toxins derived from the diphtheria bacillus. While this work was carried out in 1890, prior to many of the great discoveries of mass immunization, and much later the antibiotics, there yet remains a place for antitoxins in medical treatment or prophylaxis for some diseases, such as tetanus and botulism.

The more important approach to immunity to infectious disease now is the development of *active immunity* by injection of a vaccine. The vaccine may be either an attenuated live infectious agent, or an inactivated or killed product. In either case, protective substances generated in the bloodstream, called antibodies, help to neutralize the infectious agent when it is introduced. The principle of *passive immunization*, on the other hand, involves the development of the antibodies in another host and most frequently a different species as well. The antiserum or antitoxin (from the other host) is employed in preventing the onset of the disease, or in actual treatment of the active infection in subjects who have not had the

advantage of becoming actively immunized due either to neglect or to the fact that an effective vaccine was not available. The use of antitoxins prepared in another species (for example, horse) is not without some element of risk.

Antitoxins are prepared by injecting the donor animals with frequent and increasing doses of toxin while maintaining a level at each injection that the animal can tolerate. The initial doses are critical since these toxins may be among the most poisonous agents known. In one technique, the toxin is diluted so that the first injection contains less than the minimum lethal dose. Other programs used toxins that are inactivated with formaldehyde so that they are no longer poisonous, but may still elicit an immune response and result in antitoxin that will neutralize the unaltered toxin. This method of inactivation also was developed in the nineteenth century for preparing many of the important vaccines against diseases, such as influenza, tetanus, and diphtheria.

Small laboratory animals are helpful in carrying out research in this field, but in commercial production, larger animals are required. The horse proved to be very satisfactory for large-scale production of antitoxins, and is still used for the major portion of antitoxin production, although some material is also derived from cattle. The management of the animals and the schedules and dosages are perhaps as much an art as an exact science. The selection of the horses that have the best potential as antitoxin producers is also a critical factor. When a horse is receiving the maximum level of toxin in the hyper-immunization program, it may be injected in a single dose with enough toxin to be fatal for 100 million mice if the material was suitably distributed.

A means for enhancing the potency of the antitoxin in horses is to use an agent called an *adjuvant*. Several adjuvants have been used, including tapioca, mineral oil, and aluminum hydroxide. The mechanism by which these agents increase the intensity of the immune response is not fully understood, but local inflammatory reaction and the resulting slower release of the injected material from the original site appear to play a role. Adjuvants also are sometimes used with vaccines for human use. It has been recorded that one horse, during an eleven-year period, gave 657 gallons (∼25 hectoliters) of blood from which tetanus antitoxin and, at different times, pneumococcus antiserum, was prepared. The volume of serum removed from the horse can be increased by the return of the red cells after removal of the plasma or liquid component. It has been shown that if the red cell level can be maintained in human donors of special sera, they can safely give as much as one liter of serum per week.

The injection of serum components of another species into human patients has not been without problems. A condition known as serum sickness develops in an alarmingly high proportion of those treated in this way, which is apparently due to a generalized sensitivity that develops to the foreign serum protein. The onset of illness is usually delayed for several days after the injection of antitoxin and symptoms may be quite severe.

ANTITRADE WINDS (OR ANTITRADES). See **Winds and Air Movement**.

ANTIVIRAL DRUGS. The science of antivirals started nearly five decades ago with the discovery of the anti-smallpox drug methisazone (*N*-methyl-isatin-β-thio-semicarbazone; Marboran) [Bauer et al.., 1963]. In retrospect, the finely executed studies with this antiviral unearthed all the features and problems of the stream of compounds against other viruses to be discovered subsequently in the ensuing half century. These characteristics of antivirals are: See also Drug Discovery (The History).

1. **Narrow Antiviral Spectra** Methisazone had a highly selective effect against smallpox viruses: it was not broad spectrum, and had no effect against other viruses, unlike penicillin which inhibits bacteria of many diverse families.
2. **Molecular Varieties** A clear structure–activity relationship was noted whereby small changes in chemistry of look-alike methisazone molecules could totally abolish or improve antiviral effects.
3. **Resistance Problem** Drug-resistant and even drug-dependent viruses emerged both in cell culture and animal models.
4. **Narrow Therapeutic Range** The therapeutic index (TI) (the ratio of antiviral effect in culture versus the toxic effect in cells) declined from a high value in cell culture, to lower levels in the mouse-model pox virus infection, and to the lowest level in the final use in patients with smallpox. The TI of methisazone in humans was approximately 6, whereas, to give a comparison, the TI of aspirin is 100 and penicillin is 10,000.
5. **Models of Clinical Application** The drug could be used prophylactically to prevent infection with smallpox in persons in contact with a smallpox case, or therapeutically to alleviate symptoms in those persons who had already been infected [Bauer et al.., 1963].

The World Health Organization (WHO) smallpox vaccination campaign using attenuated (weakened) *Vaccinia virus* was so successful that the first antiviral methisazone was little used. Now, with the total eradication of smallpox, the finest worldwide eradication success against a virus, the first antiviral drug is history. However, it is perhaps not a coincidence that members of the methisazone scientific team, chemists and virologists, later discovered or developed other important antiviral drugs such as aciclovir (Zovirax against Human herpesvirus 1 (HHV-1) and azidothymidine (Retrovir against Human immunodeficiency virus (HIV)).

It is a truism that, should one attempt to enumerate antibacterials, the list would extend to thousands of molecules. In contrast, effective and licensed antivirals can still be recorded on a single page of text (Table 1). However, the clinical power and usefulness of these drugs should not be underestimated. Antiviral chemotherapy has now come of age as a practical clinical science. This already changing status was described optimistically as the 'End of the Beginning' two decades ago [Collier and Oxford, 1980], but is now reality. See also **Antibiotics**.

New technologies, whereby the genes for target viral proteins may be cloned and the viral proteins expressed in yeast or bacteria and then exposed to react with potential inhibitors on plastic beads, have enabled millions of new drugs to be screened. This is termed molecular targeting or high throughput screening. In the first decade of the twenty-first century we are likely to see the emergence of entirely new drugs against influenza viruses, HIV, common cold viruses, *Hepatitis C virus*, human herpes viruses and papillomaviruses using these new screening methods.

Discovery of Antivirals

Until very recently, new antivirals were found by a random screening process in a virology laboratory. Literally tens of thousands of molecules synthesized by chemists, or by nature as plant extracts, were tested on cell cultures. Nontoxic doses of the molecules were incubated with mammalian cells growing as monolayers in plastic bottles or microtitre trays, which were then infected with a range of human viruses. Control bottles or wells of cells that contained no drug but only virus-infected cells allowed normal viral replication to be quantified. Quantities of newly replicated virus in the controls were then compared with those cultures in the presence of the drug. A ten fold reduction in viral output is considered significant. Following such a lead, the chemist would synthesize a series of modified molecules, which would also be screened. This is laborious and time-consuming work but has led to the successful drugs listed in Table 1.

New molecular methodologies are now being applied. In a classic study [Smith, et al. 1986] used X-ray crystallographic data of a structural protein of rhinoviruses to chemically modify drugs that could bind into a cleft of the protein and so stabilize the virion, preventing viral uncoating and infection of cells. An influenza drug, zanamivir, has also been discovered using the skills of the chemists and X-ray crystallographers [Von Itzstein, et al., 1993; Laver, et al., 1999]. A prerequisite for the influenza work was a molecule, discovered in Vienna by random screening in the 1960s, which bound to the influenza viral protein neuraminidase (NA). Once the atomic structure of the NA molecule had been exposed, and the precise 11 amino acids on the NA that bound the normal sialic acid substrate had been identified, the way was clear to design a more active antiviral (zanamivir). Sialic acid binds to the site through glycerol and carboxylate groups, which form bonds with the amino acids in the site. Side-chains were added to the inhibitor, in the case of zanamivir a guanidino structure

TABLE 1. CURRENTLY LICENSED ANTIVIRAL DRUGS

Condition	Drug	Manufacturer
	Nucleoside analogues	
Human immunodeficiency virus infection	Zidovudine (AZT)	Glaxo SmithKline
	Zalcitabine (ddC)	Roche
	Didanosine (ddI)	Bristol-Myers Squibb
	Lamivudine (3TC)	Glaxo SmithKline/BioChem Pharma
	Stavudine (d4 T)	Bristol-Myers Squibb
	Nonnucleoside analogues	
	Delavirdine	Pharmacia & Upjohn
	Nevirapine	Boehringer-Ingelheim
	Efavirenz	Du Pont
	Protease inhibitors	
	Saquinavir	Roche
	Indinavir	Merck
	Nefinavir	Agouran
	Ritonavir	Abbott
Cold sore (Human herpesvirus 1)	Aciclovir	Glaxo SmithKline
Dendritic corneal ulcer	Idoxuridine	Yamanouchi
Chicken pox (varicella)	Aciclovir	Glaxo SmithKline
	Penciclovir	Glaxo SmithKline
Shingles (zoster)	Aciclovir/valaciclovir	Glaxo SmithKline
	Penciclovir/famciclovir	Glaxo SmithKline
Cytomegalovirus retinitis and pneumonia	Ganciclovir	Roche
	Foscarnet	Astra
Influenza A	Rimantadine	
	Amantadine	Alliance
Influenza A and B	Zanamivir	Glaxo SmithKline
	Oseltamivir	Roche
Chronic active hepatitis B	Interferon α	Schering-Plough
	Lamivudine	Glaxo SmithKline
Respiratory syncytial virus infection in infants	Ribavirin	Britannia
Lassa, Marburg and Ebola fevers	Ribavirin	Britannia
Hepatitis C	Interferon and ribavirin	Britannia

TABLE 2. VIRUS TARGET FREQUENCY AND MEDICAL IMPORTANCE

Virus target	Frequency and medical importance
Influenza A and B viruses	In the UK winter of 2000, 18,000 persons died of influenza and complications. A pandemic (worldwide outbreak) is expected in the near future
Human immunodeficiency virus	30 million persons infected worldwide. Particularly high attack rates in young persons in Africa and Asia. No effective vaccines
Human herpesviruses (HHV1–8)	25–35% of sexually active Europeans and Americans infected with HHV-1 or -2. No effective vaccines
Hepatitis B virus	350 million carriers of the virus globally
Hepatitis C virus	2% of the world' population infected. No effective vaccines
Common cold virus	Most families worldwide experience 2–3 infections per year. Infections can trigger asthmatic attacks and bronchitis. No effective vaccines
Papillomaviruses (wart virus)	Approximately 30% of USA citizens who are sexually active are infective. No effective vaccines
Exotic haemorrhagic diseases, Lassa, Marburg viruses	Life-threatening but fortunately of low infectiousness. Geographically restricted. No effective vaccines

in the hydroxyl position. In the second drug of this series' oseltamivir, a hydrophobic group was substituted at the position of the glycerol to make the antiviral as structurally identical to sialic acid as possible. These two new 'designer' drugs bound much more tightly to the viral NA enzyme than the original inhibitor (Figures 1 and 2) and were therefore very powerful neuraminidase enzyme inhibitors, as well as being highly active in inhibiting influenza A and B in virus-infected cell cultures, in animal models and in influenza-infected volunteers and patients [Gubareva *et al.*, 2000].

A rule-of-thumb calculation has shown that perhaps 100 of an initial 100,000 compounds in a virus screen show antiviral effects in cell culture. Subsequent antiviral testing, including pharmacology and toxicology, would reduce the number of potentially useful drugs to one or two to be tested in human trials.

Target Viruses

Table 2 lists the viral targets of antiviral chemotherapists. Obviously drugs are no longer required for some previous targets, such as smallpox. Other important viral infections, such as rubella, measles and poliomyelitis, are well controlled by vaccines or by nonbiological methods, such as purification of water supplies (rotaviruses) [reviewed by Collier and Oxford, 2000], but new viruses have emerged (an example is HIV-1). Some viruses, either because of genetic variation (HIV-1 and influenza virus) or multiple serotypes (rhinoviruses and papillomaviruses), will not succumb to vaccine induced T- and B-cell immunity. In addition, there is a continuous need for new drugs to combat the inevitable emergence of drug resistance and to reequip the antiviral portfolio. See also **Human Immunodeficiency Viruses (HIV); Measles; Poliomyelitis; and Rubella (German Measles)**.

Influenza Viruses

Each year around 8000 persons die of influenza or virus-induced complications in the UK, and corresponding numbers relative to population size in Europe, the USA and the rest of the world. A proportion of deaths are directly caused by the virus, when it replicates in the cells lining the airways, while in a proportion of patients a superinfection with bacteria may

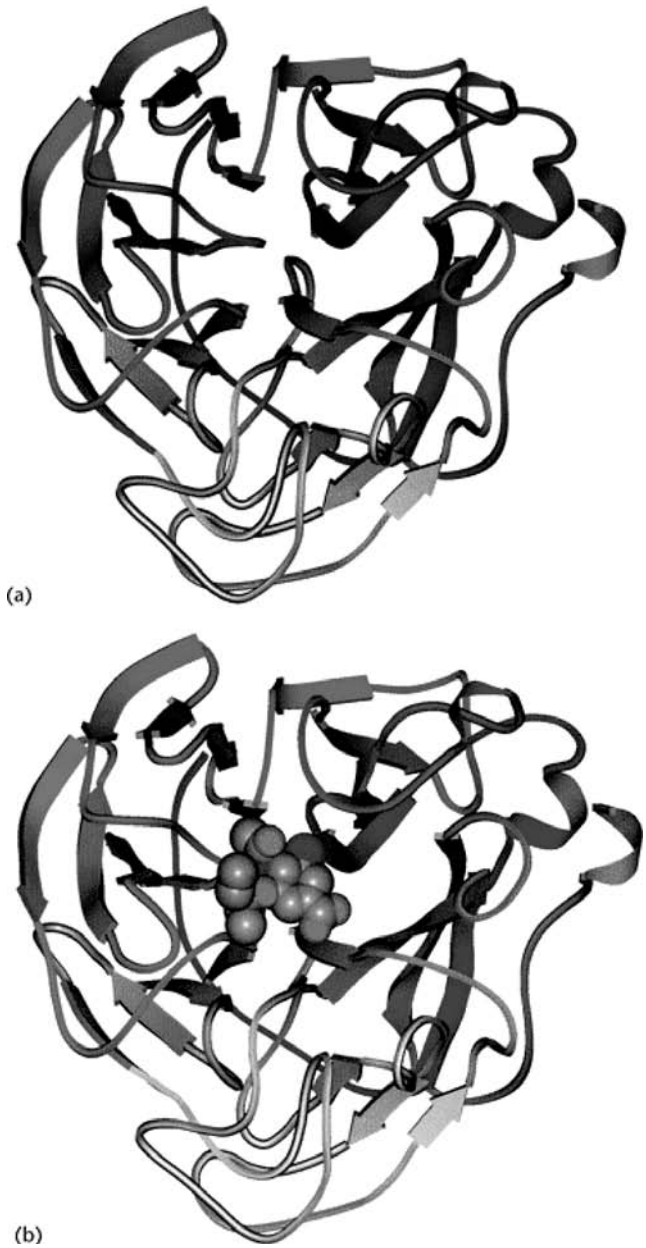

Fig. 1. Ribbon drawing of influenza A neuraminidase enzyme. (a) Normal influenza neuraminidase; (b) Oseltamivir inhibitor bound to the active site of the neuraminidase.

be the terminal event. Some bacteria produce protease enzymes that activate influenza virus to replicate more quickly. On the other hand, the virus destroys epithelial cells lining the respiratory tract, which can then be colonized more easily by potentially pathogenic bacteria such as streptococci and staphylococci. See also **Influenza**.

Influenza precipitates these very serious pneumonic complications, particularly in the elderly (over 65 years of age) or in persons of any age who have a compromised immune system, or chronic medical conditions of the respiratory tract, heart or kidney [Stuart-Harris, *et al.*, 1985]. These are known as the at-risk group in the community and are the target of new antivirals and influenza vaccines to prevent hospitalization and death. The antiviral goals are to prevent infection (prophylaxis) or to alleviate symptoms (therapy) and prevent hospitalization and death. Influenza virus is a unique virus with two epidemiological modes –the worldwide pandemics (experienced in 1918, 1957 and 1968) and the yearly epidemics–and, uniquely compared to any other virus, antiviral drugs are required to cope with both situations. In both modes the virus is spread rapidly from person to person by aerosol and the incubation period is short (1–2 days), allowing little time for intervention.

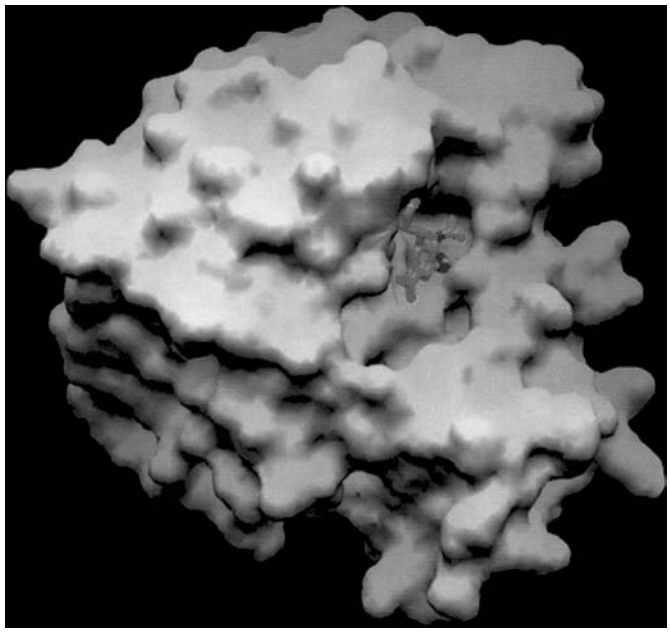

Fig. 2. Space-filling model of influenza A neuraminidase enzyme with zanamivir inhibitor bound at the active site.

Human Immunodeficiency Viruses

In 1981 a new clinical syndrome, characterized by profound immunodeficiency, was recorded in male homosexuals and was termed the acquired immune deficiency syndrome (AIDS); the causative virus was called *Human immunodeficiency virus 1 (HIV-1)*. In 1990, there were 2200 diagnosed cases of AIDS in the UK, and by 1998, 32 000. The actual number of persons infected may now reach over 2 million in the USA alone, and 30 million worldwide [Fauci, 1999]. AIDS is the fourth leading cause of death worldwide, with 2.3 million deaths. Another human retrovirus, HIV-2, was isolated later from mildly immunosuppressed patients in West Africa and appears to be less pathogenic. See also **Acquired Immune Deficiency Syndrome (AIDS)**.

The virus is spread sexually or by injection of contaminated blood or to a baby before or shortly after birth. Virus replicates particularly in the CD4 subset of cells in the immune system. After a mild, acute, influenza-like illness with an incubation time of around 3–4 weeks, the disease becomes quiescent. Approximately 60% of asymptomatic cases move into the AIDS-related complex form of the disease within the next 4 years. This phase of the illness is characterized by fever, weight loss, persistent lymphadenopathy, night sweats and diarrhea. Patients then move to full-blown AIDS with thrush, herpes infection and, most seriously, pneumonia. In 70% of infected persons the time from infection to death may be as long as 10 years. The remainder of infected persons may live as long as 17 years and form the so-called 'long-term survivors' group.

The antiviral treatment goals for an HIV antiretroviral drug are to obtain: remission of HIV disease, leading to near normal life expectancy; a decrease in mortality; and improvement in the quality of life.

Common Cold and Respiratory Viruses

At least 150 rhinoviruses (common cold viruses), 30 adenoviruses, four parainfluenza viruses and *Human respiratory syncytial virus* cause clinical problems in the respiratory tract. Although most of these infections are not life-threatening, infection can trigger serious bronchitis and asthma attacks. The antiviral goals are to reduce symptoms and transmission of virus. See also **Common Cold**.

Human Herpesviruses

The eight viruses in the human herpesvirus family (HHV1–8) cause a wide range of syndromes, varying from trivial mucocutaneous lesions to infections of the eye, encephalitis and other life-threatening infections. An important property of all herpesviruses is their ability to cause latent or dormant infections that may subsequently become reactivated. Antiviral chemotherapy has to cope with both acute infection and reactivation in diverse organs of the body. See also **Herpes Simplex Virus Diseases**; and **Herpesviruses (Human)**.

The primary infection with HHV-1 and HHV-2 is often acquired in infancy or early childhood from close contact with an older person. In many instances the infection is asymptomatic, but it may also present as acute gingivostomatitis on the gums and oral mucosa and where the lesions break down to form ulcers. In later life, eye infections with herpes are comparatively frequent, nearly always caused by HHV-1. HHV-1 encephalitis is a rare but serious life-threatening illness with a high rate of neurological complications after recovery from the acute infection. It may occur at any age.

In recent years genital infection with herpes has attracted much attention. In the male it shows as a crop of vesicles on the penis. In the female, the lesions are on the labia, vulva and perineum, sometimes extending to the inner surface of the thighs. The antiviral goals are to prevent initial infections, to alleviate symptoms of recurrent disease and to prevent reactivation.

Papillomaviruses

Genital warts caused by human papillomaviruses (HPV) are acquired most often by sexual contact and they are now one of the most common sexually-transmitted diseases. In 1996, nearly 54 000 first attacks were recorded, twice the number of first attacks of genital herpes simplex (HHV-1). There are over 70 known types of HPV; types 16 and 18, in particular, are strongly implicated in the causation of carcinoma, both of the cervix and of the penis. The viruses are spread mainly by contact, including sexual contact, and viruses replicate in epithelial cells after entry at the skin and in mutocutaneous sites. The antiviral goals are to alleviate symptoms of persistent infections, to prevent oncogenic activity and to prevent recurrence. See also **Papillomaviruses**; and **Sexually Transmitted Diseases**.

Hepatitis B Virus

Hepatitis B virus (HBV) is transmitted in blood and other bodily fluids, including cervical secretions, semen and breast milk. The patients suffer malaise as liver function is altered. It is spread by sexual intercourse, and by sharing of needles and syringes. Virus is transmitted from mothers to their babies at birth. The high prevalence areas (10–20% of persons infected) are east and Southeast Asia, the Pacific Islands and tropical Africa. The CIS (ex-USSR), the Indian subcontinent, parts of Africa, eastern and southeastern Europe and parts of Latin America are areas of medium prevalence (2–20%). Finally, the prevalence is low (< 1%) in the rest of Europe, Australia and New Zealand, Canada and the USA. Virus replicates in cells in the liver, which are destroyed by the immune reaction of the infected person. Antiviral goals are to alleviate symptoms and reduce transmission in chronically infected patients, and to prevent oncogenic activity in the liver, which is particularly noted in the Far East. See also **Liver**; and **Virus**.

Hepatitis C Virus

Only 5% or so of those infected with Hepatitis C virus (HCV) have symptoms that resemble those caused by other hepatitis viruses; frank jaundice is uncommon. However, HCV becomes more chronic in about 80% of those infected. After many years, cirrhosis of the liver may supervene in a minority of patients; this is often a precursor of hepatocellular carcinoma. The virus is spread by injection of contaminated blood, by sexual intercourse or before or at birth from an infected mother. Antiviral goals are to alleviate symptoms and reduce transmission. See also Virus.

Some Currently Licensed Antiviral Drugs

Aciclovir and Penciclovir (Nucleoside Analogues) as HHV-1 Inhibitors. The antiherpes drugs aciclovir and penciclovir possess a unique combination of biochemical and pharmaceutical properties [Elion, et al., 1977]. The drugs are phosphorylated to aciclovir monophosphate only in herpes-infected cells, as this biochemical step requires a herpes virus thymidine kinase (TK) and cannot be achieved by normal cellular TK. The viral TK is less 'precise' than the corresponding cellular TK and will accept fraudulent substrates such as aciclovir. Phosphorylated aciclovir cannot emerge from within the virus-infected cell once it has entered because of the newly added and charged phosphate group. Since the pool of 'normal' unphosphorylated aciclovir in the cell is depleted, more aciclovir molecules move across the plasma membrane to maintain the original concentration, and are in turn phosphorylated. The antiviral drug accumulates therefore only in virus-infected cells. The second specific feature of the drug is that the aciclovir triphosphate, the active moiety, binds to and specifically inhibits the herpesvirus deoxyribonucleic acid (DNA) polymerase and is essentially nontoxic and noninhibitory to cellular DNA polymerase. These two drugs terminate viral DNA formation and elongation of the new viral DNA molecule. Moreover, corresponding prodrugs, which are activated by enzymes in the liver or gut, are used to enhance antiviral drug levels in the actual organ system where the virus is replicating and causing pathological changes. The respective prodrugs are valaciclovir and famciclovir.

The early antiherpes drugs discovered 3–4 decades ago, such as idoxuridine (IDU) and trifluorothymidine (TFT), were useful at the time for treating herpetic eye infections, particularly keratitis, while adenine arabinoside (araA) previously had a role in the treatment of herpes simplex encephalitis and serious paediatric infections. The newer drugs aciclovir and penciclovir are now the drugs of choice in the clinic for HHV-1 and 2 infections. Aciclovir or penciclovir are used in the prophylaxis of herpesvirus infections in bone-marrow and heart transplant patients and can give 90% protection against infection or reactivation. The drugs are also very effective in treating herpes simplex encephalitis, if administered early. Continuous treatment prevents recurrent HHV-1 and HIV-2 infections, particularly those of the genital tract, and some patients have taken aciclovir orally for many years (reviewed by Field and Wassilew, 1997).

A molecular derivative, ganciclovir, has a mild antiviral activity against cytomegalovirus (CMV). In contrast, aciclovir and penciclovir have no significant anti-CMV activity. Ganciclovir is used to treat life-threatening CMV pneumonia after bone marrow transplants and eye infections, and also generalized CMV infections in AIDS patients. New nucleotide analogues, such as cidivir, have recently proved effective in CMV eye infections, as has the more established antiherpes drug foscarnet.

Amantadine and Rimantadine (M2 Channel Blockers) as Influenza A Inhibitors

When influenza virus infects a cell, two virus core proteins–the nucleoprotein (NP) and the matrix protein (MI)–which bind closely with the viral ribonucleic acid (RNA), dissociate and thus allow the viral RNA to enter the nucleus to replicate. This dissociation only happens at a low pH in the cytoplasmic vacuoles of the cell where the virus is located soon after infection of a cell. The viral membrane M2 ion channel normally allows these acidic ions to pass to the centre of the virus. Amantadine and rimantadine stop the induction of low pH by blocking this M2 channel and inhibit all subsequent events that would normally lead to infection. These two drugs are therefore called M2-channel blockers. The prophylactic and therapeutic effects of amantadine have been demonstrated in clinical trials in Europe, the former USSR and the USA, and the clinical data extended to the related compound rimantadine. The overall protection rate in prophylactic trials against illness caused by influenza viruses has varied between 50% and 80%. The drugs have no effect whatsoever against *Influenza B virus* because the virus has a different strategy and set of molecules to allow acidification and hence release of RNA. In the majority of controlled therapeutic studies with amantadine, a demonstrable reduction in the severity and duration of influenza-caused fever was reported in those groups receiving the drug, compared with the control groups, provided treatment was begun within 2 days of the onset of clinical symptoms.

Amantadine may be given to hospital patients and personnel to prevent hospital spread when patients with influenza A viral infections are admitted. Other at-risk groups for prophylaxis would be persons in institutions, such as old persons' homes, and unvaccinated adults with an underlying disease that places them in a potentially high-mortality group following an attack of influenza, e.g. persons with pulmonary, cardiac, metabolic or immunological deficiencies.

Amantadine might be administered prophylactically during the 3-week period of development of vaccine-induced immunity. It can be given prophylactically to household contacts of the first case of influenza in a family in order to prevent virus spreading to the rest of the family. An efficacy of 80–90% has been established when the drug is used in this sensible manner. Nevertheless, even after four decades of clinical experience the drugs are not used extensively. This rather unsatisfactory situation could now change.

Zanamivir and Oseltamivir (NA Blockers) as Influenza A and B Inhibitors

As we have noted above, two drugs that bind tightly to the influenza mushroom-shaped NA have been discovered and refined using X-ray crystallography of drug–protein interactions [Von Itzstein *et al.*, 1993]. These antivirals are effective against *Influenza A virus* and *Influenza B virus*, both preventing infection and reducing symptoms in persons already infected with the virus [Gubareva, et al., 2000]. The virus NA performs an important function at virus entry by removing sialic acid from sialylated glycoproteins in nasal or respiratory fluid. This enzymatic action allows the virus to penetrate this otherwise impermeable fluid layer to infect ciliated epithelial cells of the respiratory tract. The NA enzyme also catalyses virus release from cells at the virus budding stage. See also **Influenza**.

In a therapeutic trial of the effects of inhaled zanamivir, the first drug of the recent series to be discovered, the median reduction in the number of days of influenza illness was 1 day for all patients, 1.5 days in patients with confirmed influenza infection, and 2.5 days in the high-risk group. Moreover, the rates of complications of influenza infection were lower with the use of zanamivir than with placebo, for all patients (intention to treat analysis) and for those with influenza infection and the high-risk group. In an analysis of 2499 influenza patients, inhaled zanamivir reduced the frequency of the antibiotic prescriptions for lower respiratory complications by 40%.

Therapeutic benefits have also been found with the anti-NA drug oseltamivir in previously healthy adults with febrile influenza treated within $1\frac{1}{2}$ days of illness onset. Two studies noted that oral oseltamivir, taken at 75 mg twice daily for 5 days reduced the time of illness and illness severity (30% reduction in scores), and time to resumption of usual activities [Gubareva *et al.*, 2000]. Reductions in fever duration, cough, ancillary medication use and viral titers have also been found. The frequency of physician-diagnosed secondary complications leading to antibiotic prescriptions was halved.

In prophylaxis studies in adults who inhaled zanamivir, taken at 10 mg once daily, the likelihood of laboratory-confirmed influenza infection (with or without symptoms) was reduced by 31%, influenza illness by 67%, and influenza illness with fever by 84%. A postcontact prevention study in healthy family members, with once daily prophylaxis for 10 days, found that inhaled zanamivir reduced the likelihood of influenza illness by 79%.

Similarly, a 6-week prophylaxis trial found that oral oseltamivir, taken at 75 mg once daily, reduced the risk of influenza infection by 50%, influenza illness by 76%, influenza illness with fever by 90%, and culture-proven influenza illness by 100%. In the elderly, largely immunized nursing-home residents, 6 weeks of oral oseltamivir, taken at 75 mg once daily, reduced the risk of influenza illness by 92% in homes experiencing outbreaks. Finally, once-daily oseltamivir reduced the risk of illness by 89% in household contacts of influenza cases (reviewed by Gubareva, et al., 2000]. It is very likely that these new anti-NA drugs will radically change the manner in which influenza is treated in general practice. Patients will need to be encouraged to visit the doctor so the drugs can be given rapidly after the first symptoms.

Azidothymidine, Dideoxynucleoside, Nonnucleoside and Protease Drugs as HIV-1 Inhibitors

Azidothymidine (AZT) was the first viral reverse transcriptase (RT) enzyme inhibitor to be used for treating HIV infection. The RT is a key enzyme for viral replication and there is no counterpart in the normal uninfected cell. The enzyme transcribes the viral RNA into a DNA copy which can then be integrated in the chromosome of the cell. Not unexpectedly, chemists have chosen this enzyme as a selective target for antiretroviral 'bullets'. AZT is phosphorylated intracellularly to produce the active antiviral drug, a triphosphate that prevents viral nucleotide chain elongation in a manner similar to the antiherpes drug aciclovir. The 3′ positioning of the azido group of azidothymidine blocks the essential phosphodiester linkage, which would normally enable the next nucleotide to be added to the growing viral DNA chain. Furthermore, azidothymidine triphosphate binds preferentially to the viral RT rather than to the cellular DNA polymerase, giving some specificity of action. AZT was shown to prolong the life of AIDS patients; thereafter, chemists soon synthesized other chemically related molecules, dideoxynucleoside analogues, including didanosine (ddI), zalcitabine (ddC), stavudine (d4 T) and lamivudine (3TC) (Table 1). These drugs used in combination are much more effective than monotherapy with AZT alone. See also **Baltimore, David (1938–Present);** and **Temin, Howard Martin**.

The so-called nonnucleoside RT inhibitors comprise a wide variety of chemical structures and are powerful inhibitors of HIV in the laboratory. Many of these compounds are highly selective for HIV-1 and bind tightly to the viral RT close to the polymerase-active site in a reversible competitive manner, thus altering the ability of the viral enzyme to function. They are used in clinical practice, but mainly in combination with ATZ and viral protease inhibitors to lessen the opportunity for drug-resistant mutants to arise.

The HIV protease enzyme has the important function of cleaving certain HIV structural proteins at the postbudding maturation stage of viral replication; without such cleavages the newly released virus does not mature and is not infective for other cells. At least six new drugs have been found that selectively inhibit HIV protease but not mammalian cell proteases (Table 1); however, these drugs have short half-lives, and have variable absorption characteristics and some toxic side effects.

The most recent and certainly the most successful clinical strategy to date is to use a combination or 'cocktail' of drugs (e.g. indinavir, zidovudine and lamivudine) in AIDS patients: the primary objective is to prevent emergence of drug-resistant virus. This so-called highly-active retroviral therapy (HAART) cocktail is expensive and complicated to monitor, and patients have to take as many as 15 tablets at specific times each day. Moreover, it is now known that the virus may still persist in organs where the drugs cannot reach, or else may persist as an integrated latent form. Even in patients in whom plasma levels of viral RNA have been suppressed for 1 year, the virus can reemerge when the drugs are stopped. Nevertheless, many AIDS patients have benefited from the effects of these new combinations of drugs and can even return to work.

Drug Resistance

Medical microbiologists have assumed that resistance to antiviral drugs will develop and perhaps match the formidable and dangerous status that it has reached in the world of antibacterial chemotherapy; however, to date, with the exception of HIV, drug resistance to antivirals has not been a major clinical worry. Two contributory factors to the emergence of antibacterial resistance are the sexual transfer of resistance genes in bacteria and the vast quantities of drugs used in animal husbandry, hospitals and clinics. The use of antivirals, at least at present, is more circumspect, but some viruses, such as the influenza virus, can exchange resistance genes.

Aciclovir has been quite widely used in clinical practice but drug-resistant herpesviruses are rare and are detected mainly in immunocompromised patients. Such resistant viruses have mutations in the viral TK gene, or the TK gene may be completely nonfunctional. More rarely, mutations are detected in the viral DNA-dependent DNA polymerase enzyme. These two viral proteins are both targets of the drug and this explains why mutations can allow the virus to evade the effects of the drug.

Influenza mutants resistant to the newer anti-NA drugs have also been detected, although rarely. Such viral mutants are difficult to generate in the laboratory and, when they are detected, they tend to be less infectious and less virulent. It is quite probable therefore that such mutants will have a selective disadvantage in nature and will be 'overgrown' by the original drug-sensitive viruses. Mutations have been detected at Glu119, which interacts with the guanidino moiety of zanamivir. Oseltamivir, which does not bind at this position, still inhibits these drug-resistant mutants. A drug-resistant influenza virus has been detected in which the NA remains without changes but there is a mutation in the haemagglutin HA gene at amino acid 135. It is likely that this mutant has a reduced affinity for binding to the receptors of the cell and therefore has a much reduced requirement for NA activity to release virions from the cell at the end of the replication cycle. See also **Mutation**.

Amantadine-resistant influenza A viruses can be obtained by passage of virus in mice but only in the presence of very high concentrations of drug. Drug-resistant mutants can also be selected in cell cultures. Nucleotide sequence analysis of such drug-resistant viruses locates mutations in the viral M2 gene 7 at amino acid positions 26, 27, 30, 31 or 34 [Hayden and Hay, 1992]. These amino acids are located on the inside walls of the M2 ion channel where amantadine would normally bind. However, despite the clinical use of rimantadine in the community in Russia and Eastern Europe and in the USA, and the use of amantadine in the UK, only a few drug-resistant viruses have been detected. Importantly, viral strains responsible

for pandemics and epidemics in recent years have all been amantadine sensitive. During the therapeutic use of rimantadine, a low proportion of drug-resistant viruses have been detected (in approximately one-third of patients); nevertheless in the same individuals the drug continued to be therapeutically active. It is possible, but not proven, that influenza A viruses with mutations in M2 may be compromised in nature and may not spread so easily as drug-sensitive influenza A viruses.

In contrast, there is no doubt about the practical clinical importance of drug-resistant mutations in the HIV RT enzyme. Four RT mutations at amino acids 41, 67, 215 and 219 are dominant but mutations also occur after exposure of virus to other dideoxy nucleoside inhibitors such as ddI, ddC and 3TC. The crossresistance patterns are somewhat complex and some of the viruses show crossresistance to AZT, whereas others do not. Some viruses even have resistance-suppressor mutations and revert back to AZT sensitivity. Drug resistance occurs particularly rapidly when viruses contact the nonnucleoside RT inhibitors such as nevirapine. Combinations of at least three drugs are now used in clinical practice, each having a different mode of action against HIV. It is deduced that the chance of a virus mutating at the same time to become resistant to all three drugs is vanishingly low. It is now not unusual to utilize AZT plus 3TC plus a protease inhibitor as a drug combination. This highly active antiretroviral treatment (HAART) is proving successful, if compliance with the drugs is maintained; however, it is not easy consistently to swallow up to 15 tablets each day at regular intervals. In anticipation of the emergence of multiple drug-resistant AIDS viruses, the search for new targets to block the retroviral integrase enzyme or to blockade attachment of virus to its CD4 receptor or other immune cells is underway.

ANTLERITE. Antlerite is a relatively uncommon mineral found within the oxidized zones of copper deposits in arid regions. It is a basic sulfate of copper, $Cu_3(SO_4)(OH)_4$, crystallizing in the orthorhombic system. Hardness of 3.5, specific gravity 3.88, with vitreous luster, and emerald-green to black-green color.

Originally found in Arizona. It is the principal copper ore mineral at Chuquicamata, Chile.

ANT LION *(Insecta, Neuroptera).* Immature insects of the family *Myrmeleonidae* that lie buried at the apex of conical pits in dry sand or dust. Ants or other small insects that enter the pit slide down the loose slope and are seized by the upturned jaws below.

These insects are black or brown in color. They develop within a cocoon made of silk threads developed from larvae at the insect's tail. The immature insect remains in the cocoon stage until it becomes an adult.

ANT-LOVING CRICKET *(Insecta, Orthoptera).* *Mymecophilia*. Small peculiarly formed crickets that live in ant nests.

ANTMOMETER. See **Meteorology**.

ANTONOFF RULE. The tension at the interface between two saturated liquid layers that are in equilibrium is equal to the difference between the individual surface tensions against air or vapor of the two saturated solutions. This rule is approximate only and a number of exceptions are known.

ANURA. The frogs, toads, and allied species; a division of the *Amphibia* characterized by the absence of the tail and a tadpole larval stage. Also known as the Salientia from their jumping powers.

ANUS. The terminal portion of the rectum, which forms an external opening. See also **Digestive System (Human)**.

ANVIL CLOUD. See **Clouds and Cloud Formation**.

AORTA. The main and largest blood vessel of the arterial blood system. It arises from the left ventricle of the heart, and arching over the root of the left lung, descends along the vertebral column, passing through the chest, and pierces the diaphragm into the abdominal cavity, finally dividing into the right and left iliac arteries in the pelvis. The branches of the aorta supply oxygenated blood to every part of the body. See **Arteries and Veins (Vascular System)**; and **Heart and Circulatory System (Physiology)**.

APATITE. The mineral apatite is a phosphate of calcium with either fluorine or chlorine or sometimes both, hence the distinction between fluorapatite and chlorapatite. Sometimes both fluorine and chlorine are present. Most apatite is, however, fluorapatite, $Ca_5(PO_4)_3F$.

Apatite crystallizes in the hexagonal system in prismatic and tabular forms. Hardness, 4.5–5; specific gravity, 3.17–3.23; luster, vitreous to resinous; transparent to opaque; streak, white; cleavage, imperfect basal and prismatic; color, white, green, yellow, red, brown and purple; subconchoidal fracture. The variety called asparagus stone is yellow-green and manganapatite, which is a dark bluish-green, may contain as much as 10% manganese dioxide replacing the calcium. Werner devised the name *apatite* from the Greek word meaning "to deceive", because it was frequently mistaken for beryl and other species. Apatite has been found widely distributed both geographically and petrologically as it occurs in many sorts of rocks, metamorphic limestones, gneisses, schists, granites and syenites, pegmatite veins and even with iron ores. It has been prepared artificially. It has been mined for the manufacture of fertilizers and to a slight extent for jewelry.

Apatite occurs extensively in Europe and America, especially in New England, New Jersey, New York, North Carolina, California, and in the provinces of Ontario and Quebec in Canada.

APERTOMETER. A device designed by Abbe for measuring the numerical aperture of microscope objectives.

APERTURE. Qualitatively, any opening through which radiation or particle fluxes may pass. In optical instruments, in communications and in other fields, the term aperture has acquired various specific meanings. For example, the aperture of a lens is simply the diameter of the lens. However, the numerical aperture (N.A.) of a lens is the quantity $n \sin u$, where u is the angular radius of the lens as seen from a point on the optical axis at the object, and n is the refractive index of the medium between the object and the lens. The relative aperture (or f-number) is the ratio of the focal length of an optical system to the diameter of the entrance pupil. A related term is the aperture angle, which is the angle subtended by the radius of the entrance pupil of an optical instrument at an axial object point.

The aperture of a unidirectional antenna is that portion of a plane surface near the antenna, perpendicular to the direction of maximum radiation, through which the major part of the radiation passes.

APERTURE CARD. A punched card (see **Input/Output Devices (Computer System)**) that may contain information solely for machine storage and retrieval; this is the normal interpretation of the term. In addition, however, an aperture card may contain information that is not entered into electronic storage, such as small reproductions of diagrams, photos, etc. Thus, some of the information on the card may be fully electronically processable, whereas other information requires manual scanning and interpretation.

APES. See **Anthropoids**.

APHANITE. An aphanite is any fine-grained igneous rock whose constituents cannot be distinguished with the naked eye. The term is derived from the Greek, meaning invisible. The adjective aphanitic is applied to these rocks as well as their fine-grained groundmasses.

APHASIA. Defect of the language function due to brain damage, usually manifested in all four language modalities — speech production, speech comprehension, reading, and writing. Aphasia must be distinguished from disturbances of voice production, such as dysarthria, from poverty of speech due to intellectual impairment, from language abnormalities as in schizophrenia, and in hysterical mutism.

More than 90% of normal right-handed people have language function represented in the left cerebral hemisphere and damage of that will render them aphasic. Since normal left-handers have 70% of language function in the left hemisphere and 20% in the right, damage to either side can lead to varying degrees of aphasia.

Within the left hemisphere, the most important areas for language are Broca's and Wernicke's areas and these are the most commonly affected in strokes or various forms of cerebral thrombosis or direct brain trauma.

An excellent and detailed review of aphasia is given by Antonio R. Damasio, M.D., in the February 20, 1992, issue of the *New England Journal of Medicine*, pages 531–539.

R. C. V.

APHELION. The point in the orbit of a planet or other member of the solar system, except a satellite, where the object is most remote from the sun. It is the point on the line of apsides (see **Orbit (Astronomy)**) diametrically opposite to perihelion. See also **Perihelion**.

At present, aphelion occurs about July 1, when the earth is about three million miles farther from the sun than at perihelion, but the seasons in which aphelion and perihelion fall undergo a cyclic variation with a period of twenty-one thousand years. The date of aphelion passage is advancing slowly (toward dates later in the calendar year) at a rate of about one-half hour each year. This is a consequence of the eastward rotation of the line of apsides at a rate of about 11 sec of arc per year and the precession of the equinoxes of about 50 sec of arc per year, for a total of 61.9 sec of arc per year.

APHID *(Insecta, Homoptera).* A small delicate insect with sucking mouth. The aphid, also known as plant louse, generally lives on the sap of plants and is of major economic importance. The aphid is characterized by an intricate life cycle that results in a high rate of reproduction. In the temperate zone, aphids hatch in the spring from winter eggs; these individuals are females known as stem mothers. They bear living young without mating (viviparity, parthenogenesis) and these, in turn, are females capable of the same type of reproduction. Late in the season, a generation known as the *sexuparae* bears both male and female offspring, which mate to produce the eggs that pass the winter.

Winged aphids (Fig. 1) appear under conditions that demand migration from plant to plant. Experiments have shown that the appearance of wings is a response to definite environmental conditions, complex in nature, and not fully understood. The much more common wingless aphid is shown in Fig. 2.

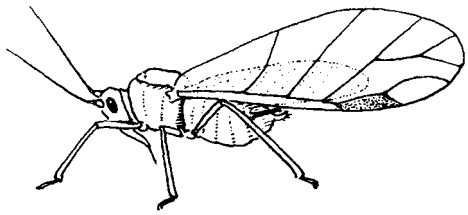

Fig. 1. Winged aphid.

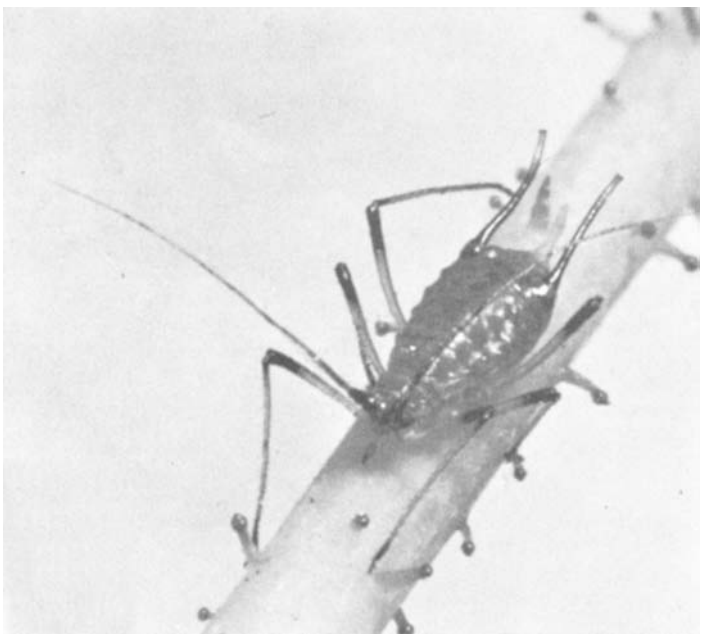

Fig. 2. Wingless aphid feeding on rosebush. (*Bernard L. Gluck from National Audubon Society*.)

The aphid injects poisonous saliva into plants, which causes discolored and unhealthy foliage and buds. A byproduct of the aphid's digestion is known as honeydew, a sweet secretion arising from the ingestion of excessive sap and sugars. Ants, bees, and wasps are vigorously attracted to this honeydew. To encourage production of larger quantities of the substance, an ant has been observed to assist an aphid by carrying the aphid in its mouth from a withered plant to a healthy plant, thus encouraging the aphid to eat more and produce more honeydews. The ant also protects the aphid from intruders. The honeydew clogs the pores of plants and also nourishes damaging fungi.

Although the aphid is destructive to many crops, it is particularly damaging to certain vegetables, including bean, cabbage, cucumber, melon, pumpkin and squash; and to certain fruit and nut crops, including apple, apricot, peach, pear, pecan, and walnut. The aphid is quite damaging to a number of decorative plants.

There are many species of aphid, nearly a species for each crop attacked, indicating the high specialization created over the centuries. Generally, all aphids are tiny ($\frac{1}{16}$-inch; 1.5 millimeters) in length, ranging in color from light green to dark-green and black. Most varieties have a rather prominent rearward protuberance, often called a "tailpipe." Although the damage varies from one crop to the next, generally the aphid causes leaves to curl and thicken, turn yellow, and die.

Most aphids overwinter in the egg stage; eggs are laid on the twigs and bark of the trees. To kill these eggs and prevent a rapid buildup of aphids

later, it is well to use a dormant oil spray. Oil sprays should be applied before any color is shown in buds of plant. Dormant oil sprays must not be used when foliage is on the tree or plant, or when the temperature is higher than 85 °F (29.4 °C) or lower than 35 °F (2 °C). When aphids become numerous during the growing season, sometimes they can be washed off with soap formulations applied under fairly high pressure, but specific treatment may involve stronger chemicals, the selection varying from one infested plant to the next.

To control root-feeding aphids, such as the *woolly apple aphid*, the soil immediately under the plant should be regularly loosened and cultivated to a depth of 1 to 3 inches (2.5 to 7.5 centimeters). Attacks by the woolly aphid can be avoided by planting varieties that are resistant. Also, trees and plants that have been kept in a vigorous growing condition are less likely to suffer damage from these insects. Woolly apple aphids also feed in wounds of trunks and branches. The wounds should be treated with a wound dressing to prevent attack by aphids.

When natural enemies of the aphids are abundant, aphids usually do not require additional control measures. Before applying chemicals, check the plants carefully to see if a natural control agent, such as the larvae of lady beetles, is present. Syrphid flies and ant lions also are natural enemies of the aphid. When the spring is warm, natural enemies are usually present in sufficient numbers to control aphids completely. The greatest damage occurs after a cold spring; aphids increase more rapidly than their natural enemies in a chilly season.

Examples of the highly specialized aphids are:

Bareberry plant louse (*Rhopalosiphium berberidis*)
Beet aphis (*Pemphigus betae*)
Birch aphis (*Callipterusbetulaecoleus*)
Black aphis (*Aphis persicae-niger*); affects peach
Bud aphis (*Siphocoryne arenae*); affects apple
Cabbage aphis (*Aphis brassicae*)
Corn-root aphis (*Aphis maidiradicis*) See entry on **Ant**.
Currant aphis (*Myzus ribis*)
Gall aphis (*Phylloxera sp.*); affects spruce
Leaf or green aphis (*Aphis pomi*); affects apple
Lettuce aphis or green fly (*Macrosiphum lactucae*)
Lupine aphis (*Macrosiphum albifrons*)
Melon aphis (*Aphis gossypii*); also affects squash, watermelon
Oleander aphis (*Aphis nerii*)
Parsnip louse (*Hyadaphis pastinacae*)
Pea aphis (*Macrosiphum pisi*); also affects bamboo
Root louse (*Aphis forbesii*); affects strawberry
Rosy aphis (*Aphis sorbi*); affects apple and quince
Spinach aphis (*Myzua persicae*); also affects green peaches
Squash aphis (*Nectarophora cucurbitae*)
Woolly aphis (*Schizoneura lanigera*); affects apple.

Oriental black citrus aphid (Toxoptera citricada). This insect is a serious pest of citrus in South America. The oriental black citrus aphid is black and, when fully grown, is about $\frac{1}{16}$-inch (1.5 millimeters) long. The antennae and legs are sometimes brownish, rather than black. The aphids generally are wingless. Occasionally, winged forms appear. The winged aphids have transparent wings; the forewings are much longer than the rear wings. The aphids are most numerous in spring and early summer. Development takes about 12 days. These insects feed on leaves of citrus and cause new growth to be stunted. A heavy infestation can cause the trees to become seriously damaged. Besides damaging the trees directly, these aphids carry *tristeza*, a citrus disease that kills the roots and causes the trees to die.

APHIS-LION *(Insecta, Neuroptera).* The larva of the golden-eyes or lacewing flies (family *Chrysopidae*), so called because they feed on aphids and other small insects.

APHYTIC. A paleobotanic division of geologic time, signifying the period of time that preceded the first occurrence of plant life. See also **Paleobotany**.

APICAL GROWTH. Growth at the tip of an organ, as occurs in the roots and stems of all higher plants. Examination of the stems of most plants will show that growth in length occurs only in the apical portion, and only for a relatively short period of time, usually a matter of a few weeks. This may be determined by observing the distances between successive leaves: near the growing tip the leaves are very small and close together; as one goes back along the stem the size of the leaves increases and also the distance between them; but after the leaf is mature, little elongation of the stem occurs, as shown by the uniform distances between the mature leaves. Older stems increase constantly in diameter, but only exceptionally in length. One notable such exception, known as intercalary growth, is found in grasses and some other plants. Here a group of cells in the region of the node are capable for a time of active division and of causing increase in the length of older portions of the stem. Both here and in the tip of the stem increase in length is due to elongation of cells produced by an actively dividing tissue known as a meristem.

API GRAVITY. See **Petroleum**; and **Specific Gravity**.

APLACOPHORA. A class of *Amphineura (Mollusca)* made up of animals of worm-like form with foot reduced to median ventral ridge and mantle enlarged.

APLANATIC LENS SYSTEM. A system which satisfies the equation, $ny \sin u = n'y' \sin u' =$ constant. Unprimed letters refer to object space, primed to image space. n, n' are indices of refraction; y, y' are distances of a point object and its point image from the optical axis; and u, u' are angles made by a ray with the optical axis. The equation is known as Abbe's sine condition.

A triple *aplanat* is a compound lens made of two diverging lenses of flint glass between which is cemented a converging lens of crown glass.

APLANATIC POINTS. Two points on the axis of an optical system which have the property that rays proceeding from one of them shall all converge to, or appear to diverge from, the other. The two foci of an ellipsoid of revolution are aplanatic points. An aplanatic surface is an optical surface for which two aplanatic points exist.

APLITE. This term is applied to fine-grained, sometimes sugary-textured igneous rocks, composed almost wholly of quartz and feldspar. Except for size of grain, aplites resemble permatites both in mineral composition and in mode of occurrence in dikes and veins, save that the rare minerals often present in pegmatites are wanting here. The word aplite is derived from the Greek word meaning simple, referring to its ordinarily simple mineral composition.

APOB. See **Meteorology**.

APODEME. An internal projection of the hard outer covering (exoskeleton) of arthropods. Apodemes provide muscle attachments and in some species are extensively developed. They are collectively termed the endoskeleton.

APODIFORMES *(Aves).* This order includes the swifts and hummingbirds, which comprise those birds that have the longest primaries in proportion to their total length. Perhaps both forms represent split-offs from an ancestral "swift-sparrow" stock occurring only after the rollers and their relatives (*Coraciformes*) had already separated from the original common stock of the arboricoles, which yet more primitively had encompassed the range from the ancestral owls to the ancestral *Passeriformes*.

Swifts and hummingbirds have several characteristics in common. The wings are flat and lack, or possess only very short supporting feathers (to cover the space between wings and body). They have four complete pairs

of ribs; the posterior edge of the sternum is not notched. The legs are short, the leg muscles are very weak, and the talons are pointed. The eggs are relatively elongated and are generally white.

Despite their German name "sail birds," none of the species of the swifts can actually sail or soar in the air, making use of rising convection currents. Aside from the already mentioned characteristics they share with hummingbirds, swifts have the following features. The length is 10–33 centimeters (4–13 inches). The bill is short and broad, the opening is wide, and the salivary glands are large. The tongue is small and triangular. They have 7–10 secondaries; plumage ranges from gray to black and brown (in one tree swift species, it is olive and blue), and often has white markings. The iris is brown, and the bill and feet are black. The clutch numbers from 1–6, and both sexes incubate and feed.

Swifts occur in all parts of the world except the polar regions. There are two families: 1. The Swifts (*Apodidae*); and 2. the Tree Swifts (*Hemiprocnidae*); there is a total of 77 species (from 65–81, according to other authorities).

One of the most clearly characterized, most sharply defined, and most homogeneous families is the hummingbirds (*Trochilidae*). Hummingbirds are distinguished from swifts by the following characteristics. They range in size from small to very small, with a length of 6–22 centimeters ($2\frac{1}{2}$–$8\frac{1}{2}$ inches) and a weight of 2–20 grams (0.07–0.7 ounce). The large eyes are set in wide sockets. The bill is usually long, narrow, tube-shaped, straight or curved, and very thin throughout its length. Although the neck is long and flexible, the head is usually retracted between the shoulders. The wings are long to very long. The bird has 10 well-developed primaries, with the outermost almost always being the longest, but it has only 6 (rarely 7) secondaries. The origins of the powerful flight muscles are on a particularly well-developed sternum. The shins and feet are short, the leg and foot bones are thin, but the toes, of which there are 3 forward and 1 reversed, are well developed, short, with sharply pointed talons. The feet are suitable only for perching on branches, not for walking. The body plumage is moderately dense and the feathers are firm and adherent to each other, not downy.

Despite the richness of species, the family of the hummingbird is one of the most homogeneous known. The subdivision into tribes, genera, subgenera, species, and subspecies is therefore extremely difficult. There are approximately 120 genera with about 400 distinct forms, of which we consider 321 to be species. They occur only in America. See also **Swifts and Hummingbirds**.

APOGEE. See **Meteorology**.

APOLLO LUNAR MISSIONS. The Apollo program was designed to land humans on the Moon and bring them safely back to Earth. Six of the missions (Apollos 11, 12, 14, 15, 16, and 17) achieved this goal. Apollos 7 and 9 were Earth orbiting missions to test the Command and Lunar Modules, and did not return lunar data. Apollos 8 and 10 tested various components while orbiting the Moon, and returned photography of the lunar surface. Apollo 13 did not land on the Moon due to a malfunction, but also returned photographs. The six missions that landed on the Moon returned a wealth of scientific data and almost 400 kilograms (882 lbs) of lunar samples. Experiments included soil mechanics, meteoroids, seismic, heat flow, lunar ranging, magnetic fields, and solar wind experiments. See also **Astronauts**; **Lunar Exploration**; **Lunar Roving Vehicle**; **Moon (Earth's)**.

APONEUROSIS. A sheet of tough white glistening fascia or membrane that surrounds muscle and muscle fibers or connects a muscle to the part it moves. The tensile strength and resistance of muscle tissue are dependent upon the fascial tissue around the muscular fibers. See also **Tendon**.

APOPHYLLITE. The mineral is a hydrous silicate of potassium, calcium, and fluorine, corresponding to the formula, $KCa_4Si_8O_{20}(F, OH)\cdot 8H_2O$. The true crystallographic symmetry is evident on crystals by the luster difference between the basal pinacoid facial planes and other crystal faces. Also, prism faces show vertical striations; basal planes do not. It crystallizes in the tetragonal system in square prisms resembling cubes terminated by based pinacoid or pyramids, often with both. Prism faces show vertical striations; basal pinacoid either dull or rough. Cleavage is perfect, parallel to the base; hardness, 4.5–5; sp gr, 2.3–2.4; luster, vitreous to pearly; transparent to translucent or nearly opaque; color may be white, grayish, greenish, yellowish, or reddish. This mineral was named by Haüy from the Greek words meaning from a leaf, referring to its exfoliation when heated with the blow pipe.

Apophyllite is a secondary mineral found with the zeolites and has been classed with them by some writers, but it contains no aluminum, which element is understood to be an essential in a zeolite. It occurs in cavities in basalts and less often filling openings in granites or other crystalline rocks; it also is a gangue mineral in certain ore veins.

There are many localities for apophyllite: Bohemia, Trentino, Italy, the Hartz Mountains, and Iceland. Fine specimens have been obtained from the Ghats Mountains in India. The Triassic trap rocks of New Jersey, Connecticut, and Nova Scotia have also furnished many specimens.

APOPHYSIS. In zoology, an apophysis is a protuberance or outgrowth of an organic structure, such as a process on a bone.

In geology, an apophysis is a tongue or other direct offshoot of a larger vein or dike.

APPARENT FORCE (Fictitious Force, Inertial Force, Transport Force). A force (mass times an acceleration) introduced on the side of an equation on which all supposedly real forces appear.

For Newton's dynamical law of motion for a body of mass m acted on by a force $\mathbf{F}$,

$$\mathbf{F} = m\mathbf{a},$$

to be valid requires that the acceleration $\mathbf{a}$ be specified relative to an inertial reference frame. If the acceleration in a noninertial reference frame (e.g., a rotating reference frame) is $\mathbf{a}^*$, then

$$\mathbf{a} = \mathbf{a}^* + \mathbf{a},$$

and the previous dynamical equation may be written

$$\mathbf{F} - m\mathbf{a}_i = m\mathbf{a}^*,$$

where the quantity $-m\mathbf{a}_i$ is the inertial or apparent force and $\mathbf{a}_i$ is the inertial acceleration. Examples of apparent forces are the centrifugal force and the Coriolis force. Within classical (Newtonian) mechanics inertial forces are fictitious, merely masses times accelerations. But in general relativity, inertial forces are equivalent to real forces resulting from interactions between bodies because it is impossible to distinguish between inertial and gravitational accelerations; both are independent of the mass of the body.

See also **Apparent Gravity**; **Coriolis Force**; and **Inertial Force**.

AMS

APPARENT GRAVITY. For a rotating planet such as Earth the resultant of the force (per unit mass) due to gravity and the centrifugal force. Also called *effective gravity*, *virtual gravity*.

Apparent gravity is given by

$$\mathbf{g}^* = \mathbf{g} - \Omega \times (\Omega \times \mathbf{r}),$$

where $\mathbf{g}$ is the force (per unit mass) due to gravitational attraction, Ω is the angular velocity of the planet, and $\mathbf{r}$ is the position vector relative to its center. Like $\mathbf{g}$, $\mathbf{g}^*$ depends only on position. Within the earth's atmosphere the magnitude of the centrifugal force is less than 0.03% of $\mathbf{g}$. See also **Apparent Force**.

APPARENT HORIZON. The line between the sky and the earth projected on the celestial sphere. This line is often irregular, due to the earth's topography. On flat surfaces, such as the sea or a level plane, the line approximates a great circle if the observer's elevation above the surface is insignificant and a small circle if the elevation is appreciable.

APPARENT MAGNITUDE. The apparent magnitude (m) of a star, planet or other celestial body is a measure of its apparent brightness as seen by an observer on Earth. The brighter the object appears, the lower the numerical value of its magnitude.

The scale upon which magnitude is measured has its origin in the Hellenistic practice of dividing those stars visible to the naked eye into six *magnitudes*. The brightest stars were said to be of first magnitude ($m = 1$), while the faintest were of sixth magnitude ($m = 6$), the limit of human visual perception (without the aid of a telescope). Each grade of magnitude was considered to be twice the brightness of the following grade. This somewhat crude method of indicating the brightness of stars was popularized by Ptolemy in his *Almagest*, and is generally believed to have originated with Hipparchus. This original system did not measure the magnitude of the Sun. Because the response of the eye to light is logarithmic, the resulting scale is also logarithmic.

In 1856, Norman Pogson formalized the system by defining a typical first magnitude star as a star that is 100 times as bright as a typical sixth magnitude star; thus, a first magnitude star is about 2.512 times as bright as a second magnitude star. The fifth root of 100, an irrational number about (2.512) is known as *Pogson's Ratio*. Pogson's scale was originally fixed by assigning Polaris a magnitude of 2. Astronomers later discovered that Polaris is slightly variable, so they first switched to Vega as the standard reference star, and then switched to using tabulated zero points for the measured fluxes. The magnitude depends on the wavelength band. See also **Magnitude**.

The modern system is no longer limited to 6 magnitudes or only to visible light. Very bright objects have *negative* magnitudes. For example, Sirius, the brightest star of the celestial sphere, has an apparent magnitude of −1.44 to −1.46. The modern scale includes the Moon and the Sun; the full Moon has an apparent magnitude of −12.6 and the Sun has an apparent magnitude of −26.8. The Hubble Space Telescope (HST) has located stars with magnitudes of 30 at visible wavelengths and the Keck telescopes have located similarly faint stars in the infrared. See Table 1.

TABLE 1. SCALE OF APPARENT MAGNITUDES

App. Mag.	Celestial Object
−26.73	Sun
−12.6	Full Moon
−8.0	Maximum brightness of an Iridium flare
−4.4	Maximum brightness of Venus
−4.0	Faintest objects observable during the day with the naked eye
−2.8	Maximum brightness of Mars
−1.5	Brightest star at visible wavelengths: Sirius
−0.7	Second brightest star: Canopus
0	This used to be Vega 0.03
∼3	Faintest stars visible in an urban neighborhood
∼6	Faintest stars observable with the naked eye
12.6	Brightest quasar
27	Faintest objects observable in visible light with 8-m (26 ft) ground-based telescopes
30	Faintest objects observable in visible light with the Hubble Space Telescope (HST)
38	Faintest objects observable in visible with the planned Overwhelmingly Large Telescope (OWL) 2020.

The 20 brightest stars as seen from Earth (by apparent magnitude at visible lengths) according to the Hipparcos sky survey are listed in Table 2.

TABLE 2. THE 20 BRIGHTEST STARS

	Magnitude	Bayer Designation	Proper Name	Distance (ly)
0	−26.73		The Sun	0.000 016
1	−1.44	α CMa	Sirius	8.61
2	−0.62	α Car	Canopus	312.73
3	−0.05 var	α Boo	Arcturus	36.69
4	−0.01	α_1 Cen	Alpha Centauri A	4.40
5	0.03	α Lyr	Vega	25.31
6	0.08	α Aur	Capella	42.21
7	0.18	β Ori	Rigel	772.91
8	0.4	α Cmi	Procyon	11.42
9	0.45	α Eri	Achernar	143.81
10	0.45 var	α Ori	Betelguse	427.47
11	0.61	β Cen	Hadar	525.22
12	0.76	α Aql	Altair	16.76
13	0.77	α Cru	Acrux	320.72
14	0.87 var	α Tau	Aldebaran	65.10
15	0.98	α Vir	Spica	262.20
16	1.06	α Sco	Antares	604.02
17	1.16	β Gem	Pollux	33.73
18	1.17	α PsA	Fomalhaut	25.08
19	1.25	β Cru	Becrux	352.62
20	1.25	α Cyg	Deneb	3229.35

APPARENT MOLAR QUANTITY. For a solution containing n_1 moles of solvent and n_2 moles of solute, an apparent molar quantity is defined as

$$\frac{X - n_1 x_1}{n_2}$$

where X is the value of the quantity for the whole solution and x_1 the molar quantity for the pure solvent; e.g., the apparent molar volume of the solute is

$$\frac{V - n_1 v_1}{n_2}$$

V being the total volume and v_1 the volume per mole of the solvent.

See also **Molal Concentration**; **Molar Concentration**; **Mole (Stoichiometry)**; **Mole Fraction**; and **Mole Volume**.

APPARENT SOLAR DAY. The interval of time between two successive transits of the sun across a meridian. Also called *true solar day*. This interval is about four minutes longer than the sidereal day, largely because of the sun's apparent annual motion eastward along the ecliptic (actually, the earth's "westward" motion along its orbit), which motion delays the sun's return to meridional transit. Also, this interval is inconveniently nonuniform due to systematic variations in the earth's orbital speed around the sun and the sun's changing declination. The concept of the mean solar day has been invented to circumvent these practical difficulties.

APPARENT TEMPERATURE. A measure of human discomfort due to combined heat and humidity. It measures the increased physiological heat stress and discomfort associated with higher than comfortable humidities. The apparent temperature is less than the actual air temperature when the humidity is relatively low and that the apparent temperature indicates the reduced stress and increased comfort associated with the higher rate of evaporative cooling of the skin.

Apparent temperatures greater than 80 °F (27 °C) are likely to produce some discomfort. Values in excess of 105 °F (41 °C) may be dangerous and even life-threatening, with severe heat exhaustion or heat stroke possible if the exposure is prolonged or physical activity is high. The degree of stress may vary with age, health, and body characteristics (see Table 1).

The apparent temperature does not consider the effects of air movement (wind speed) or exposure to sunshine on the degree of discomfort or stress. The apparent temperature is determined by the following Quasi-empirical equation:

Apparent temperature $= 1.03T + T(\exp((DP - 59)/17) - 1)/19 - 3$

where T = Observed temperature (°F), DP = Dew point (°F).

TABLE 1. CATEGORIES OF APPARENT TEMPERATURE

Category	Classification	Heat Index/ Apparent Temperature (°F)	General Affect on People in High Risk Groups
I	**Extremely hot**	**130 or Higher**	Heat/Sunstroke **HIGHLY LIKELY** with continued exposure
II	**Very hot**	**105–130**	Sunstroke, heat cramps, or heat exhaustion **LIKELY**, and heatstroke **POSSIBLE** with prolonged exposure and/or physical activity
III	**Hot**	**90–105**	Sunstroke, heat cramps, or heat exhaustion **POSSIBLE** with prolonged exposure and/or physical activity
IV	**Very warm**	**80–90**	Fatigue **POSSIBLE** with prolonged exposure and/or physical activity

APPENDAGE. A supplementary structure attached to an organ or body. Externally many animals have appendages that serve for defense, for locomotion, for securing food, and as sensory organs.

The simplest external appendages are mere outgrowths of the body wall, either solid or hollow; the tentacles of coelenterates are an excellent example. In the annelid worms both tentacles and parapodia appear as external appendages, in the echinoderms the rays or arms may be radiating divisions of the body or appendages, and in the mollusks tentacles of complex structure occur. In all cases these structures allow greater facility of movement than is possible for the body as a whole and so compensate the lack of freedom that attends increased size and complexity or sessile habits.

The most elaborate appendages are the joined appendages of the arthropods and chordates. Although they are not fundamentally related, the appendages of both phyla are similar in principle. They consist of a series of segments connected by movable joints with each other and with the body, and are provided with muscles that operate them as a series of levers. In arthropods the skeleton is external to the muscles, in the vertebrates internal.

The jointed appendages of arthropods are specialized in various species for swimming, walking, running, jumping, feeding and grasping, and in the form of antennas and palpi as sensory organs. In the jumping appendage powerful muscles result in the extension of one segment of the leg, as in the familiar grasshoppers. Grasping is accomplished by the folding back of one segment against another in the insects or by the development of a process on the next to the last segment which works against the terminal segment in a forceps-like relation; the latter is the chelate type of appendage. Arthropod appendages were originally metameric, one pair appearing on each segment of the body. In existing species they are variably limited as described under the term *Arthropoda*.

The vertebrate appendage is also specialized for various purposes, including jumping, swimming, flight, and burrowing. The primitive form appears to be the paired fins of the fishes (*Osteichthyes*), and the arms and legs of humans are good examples of fairly specialized appendages. Two pairs, the pectoral or anterior pair and the pelvis or posterior pair are typical; only in highly specialized forms such as the snakes is this number reduced.

The vertebrate appendage differs from the arthropod appendage in the terminal series of digits. These structures have been developed in some animals so that they can be opposed to each other for grasping, as in the opposition of the human thumb to the four fingers. In other forms they have been reduced in importance.

See also **Biramous Appendage**; and **Pentadactyl Appendage**.

APPENDICITIS. Inflammation of the vermiform appendix. See **Appendix (or Appendix Vermiformis)**. The infection may be acute and lead to perforation of the appendix if not promptly attended, or it may subside spontaneously. Pain, tenderness, and spasm in the right lower quadrant of the abdomen are typical symptoms of appendicitis — but these are also symptoms of other conditions, such as duodenal ulcer disease, cholecystitis (inflammation of the gallbladder), gastrointestinal actinomycosis, and gastroenteritis resulting from *Salmonella* infection, among others. The symptoms of acute appendicitis develop rapidly into a severe generalized abdominal pain, and rebound tenderness is often present. In children, crying, vomiting, and refusal of food may be very early symptoms of appendicitis. Because such symptoms commonly occur from dietary indiscretions, parents may administer a laxative before consulting a physician, with the possible result that perforation of the appendix may be precipitated. Thus, a laxative or enema is not advised in the case of abdominal pain without first consulting a physician.

Immediate surgery (*appendectomy*) is indicated in acute appendicitis. Delay invites complications, such as peritonitis. See **Peritonitis**. Devoid of complications, the prognosis for successful recovery from appendicitis is excellent.

APPENDICULARIAN *(Chordata, Tunicata).* A free-swimming tailed tunicate with a permanent chordate tail. These forms make up the class *Larvacea*.

APPENDIX (or Appendix Vermiformis). A blind worm-like tubular portion of the intestine arising from the base of the cecum. Its size and position vary greatly, the length averaging $3\frac{1}{2}$inches (8.9 centimeters), although it has been found to vary from $\frac{3}{4}$–9 inches (1.9–22.9 centimeters). Its position often varies from the normal so that it has been reported in every possible situation in the abdomen, depending on the position of the cecum and the length of the organ and its attachments.

An appendix is found only in humans, the higher apes, and the wombat, and possibly in some rodents. In herbivorous animals the cecum attains a very large size and it is thought by some that the appendix represents the degenerated remains of the herbivorous cecum. Others believe that it is a lymph organ, functioning as do other lymph glands in the body. By many it is considered to be in the process of gradual obliteration in the human species. It is subject to inflammatory processes because of its limited blood supply, and since it is a blind tube, it is subject to obstruction from fecal impacting. See also **Appendicitis**.

APPETITE (Loss). See **Anorexia**.

APPLE LEAF SKELETONIZER *(Insecta, Lepidoptera).* The adult of this species (*Psorosina ammondi*, Riley) over-winters as a small dark-brown moth. Eggs are laid in early spring. The larva is a caterpillar that feeds on the underside of leaves and which later constructs shelters on the upper surface of leaves by drawing leaves together with silken webbing. The leaves become a mass of webbing and grass and are damaged by suffocation. The insect is distributed throughout the United States, but is most abundant in the central latitudes. The caterpillar is brownish-green and about $\frac{1}{2}$-inch (12 centimeters) long, with four shining black tubercles on back just to the rear of the head. This is not regarded as a serious pest because it occurs infrequently. The insect is mainly controlled by predators and parasites. When infestation is small, handpicking is effective. When infestations are large during the growing season, chemical controls, such as lime, may be used.

APPLE LOSSLESS (OR APPLE LOSSLESS AUDIO CODEC, ALAC). See **Data Compression**.

APPLE REDBUG *(Insecta, Hemiptera).* A sucking insect that attacks apple, haw, and pear and which occurs east of the Mississippi River in the United States and in southeastern Canada. The adult is orange-red with

dark markings, up to $\frac{1}{4}$-inch (6 millimeters) long. The nymph is bright red, somewhat smaller than the adult. This insect, *Lygidea mendax* (Reuter), punctures the fruit, causing spots and deformation. These insects pass the winter in the egg stage. The eggs are laid in the bark of branches of trees and in the bark pores. They hatch in early spring. When light to moderate infestations are found during the season, cultural precautions for the next season may be the best practice. This involves using a dormant fruit tree oil spray that will kill the overwintering eggs. Treatment is similar to that for the aphid. See **Aphid or Plant Louse**. Where the infestation may be heavy during the growing season, control chemicals may be effective. Nicotine sulfate spray is also effective if applied at the cluster-bud stage.

APPLIED MICROBIOLOGY. See **Microbiology**.

APPLIED RESEARCH. The experimental investigation of a specific practical problem for the immediate purpose of creating a new product, improving an older one, or evaluating a proposed ingredient. The experimental program is set up to answer the question "What happens?" rather than "Why does it happen?" Examples are the determination of the value of a new rubber antioxidant, the substitution of one drying oil for another in a paint formulation, and the development of a new synthetic product. While applied research has produced the multitude of new materials that have revolutionized industry, agriculture, and medicine in the last 50 years or so, its achievements have usually been practical outgrowths of prior fundamental research.

APPROXIMATE CALCULATION. It is often necessary, especially in physical problems, to make approximate, rather than precise, calculations. Typical cases include: the solution of polynomial or transcendental equations; evaluation of integrals that cannot be given in terms of simple functions; solution of differential equations with assigned boundary conditions.

Sometimes graphical or mechanical methods are convenient and these, while limited in their precision, frequently yield results of complete satisfaction. Numerical methods are more generally applicable, for with computers an answer can usually be obtained with any reasonable number of significant figures desired. In these cases, the procedure can be classified as one of two general classes: polynomial approximation or iteration.

The literature of this subject is very large and only a brief survey of it can be given here. Moreover, the methods involved can be modified in many different ways and there is no generally accepted name given to the various procedures.

Approximating methods also are described under **Curve Fitting**; **Differentiation (Numerical)**; **Integration (Numerical)**; and **Interpolation**.

APTERYGOTA. The primitive wingless insects with varying number of paired appendages on the abdomen and metamorphosis slight or absent. A subclass is made up of the orders *Protura*, *Thysanura*, and *Collembola* in which the existing species are wingless and there is no evidence to show that wings have occurred in any ancestral form.

AQUACULTURE. This group of disciplines and practices, fundamentally centuries old in basic concept, essentially parallels agriculture (land crops and plants) and animal husbandry (livestock) in the quest to increase productivity of natural food substances, while simultaneously achieving efficiency and convenience of harvesting by way of concentrating the sources into smaller spaces. Possibly, the most useful synonym for aquaculture would be *fish farming* (where the term fish is interpreted broadly to include mollusks and crustaceans). Aquaculture can be broken down into several categories, usually in terms of environments and species involved. Possibly the most meaningful breakdown is (1) those operations directed toward the culture and harvesting of freshwater fishes; and (2) those operations directed toward marine animals, from which the terms *sea farming* or *mariculture* have developed. There are always the inevitable complications that detract from a crisp categorization — for example, the application of aquaculture to estuarine and brackish waters involving species that may be fully or partially tolerant to both fresh and saline waters. While most aquaculture operations are fully land-based or operate in the tidal zone between land and open water, there are also cultural operations that take place in naturally open and large bodies of water, such as lakes or various locations in the seas and oceans.

Bardach et al. (1972) defined aquaculture as "the farming and husbandry of freshwater and marine organisms." Glude (1977) called aquaculture "the culture or husbandry of aquatic animals or plants by private industry for commercial purposes or by public agencies for augmenting natural stocks." Brown (1977) uses the term "*sea ranching* — [a method that] involves releasing hatchery-reared animals of various sizes into marine waters for rearing and the subsequent recapture of the adult fish upon their return to the point of release." The general term fish culture is used by Edmunds and Lillard (1979).

Records indicate that aquaculture was practiced several thousand years ago in the Mediterranean area. It has been established that the Romans were successful in cultivating fishes in the brackish waters off the coast of Italy. Various Egyptian art forms depict the pond culture of fish. Records of the Chou and Shang Dynasties in China include reference to raising fish in ponds, projects of interest to the ruling class. Pioneered by Wen Fang in Honan Province (circa 1135–1122 B.C.), a treatise on these practices appeared in the Chinese literature as early as 475 B.C. To this day, aquaculture continues important to the food economy of China (Dill, 1967).

But, as pointed out by Sandifer and Smith (1978), despite its antiquity, aquaculture is a relative newcomer to the business of food production compared with agriculture and conventional fisheries. Consequently, aquaculture accounts for less than 1% of food production (Wheaton, 1977). Nevertheless, total food production from aquaculture exceeded 6 million metric tons in 1975. As aptly pointed out by Moiseeve as early as 1973, it is not the current levels of production, but rather the large potential productivity (hundreds of millions of metric tons) that is of such interest to a protein-short world population. For some of the developed countries, increased protein from aquaculture is not yet a serious consideration. Some authorities are quick to point out that aquaculture may be required within the relatively near future if the desire for seafood luxuries, such as shrimp and other shellfishes, continues at the pace enjoyed during the last few decades. In some countries, during the period 1960 to 1976, the demand for shrimp increased by about 80%, as compared with increased shrimp landings of less than 65%.

Compared with its relatively small beginning and slow development for many years, during the past decade fish culture in the United States has expanded steadily. Reasons given are high fish prices, the realization that conventional sources of fish are not limitless, the increased costs of catching fish in conventional fashion, and problems of pollution etc. that have interfered with natural fish habitats. As the vital need of the developed nations for increased energy sources becomes even more critical, trade-offs favoring energy will increase — as, for example, where historical and natural fisheries may be adversely affected by thermal and chemical pollution, among other factors. Aquaculture may provide an effective means in some instances for essentially abandoning traditional fisheries where there is a serious conflict with energy production.

The Worldwide National Oceanic and Atmospheric Administration estimates that 10% of the total fish production (1977) was derived from aquacultural operations, whereas this figure for the United States was about 3%, with the activities concentrated mainly on salmon, oyster, catfish, trout, shrimp, and clam species. Aquaculture will have to play an increasingly important role in meeting the global demand for fisheries products as the world population continues to expand and fisheries stocks approach their biological limits. Although world aquaculture production reached an all time high of 28.8 million metric tons valued at $45.4 billion (US$) in 1997, aquaculture production will have to expand at least two fold to meet world demand for fisheries products by the year 2025. Aquaculture will also play an important role in economic and community development throughout the world as the world moves to a more global economy.

The progressive development and expansion of aquaculture will be dependent on the generation, dissemination, and adoption of knowledge and technology consistent with broad societal, national and international goals. As aquaculture production expands to meet global demand for fisheries products, it is essential that efficient and environmentally sustainable systems be developed and utilized.

The World Aquaculture Society (WAS) is strategically positioned to play an important role in assuring the progressive development of aquaculture worldwide by meeting the increased global demand for science based information and technology.

Much of the research on aquaculture in the United States has been directed: 1) toward determination of optimum growth conditions, to the formulation of rations which provide maximum feed conversion rates; 2) toward a reduction in the time required to produce a marketable product, and 3) toward closing the life cycle of the shellfish when held in captivity. Edmunds and Lillard (1979) report that recent developments in closing the life cycle for shrimp and polyculture are technological advances which dramatically increase the economic feasibility of aquaculture for the affected species. Among other observations, these researchers found that cultured shrimp were equal or superior to wild shrimp in sensory quality. Their general findings ran counter in many instances to observations that cultured fishes of the various species are frequently inferior to the wild catches. References relating to the potential of aquaculture in the United States, as listed, include: (Anon. (1) through (5); Rutherford, 1975; Shoemaker, 1975; Gallese, 1976; Twitty, 1976; and Booda, 1976).

For many years, a number of countries have developed their sea resources in coastal regions. These estuarine regions have supported the culture of fish and invertebrates in tremendous numbers as well as great fisheries. In weight yield per surface area, these estuaries are much richer in food resources than the open sea.

Indian Ocean Regions. There are extensive culture fisheries in the estuarine areas of the Indian Ocean coastal zone. These brackish water swamps are banked with dikes to take in water at high tide, and the suspended silt settles on the bottom, slowly raising its level. Within several years, the land is built upto the point where it can be used as rice paddies. When the land level is high enough, intake of tidal water is discontinued and rainwater leaches the salt from the soil. After 2 to 3 seasons, the paddy may be planted. The plot will have a canal system inside the dike; these canals are used for culturing brackish water fishes. But, during this silting period, the area is used for growing fish. The tidal water brings in the fry of commercially important fish, including prawns. Screens prevent the escape of fish or the ingress of extraneous fish, and sluice gates control the tidal flow.

The once incidental use of swampy land for raising fish promoted a system of intensive brackish water fish culture in India and Pakistan. Fish ponds of different design and shape began to be constructed for the sole purpose of commercial fish culture.

On the islands of Java and Madura (Malaysia), ponds or "tambaks" produce upwards of 40 million pounds (18 million kilograms) of fish annually. The industry is based upon the *milk fish* (*Chanos chanos*). See Fig. 1. Post larvae and juveniles are collected from inshore areas from September to December and from April to May and transported to the fish pond areas in flat, watertight bamboo baskets. The annual requirements for the tambaks of these islands is estimated at upwards of 200 million fry.

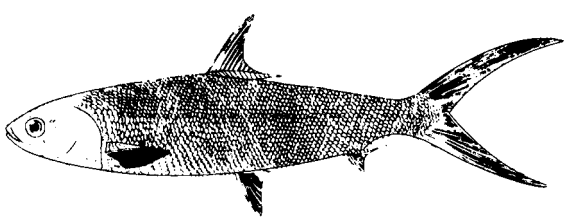

Fig. 1. Milk fish.

In India, grey mullet, pearl spot, prawns, or milk fish are seined from nearby areas and transported to fish ponds called "porong" ponds. Each porong-type farm has fry ponds of varying areas, ranging from about 1000 to 10,000 square feet (90+ to 900+ square meters), and rearing ponds of 10,000 to 48,500 square feet (900+ to 4500+ square meters). The irregularly shaped sections are connected by secondary sluice gates and the whole complex is controlled by a main gate located in a deep portion, having a channel in the middle. The ponds are drained and dried to eradicate predatory and weed fish and to hasten decomposition of organic matter. Then from 1.2 to 2 inches (3 to 5 centimeters) of tidal water is taken in and allowed to stand. Within 3 to 7 days, a brownish-greenish-yellowish layer of microorganisms (mainly bacteria, unicellular and filamentous blue-green algae, and diatoms) develops on the bottom. Growth and production of fish in the ponds depends upon the growth of algae. The product is marketable within 6 to 10 months. The ponds are drained at low tide to capture the fish. The tendency of the fish to swim against the current is used for partial fishing. When tidal waters are let into the ponds, the fish swim against the current and then can be led to a catching pond.

In Java and Madura, annual production approaches 25 million pounds (11.3 million kilograms) of milk fish; about 10 million pounds (4.5 million kilograms) of penaeid prawns; and 6 million pounds (2.7 million kilograms) of other fish.

The sometimes-called giant Malaysian prawn (*Macrobrachium rosenbergii* de Man) is widely distributed in the Indo-Pacific region, ranging from Australia to New Guinea to the Indus River delta (Johnson, 1960; George, 1969; Malecha, 1977). There also have been reports of populations from the Palau Islands (McVey, 1975). In their review of the aquaculture of Malaysian prawns, Sandifer and Smith (1978), observe that adults are usually found in freshwater reaches of rivers, and during the breeding season, mature females migrate downstream into estuarine areas where the eggs are hatched. Presumably, the larvae are then swept further downstream into more saline waters where they develop. But, after a few weeks after the larval phase, the postlarvae begin to migrate toward freshwater where they grow to adults. Sandifer and Smith have diagramed the life cycle of the Malaysian prawn. See Fig. 2.

Controlled-environment experiments on cultivating Malaysian prawns have been conducted in recent years by the Marine Resources Research Institute, Charleston, South Carolina and these are reported in the Sandifer and Smith reference. The climate in this area permits prawn cultivation during only the warmer half of the year. Experiments, however, have shown that one crop of marketable prawns can be reared annually in ponds in South Carolina. It has been observed that a broad area of the state's coastal plain may be suitable for prawn farming. The researchers observe that to become commercially attractive, very intensive culture systems must operate continuously at high efficiencies and produce much greater yields per unit of area than a conventional pond system. External heat is required (possibly solar) for year-round operation. Culture containers (above ground) in form of tanks may be a limiting factor. Earthen ponds are being studied. Other configurations, including Shigueno-type tanks and aquacells are under consideration. Summarizing current problems, the researchers observe prawn nutrition, behavior, physiology, and genetics; culture systems design and optimization; pilot plant demonstrations; and economic feasibility analyses. A successful controlled-environment culture of *Macrobrachium* will likely require (1) the development of more nutritionally complete, cost-effective rations; (2) the determination and maintenance of optimal conditions for prawn survival and growth under crowded conditions; (3) genetic manipulation to produce prawns better suited for intensive culture than are the essentially wild animals available today; (4) reduced system costs; (5) improved management techniques; and (6) greater production efficiency.

Mosquitofish (Nothobranchius taenipygnus), a tiny fish a little less than 1 inch long (2.5 centimeters) at the age of 3 to 4 weeks has been suggested by some authorities as a protein source in Africa and Asia. The fish will live in a few inches of water. Areas from 6 to 12 inches (15 to 30 centimeters) allow the maximum number to be bred in the minimum volume of water. Young *Nothobranchius* feed on algae and protozoa, but older fish prefer insect larvae. Apart from some chemical fertilizers to increase the growth of algae in the feeding pools, little has been done to provide supplies of feed. It is interesting to note that in 1977, researchers of the Sutter-Yuba Mosquito Abatement District in California reported on a formulation of a specific floating feed designed for rearing of mosquitofish. It is the plan to breed these fish in sufficient numbers to release them in California rice paddies for controlling mosquitos. This is an aquaculture project with a possible double advantage.

China. An excellent summary of aquaculture in China is provided by Ryther (1979). It is estimated that freshwater fish production in China probably exceeds that of the rest of the world combined, perhaps by as much as severalfold. Various estimates have placed the total area of freshwater culture in China at about 25 million acres (10 million hectares). Yields from the smaller, more intensively managed fish ponds have been estimated to range from a low of 893 pounds per acre (1000 kilograms per hectare) to 8930 pounds per acre (10,000 kilograms per hectare), with a probable average of about 2680 pounds per acre (3200 kilograms per

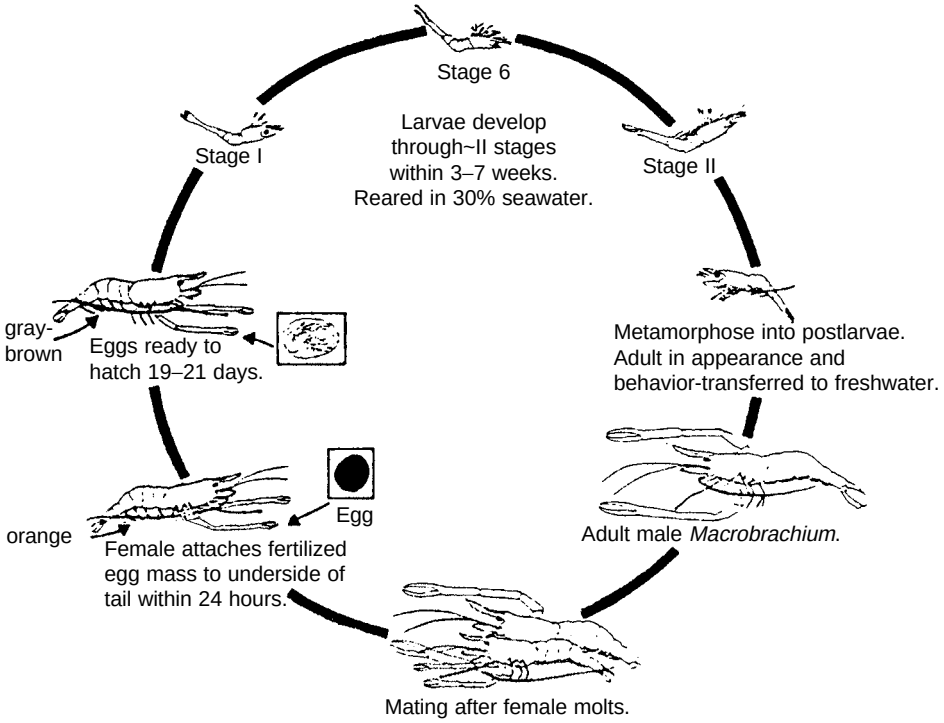

Fig. 2. Life cycle of Malaysian prawn. (*After Sandifer and Smith*.)

hectare). It has been reported that the Ching Po Fish Farm (near Shanghai) produced 5000 pounds per acre (5600 kilograms per hectare) in 1978, with an objective of reaching 6700 pounds per acre (7500 kilograms per hectare).

It has been estimated that the combined yields from aquaculture and marine fishing in China are equivalent to a per capita catch consumption of about 45 pounds (20.4 kilograms) against a backdrop of perhaps a billion people or more.

Ryther reports that the success of aquaculture relates to a number of factors: (1) multiple use of aquatic resources where several species are cultured in the same facility; (2) fish pond culture in China always has been considered an integral part of agriculture. Emphasis is given in polyculture to those species that are low in the food chain. Most of the fish species favored in Chinese pond culture are cyprinids (minnows), of which the 4 species (carp) illustrated in Fig. 3 are currently the most important. As stated earlier, it must be stressed that aquaculture in China dates back thousands of years.

By contrast, marine aquaculture or mariculture represents a much more recent endeavor, extending back only a comparatively few decades on a large scale. Culture includes species of sea plants as well as sea animals. Probably the most important cultivated marine organism is the brown seaweed (*Laminaria japonica*), a cold-water species of kelp. See also the entries on **Algae**; and **Seaweeds**. Other cultured species include sea cucumbers, penaeid shrimp, pearl oysters, crab, mullet, and milk fish, but all are not in a fully developed state ready for commercial production. Mariculture has lagged somewhat, possibly largely because of the heavy accent on freshwater aquaculture, which is intimately tied to agriculture and a water conservation program. Aquaculture technology in China is headquartered in the City of Tsingtao, in which are located the Institute of Oceanography (Chinese Academy of Sciences), Shantung College of Oceanography, and the Yellow Sea Fisheries Institute (National Bureau of Fisheries). A significant part of the current research is directed toward algae and seaweed production.

Europe. In Italy, the Volturno River discharges into Lake Patria. The communication of the estuary with the sea consists of a very narrow shallow watercourse. Nutrients enter the lake from volcanic subsoil. Lake Patria teems with mullet and eels. The soft, muddy subsoil makes mussel farming on the bottom impossible, but by hanging cultures above the bottom, the mussels grow and fatten rapidly.

The Oosterschelde, in the southwestern section of the Netherlands, is an estuary with a different pattern. The Oosterschelde is an embayment penetrating far into the land that receives little influx from the surrounding fertile arable land. Yet river and seawater meet under the influence of the tides. The Rhine, the Meuse, and Scheldt Rivers discharge fresh water rich in nutrients and organic materials into the North Sea. Tides and winds bring about a thorough mixing and microorganisms mineralize the remains of freshwater organisms and other organic material. It is this mixed coastal water that pours into the Oosterschelde with the tides. The high and constant salinity, together with the discharge of nutrients conducive to rich plankton development, makes good oyster water. Under natural conditions, the oyster population was limited by an unprepared bottom and by failure of the oyster larvae to settle on beds where growth and fattening would be optimal. An exploitation of the natural resource by applying techniques of cultivation has resulted in a 30-fold increase in production over what nature formerly yielded.

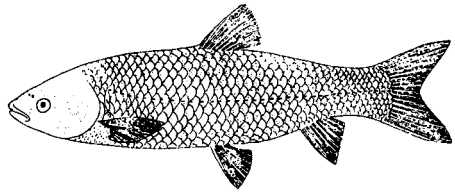
The Galacian bays of Spain are examples of estuaries in which shelter is a more important factor than discharge of nutrient-rich freshwater, since the seawater is sufficiently rich through upwelling. In the early 1950s, experiments were carried out to take advantage of the favorable conditions in these estuaries by growing mussels in hanging cultures following experiences gained in the Mediterranean Sea. Instead of racks, which are unsuitable where the tidal range is great, rafts were used. At first these were old boats equipped with outriggers. The success was promising and led to some 1500 installations consisting mainly of specially constructed rafts. Each raft carries 800 ropes; each rope is about 20 feet (6 meters) long and carries 100 pounds (45.4 kilograms) of marketable mussel. It takes eight months to rear a mussel seed to marketable size. See also **Mollusks**.

The Japanese use a similar technique to cultivate oysters. By growing oysters on long ropes hanging from simple rafts, the plankton of the whole water column is available to the oyster, and there can be a 50-fold increase in yield.

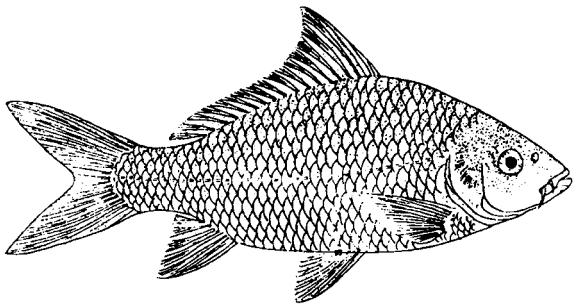
Another type of estuary, with extensive tidal flats and channels of varying depth through which tidal currents run, is located behind the Frisian Islands of Texel, Vlieland, and Terschelling, the Dutch Wadden Zee (western section). These flats are productive with mussels and cockles, brown shrimp, and polychaete worms of various species. Young flatfish and sole use this area as nursing grounds.

Several other examples of idealized situations for maritime culture could be described. Reference to McLeod (listed) is suggested.

Israel. Aquaculture commenced in Israel in the late 1930s and by the 1970s accounted for about 10% of the country's total annual value of agricultural production. Initial experiments utilized land and water unfit for ordinary agriculture. Productive ponds today are common throughout Israel with frequent integration of agricultural crops and fish ponds, all



Grass carp *(Ctenopharyngodon idellus)*



Common carp *(Cypnnus carpio L.)*

Fig. 3. Four species of carp. (*S. Ling.*)

practicing required water conservation and reclamation. The Jordan River provides Israel with about one-third of its fresh water, the other two-thirds coming from ground water. Over 95% of the available fresh water is utilized, with emphasis being placed on use of brackish water in various agriculture/aquaculture practices. Several reasons for the development of an extensive fish culture industry in Israel include: (1) the skill of immigrants from Central Europe in the breeding and cultivation of carp of; (2) the need to provide dietary protein, complicated by shortages of fresh water and good agricultural land; and (3) the low productivity of Eastern Mediterranean fisheries, and (4) projected declines in catches, placing additional emphasis on expansion of intensive fish farming enterprises. In Israel, by the early 1970s, 8 pounds (3.6 kilograms) out of the 22 pounds (10 kilograms) of fish per capita consumed annually were pond-raised. The Fish Breeders Association is the governing body, controlling all aspects of freshwater fish production in Israel. All fish farmers are members of the association and pay a tax according to the area of their ponds and their production.

Fish raisers in Israel have found that only 4100 square yards (3400 square meters) of water area are required to produce one ton of fish, and portions of this can be used for irrigation. The basis of much of the technology is in controlled aeration of the pond area, thus permitting a two- to five-fold increase in fish stocking and the use of more sophisticated feeding methods. Yields of 2.8 to 12.1 tons per acre (7 to 30 tons per hectare) have been achieved by application of advanced technology as compared with yields of 1.2 to 1.6 tons per acre (3 to 4 tons per hectare) when using conventional procedures. The significant increase has been accomplished without a great change in the feed conversion ratio and total cost of production per ton. Other developments similarly have contributed to productivity of Israeli fish ponds. This has involved the use of supplemental feeding (25% protein pelleted feed), which has allowed an increase in pond stocking rate and improvement of tilapia yield in polyculture without depressing carp growth rates. Secondly, establishment of an optimum stocking density for both tilapia and mullet in the carp ponds has permitted more efficient exploitation of the pond's natural productivity.

High yields have been achieved through the use of multispecies (polyculture) culture. In polyculture, a range of fish species with a variety of feeding habits are stocked together, thus improving both the use and efficiency of conversion of the food.

The principal fish bred in the pond is carp, which feeds on grain and food wastes. Tilapis (Saint Peter's fish) and gray mullet are bred together with the carp. As noted, since each requires a different type of food (and occupies separate aquatic tropic levels), maximum use of land and water is achieved.

The species *Tilapia aurea*, introduced into carp ponds, originally presented a problem of wild spawning and resultant overcrowding and small size. Earlier investigations with tilapia were directed to finding ways to control unwanted spawning in the fish ponds. Prolific reproduction and reproduction at small sizes by tilapia results in gross overcrowding and consequent stunting of their growth. Lines of research aimed at controlling spawning included use of monosex culture (one sex of a fish present in a pond) and cultivation of tilapia in full-strength seawater where they can survive, but do not spawn. Another approach is the use of a predator fish (sea bass) that does not reproduce in fresh water and will control wild spawning.

Other cultured fishes in earlier stages of development include trout as well as (*Macrobrachium rosenbergii*), the Malaysian prawn. There is also early development of desert aquaculture in the lower Negev, including the integration of brackish pond aquaculture with intensive agricultural production in regions of high temperature and critical water availability. Cultivation of fish, such as tilapia, with variable-salinity tolerances, as well as adapted marine species, offers potential for polyculture in desert areas in other parts of the world, as well as in Israel.

Specific Aquacultural Objectives. Whether freshwater or marine species, the objectives of various countries as regards aquaculture cover a rather wide range. As of the early 1980s, these objectives in terms of species are given in Table 1. Only the main targets are given; the table is not meant to be all-inclusive.

Shortcutting the Conventional Food Chain. The small size of most of the food in the sea is one of the most serious constraints imposed by nature. In the ocean, unlike the land, most of the food is cycled through all but the final portions of the food chain in microscopic steps. The reasons for this are obscure, but they probably related to the absence over most of the ocean of a substrate in which large plants can attach at depths shallow enough for them to receive the light required for photosynthesis.

Each of the microscopic steps up the marine food chain is perhaps only 10 to 15% efficient, so that of the great amount of potential food initially fixed by photosynthesis in the phytoplankton, only a very small portion emerges in the form of fish to be caught.

The codfish, for example, eats predatory crustaceans and gastropods and small fish, which in turn, eat small herbivorous invertebrates. Thus, each million weight unit of cod production requires 10 million weight units of smaller fish and crustaceans, which in turn, requires 100 million weight units of small herbivorous invertebrates. These, in turn, consume 10 times their own weight in plant matter and a vast amount of bottom land.

McLeod (1969) estimates that about 70% of the total annual food requirements of the adult winter flounder are met by detritus and phytoplankton-eating invertebrates. Through a series of calculations, McLeod estimates that to produce 100 weight units of winter flounder,

TABLE 1. WORLDWIDE AQUACULTURE ACTIVITY

Country	Principal Species Cultured or Under Study for Potential Culture
Australia	Rainbow trout; crayfish (marrons and yabbies); native fish (Murray cod, golden perch, silver perch, catfish)
Austria	Rainbow trout; carp; tench; grass carp; lake whitefish
Belgium and Luxembourg	Rainbow trout; brown trout; carp; tench; roach; pike; pike perch; European eel
Canada	Salmon; trout; char
China (People's Republic of)	Common carp; crucian carp; grass carp; bighead; seaweeds
Denmark	Rainbow trout; brown trout; European eel
France	Rainbow trout; brown trout; carp; European eel; coho salmon; crayfish
Germany	Rainbow trout; brown trout; carp; European eel; tench; northern pike
Hungary	Carp; barbel; sturgeon; tench; bream; Danubian wels; pike-perch; pike; asp; brown trout; perch
Indonesia	Milk fish; common carp; grass carp; silver carp; kissing fourami; nilem; sepat siam; catfish; tilapia; shrimp
Ireland	Rainbow trout; brown trout; European eel
Israel	Carp; tilapia; mullet; silver carp
Italy	Rainbow trout; European eel; black bullhead; carp; mullet; sea bass; gilthead
Japan	Rainbow trout; freshwater eel; common carp; crucian carp; auy or sweetfish; loach; mullet; yellowtail; red sea bream (red porgy); horse mackerel; shrimp
Korea (South)	Carp; Japanese eel; rainbow trout; loach; grass carp; catfish; blue gill; bass
Netherlands	Roach; pike-perch; carp; pike; rainbow trout
Norway	Atlantic salmon; rainbow trout
Papua New Guinea	Rainbow trout; brown trout
Philippines	Milk fish
Portugal	Rainbow trout; brown trout; carp; steelhead trout; Atlantic salmon
Spain	Rainbow trout; Atlantic salmon; European eel
Sweden	Rainbow trout; Atlantic salmon
Switzerland	Rainbow trout; brown trout; carp; northern pike; lake whitefish; steelhead trout; char; pike-perch; perch
Taiwan	Milk fish; tilapia; Japanese eel; gray mullet; shrimp; carp
United Kingdom	Rainbow trout; carp; Atlantic salmon; turbot; Dover sole
United States	Rainbow trout; catfish; American eel; prawns; crayfish; salmon
Russia	Sturgeon; trout; carp; Pacific salmon

a total of 4088 weight units of direct and indirect vegetable matter is required.

For this reason, large-scale, controlled fish farms can be achieved only in restricted lagoons and estuaries, where the migratory propensities of genetically improved fish can be curbed, and where fertilization of the water with essential nutrients is accomplished by artificially induced upwelling or by direct introduction, and where both nutrients and fish can be retained.

In shallow waters, rice paddies, or estuaries, the autotrophic (plants) and heterotrophic (animal) layers are in close contact. In the sea, the autotrophs are small and the heterotrophs are large, whereas on land, the autotrophs are large (trees) and the heterotrophs are small. Organic detritus is the chief link between these levels of primary and secondary productivity, rather than a grazing food chain as on land. Although these productive areas may be less stable than the land, the advantages in such a detritus food chain is that microbial manipulations can be used to produce protein, which is available as food. Thus, an estuary has food all the time for its populations.

Certain steps in the food chain of the sea can be circumvented to increase the ultimate yield by a factor of 6 to 10 for each step circumvented. A filter-feeding creature, like a mussel, clam, or oyster, can aggregate phytoplankton in one step into protein. Instead of moving uneconomically large masses of water to extract the plankton, efficient creatures can be used to concentrate the plankton wherever the natural movement of the water is sufficient to keep replenishing the plankton food supply. The concentration of plankton by natural advection is important in many places in the sea — at boundaries between current systems and around islands and shoals — and this can be a highly efficient concentrating mechanism. It can increase the local supply of plankton by a factor of 50 or more over the basic productivity of the contributing water.

Introduction of New Species. Closely allied to the technology of aquaculture is the introduction of new species. Reasons for introducing "new" species into a region include the market for a given species that may have to be imported from distant places to the establishment of a new industry and thus bolster the regional economy. In an excellent summary of the introduction of exotic species in aquaculture, Mann (1979) cites a number of examples, including (1) introduction of the Japanese oyster to the Pacific coast of North America and to France; and (2) introduction of the *Tilapia mossambica* (Fig. 4), a native freshwater fish of Africa, to a number of countries, including Indonesia, Malaysia, Hong Kong, the Philippines, Vietnam, Cambodia, Laos, Taiwan, and China. The latter introduction was so successful that the fish is now one of the most important pond-cultured fish in southeast Asia. Infrequently, introductions of species can produce catastrophic instead of beneficial results and thus much trial and experimentation must go into planning such ventures. To date, as mentioned by Mann, the most disastrous introductions have occurred in terrestrial systems — rabbits in Australia, Dutch elm disease in the United States, European rats in the Pacific islands, and the giant snail, which has spread from West Africa throughout much of Asia. Guidelines for future introductions of aquatic species are being worked out by a number of organizations, including the International Council for the Exploration of the Sea (ICES).

Major Aquaculture Ventures in the United States. *Salmon*. Historically, the domestic cultivation of salmon in the Pacific Northwest has been a major aquaculture venture in the United States. Much technical attention has been directed toward maintaining salmon productivity. A new turn was taken in late 1970, when a pilot project was commenced to evaluate the rearing of Pacific salmon under captive conditions. With the cooperation of the National Marine Fisheries Service (NMFS), a joint government-industry[1] pilot program was initiated. Farms are located in the Puget Sound area of Washington. They involve two freshwater sites and two saltwater sites which sit across from each other at Manchester and Bainbridge Island, Washington.

The Pacific coho salmon is an anadromous fish. It spends its early life cycle within freshwater and is not transported into saltwater until it possesses the physiological ability to osmoregulate within the saltwater environment. At this time, the coho salmon from a morphological standpoint has also lost its vertical or parr marks and has obtained a silvery coat, which represents the deposition of guanine and hypoxanthine.

The coho salmon spends the following 6 to 12 months in saltwater, developing to approximately 340 grams. At this time, the salmon may be harvested as a pan-sized fish, or permitted to mature. If allowed to mature, these salmon then become brood stock, are spawned directly from saltwater, and are utilized as a source of future progeny. The new season commences with the return of the adult salmon to freshwater to spawn. The coho orient against the most rapidly flowing portion of a stream and will readily enter a box-like trap wherein they are captured and retained until sufficient quantities are obtained for spawning. See also **Salmon**.

In the process, once sufficient coho salmon have been gathered within the trap, they are checked for maturity, killed, and segregated by sex, body size, and conformation. Eggs are then removed from the two ovarian sacs of the female. Milt previously artificially stripped from male coho salmon and collected within a bucket immediately contacts the micropore of the egg and enters. After fertilization, water is added to the bucket, and the excess milt is washed away and the eggs are permitted to "harden" prior to movement into the hatchery.

The eggs then are incubated. Healthy eggs under incubation are normally pink to reddish-orange and somewhat transparent. Inspections are frequently made and dead eggs are removed to prevent fungal growth. Three weeks after hatching the small coho fry will have absorbed their yolk sacs and are ready for placement within freshwater pools. They remain there until they have the physiological capacity to undergo smoltification, that is, the ability to osmoregulate in saltwater. The young salmon are vaccinated and transferred to saltwater rearing pens. Throughout the history of the pilot project, bag-type net pens supported by flotation have been a key element in the salmon-culturing program. The present net pen system can produce over 660,000 pounds (300,000 kilograms) of protein annually. To feed the salmon a total of seven feedstorage bins are servicing sites and can store approximately 300,000 pounds (136,000 kilograms). The saltwater diets are formulated by linear programming techniques.

Catfish. One of the more recent ventures in aquaculture in the United States has been that of catfish farming.

Catfish farmers use ponds, raceways, or cages. Three species of catfish are produced — the *channel catfish* (*Ictalurus punctatus*), the most common species raised; the *blue catfish* (*I. furcatus*), sometimes confused with the *channel catfish*; and the *white catfish* (*I. catus*). There are also bullheads (*Ictalurus* sp.), which are more difficult to manage and they often overpopulate ponds and can be quite troublesome, as well as bringing lower prices.

AQUAMARINE. A form of the gem beryl. See **Beryl**.

AQUA REGIA. Also known as nitrohydrochloric acid, aqua regia is made up of three parts hydrochloric acid and one part nitric acid, each of the usual concentrated laboratory form. Aqua regia will dissolve all metals except silver. The latter is converted to silver chloride. The reaction of metals with nitrohydrochloric acid typically involves oxidation of the metal to a metallic ion and the reduction of the nitric acid to nitric oxide. Aqua regia also dissolves the common oxides and hydroxides of metals with the exception of silver, the ignited oxides of tin, aluminum, chromium, and iron, and the higher oxides of lead, cobalt, nickel, and manganese, the latter dissolving effectively in hydrochloric acid alone.

AQUARIUS MISSION. See **Earth Observing System (EOS); and Earth System Science Pathfinder (ESSP) Program**.

AQUARIUS (the water bearer). A relatively large constellation, important solely because it is the eleventh sign of the zodiac. It contains no bright or particularly striking features. There is a theory that this constellation received its name because it appears over the Euphrates valley during that region's rainy season.

AQUEDUCT. An artificial conduit built to carry water is called an aqueduct. Generally speaking, aqueducts are built to convey a fresh water supply to congested districts from suitable sources more or less distant, and are therefore peculiar to cities. The first settlers in a place may depend upon local springs, streams, and wells, but with the growth of population there comes a time when these will prove inadequate, and suitable distant water supplies may have to be trapped through the medium of the aqueduct. An aqueduct may be either a pressure or grade-line type. Pressure conduits are commonly employed for small capacities or adverse topography, open or grade-line conduits for large capacity or favorable topography. Circumstances may require both types on the same project as the most economical combination. Pressure tunnels can convey water at pressures considerably above atmospheric, and are constructed with curved cross-sections. They are most frequently found in tunnel sections cut through hills and mountains, and in siphons. The principal distinguishing hydraulic characteristic of the pressure aqueduct is that it may depart from the normal open flow line both above and below the normal hydraulic gradient. However, siphon action, for sections above the hydraulic gradient, should be avoided wherever possible. Grade-line sections of aqueducts are usually built with open cut and fill construction following a hydraulic grade-line which will yield the requisite flow in the aqueduct at approximately atmospheric pressure, i.e., the fall per mile being just sufficient to overcome the friction loss in the same distance.

Some of the most important of the ancient aqueducts, those supplying the city of Rome, included the Marcian, with a length of 58 miles (93 kilometers), the Julian, a length of 17 miles (27 kilometers), and the Claudian, with a length of 43 miles (69 kilometers). These were high level aqueducts of the grade-line type, principally cut and fill where possible, with grade-line tunnels for piercing hills, and resting on multiple arches when spanning valleys. These older aqueducts rarely had cross-sections

[1] Source: Union Carbide Corporation.

greater than 30 sq. ft (2.8 sq. meters) in area. The Catskill aqueduct which conveys the water of the Ashokan Reservoir to the City of New York, approximately 100 miles (160 kilometers) away, has a capacity of 500,000,000 gallons (18,925,000 hectoliters) a day and is a splendid example of modern engineering on a large scale. It has in places cross-sections greater than 150 sq. ft. (14 sq. meters) in area, inverted siphons, one going more than 1000 feet (300 meters) below sea level, as well as a score of tunnels.

Irrigation projects throughout the world have required aqueducts and other kinds of waterways to transport immense quantities of water over long distances. The California Water Plan, originally put in place over a half-century ago and comprising a system of dams and waterways, is admired by agricultural and hydrological engineers worldwide.

AQUICLUDE. See **Meteorology**.

AQUIFER. See **Hydrology**.

AQUIFERS. An aquifer is a geologic formation or geologic unit from which significant amounts of groundwater can be pumped for domestic, municipal, or agricultural uses. The four major types of rock formations that serve as aquifers are unconsolidated sand and gravel, sandstone, carbonate rocks, and fractured volcanic rocks. Aquifers may also occur in other geologic formations, particularly in fractured zones of igneous, metamorphic, or sedimentary rocks.

Origin

The word aquifer was probably adopted around the early twentieth century from the French word aquifère, which originates from the two Latin words aqua (water) and ferre (to carry, to bear). Hence, literally translated from Latin, aquifer means 'that which carries water.'

Further Definitions

There is no strict definition of the hydrogeologic attributes or volumetric extent necessary to make a geologic formation or geologic unit an aquifer. Rather, the term aquifer is used for local formations that have relatively higher permeability than surrounding formations. Geologic units that form an aquifer in one setting may therefore not be considered to constitute an aquifer in other settings. For example, a small intermontane valley aquifer that consists of very shallow, sandy loam deposits a few feet thick may supply enough water to maintain a pumping rate of 0.5–2 gallons per minute (1.9–7.6 liters per minute), enough for domestic water supply wells and some stock supply wells. This may be significantly more water than would be provided by the hardrock formations underlying and bounding such a shallow aquifer. In contrast, the same sandy loam deposits of the same thickness would not be considered an aquifer if they were part of an unconsolidated sedimentary sequence in a larger alluvial basin, where gravel and sand aquifers yield from 50 to more than 1,000 gallons per minute (189 to more than 3,785 liters per minute).

Role of an Aquifer in the Hydrologic Cycle

Aquifers are part of the hydrologic cycle. They receive water through

- recharge from precipitation,
- recharge from irrigation return water,
- seepage from rivers and streams,
- lateral transfer of water from neighboring aquifer basins, and
- leakage from aquifer formations situated either above or below the aquifer.

Water that collects in aquifers from those sources over periods of years, decades, centuries, and even millennia is discharged back to the surface through (Fig. 1).

- springs,
- subsurface discharge into rivers and streams,
- lateral outflow to downgradient aquifers,
- vertical leakage to overlying or underlying aquifers, and
- man-made wells.

Limitation to Formations with Appropriate Water Quality

The term aquifer is applied to formations that produce low to moderate salinity water (appropriate for domestic, municipal, or agricultural uses). Geologic formations containing exclusively brackish or saline groundwater (even if they are made of highly permeable material) are typically not referred to as aquifers unless the salinity was induced through human activity (e.g., in seawater intrusion, which is the advance of saline seawater into an overpumped aquifer).

Aquifer Size

Aquifers can be vastly different in size: a small local aquifer in a mountainous setting may be only a few feet thick and extend over an area of a few acres to tens of acres. Other aquifers span entire regions. For example, the Ogallala aquifer in the western-central United States underlies most of the High Plains region, which extends eastward from the Rocky Mountains through parts of Texas, Oklahoma, Colorado, Kansas, and Nebraska. The aquifer consists of alluvial sediments, predominantly sands and gravel. It is an important production aquifer.

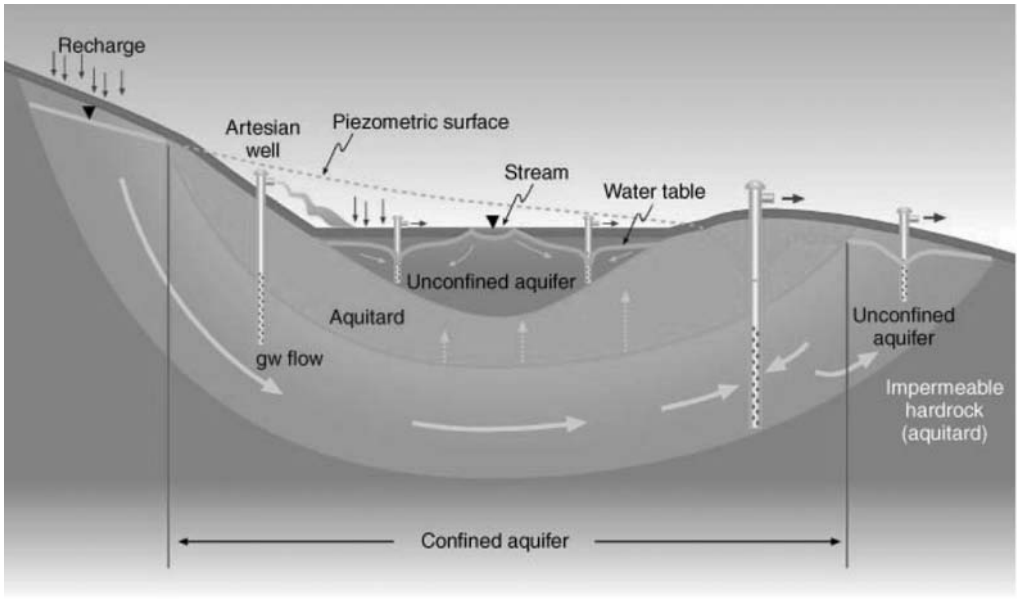

Fig. 1. Schematic representation of uncontinued aquifers, confined aquifers, aquitards, and aquicludes. Blade vertical arrows indicate recharge. Black jorizontal arrows indicate pumping. Light colored arrows indicate the direction of groundwater movement.

An aquifer is characterized by its geologic extent (regional extent and thickness), the type of geologic formations that makes up the aquifer, the hydraulic conductivity, the transmissivity (which is defined as the product of hydraulic conductivity and aquifer thickness), the specific yield (the drainable porosity), the specific storage (the amount of water and rock compressed by hydrostatic pressure in a confined aquifer, see below), and the specific capacity (specific capacity is the amount of water pumped from a well per foot of water level drawdown created by pumping). The hydraulic conductivity of aquifers typically ranges from 1 m/day to more than 100 m/day. The specific capacity of wells located in aquifers may range from less than 0.1 gpm/ft (small, low-yielding aquifers suitable for domestic water supplies) to more than 100 gpm/ft (large production aquifers suitable for municipal and irrigation pumping).

Aquifer Characterization

The amount of water that can be pumped from an aquifer depends primarily on four parameters: the hydraulic conductivity (also called the permeability) of the aquifer, the thickness of the aquifer, the specific yield or specific storage of the aquifer (related mostly to its porosity), and the amount of competition for water between wells. All four of these may change from location to location. The amount of pumping wells and the rate at which wells are pumping may be different from area to area; the thickness of the aquifer naturally changes with the thickness of the geologic formation. With respect to hydraulic conductivity, porosity, and specific yield or specific storage, hydrogeologists have found that small variations that occur in the geologic composition of aquifer formations often result in large localized changes in hydraulic conductivity. This latter phenomenon is referred to as "natural aquifer heterogeneity." As a result of all this variability, each well within the same aquifer will have a different specific capacity. Sometimes, the specific capacity of wells can vary quite significantly from well to well, especially in fractured rock aquifers, but also in unconsolidated aquifers with sand and gravel.

Hydraulic conductivity, thickness, and specific yield or specific storage of an aquifer are determined indirectly by using literature values available for specific geologic formations, by using computer models in conjunction with local observations of groundwater fluxes or groundwater table fluctuations, or directly by performing an aquifer test (pumping test).

Aquifers, Aquitards, and Aquicludes

Aquifers are the major hydrogeologic units within the hydrogeologic framework of a region from which groundwater is or can be extracted. The description of local or regional hydrogeology centers around the description of aquifers, that is, of those geologic formations with the highest significance — locally or regionally — with respect to (potential) groundwater production. Geologic formations that bound aquifers are referred to as aquicludes or aquitards. Aquicludes are, for all practical purposes, impermeable. Important aquicludes are thick, continuous clay formations and unfractured igneous rocks. Aquitards are geologic formations that have a lower hydraulic conductivity than adjacent (aquifer) formations and therefore act as a partial barrier to groundwater flow between overlying aquifers. Aquitards can consist of material similar to aquifers, but either the amount of fine sediments is much larger (in unconsolidated formations) relative to the aquifer formation, or the degree of fracturing and size of fractures is smaller than that in the aquifer formation (in hardrock formations).

Confined and Unconfined Aquifers

Aquifers can be either unconfined or confined, depending on the existence of an overlying aquitard or aquiclude. In an unconfined aquifer, there is no overlying aquitard or aquiclude. Recharge to the aquifer from the land surface or from and to streams is not restricted. The water table moves freely up and down, depending on the water stored, added to, or removed from the unconfined aquifer. The water level in a borehole drilled into an unconfined aquifer will be the same as the water level in the aquifer (if we ignore the effects of the capillary fringe).

In a confined aquifer, on the other hand, water is "sandwiched" between two aquitards or between an aquitard and an aquiclude above and below the aquifer. Water in a confined aquifer is under hydrostatic pressure created by the weight of the overlying geologic formations and the water pressure created by the higher water levels in the usually remote recharge area of a confined aquifer. Due to the pressure in confined aquifer, the water level in a borehole drilled into a confined aquifer will rise significantly above the top of the aquifer. An artesian well occurs where the pressure is so large that the water level in a well drilled into the confined aquifer rises above the land surface. A confined aquifer does not have a water table — it is completely filled with groundwater. The water level in wells drilled into a confined aquifer, instead, corresponds to the hydrostatic pressure head or potentiometric surface of the aquifer, which is located higher than the upper boundary of the aquifer itself. If the hydrostatic pressure head falls below the top of the confined aquifer, it becomes unconfined.

An aquifer that is confined by an aquitard rather than an aquiclude is referred to as a "leaky aquifer" or a "semiconfined aquifer." The aquitard is not always a contiguous layer of less permeable material. Local accumulations of multiple, smaller clay lenses and other clay-rich or otherwise impermeable layers dispersed within a more permeable formation may render the entire formation an aquitard. The actual low permeable lenses are not contiguous, but the overall effect of their presence within such a heterogeneous formation on the regional aquifer below is identical to that of a continuous aquitard formation.

Perched Water Table

Occasionally, water collects above an impermeable or low permeability layer within the unsaturated (aerated) zone and forms a "perched" water table. By definition, a "perched" water table is a saturated groundwater zone separated from the aquifer below by a zone that is unsaturated or aerated. This should not be confused with an unconfined shallow aquifer that is separated from a deeper confined aquifer through thick but saturated layers of clay.

AQUILA (the eagle). A constellation lying in the Milky Way, and hence containing rich star fields when viewed with a low-powered telescope. The distinguishing feature of this constellation is the group of three stars almost in a straight line, with the bright star Altair (α Aquila) between two fainter ones. Several novae have appeared in this constellation, the most famous one being Nova Aquilae III of 1918. See map accompanying entry on **Constellations**.

ARACHIDIC ACID. [CAS: 506-30-9] Also known as eicosanoic acid, formula $CH_3(CH_2)_{18}COOH$. A widely distributed, but minor, component of the fats of certain edible vegetable oils. Shining, white crystalline leaflets; soluble in ether, slightly soluble in water. Sp gr, 0.8240 (100/4 °C); mp 75.4 °C; bp 205 °C (1 millimeter pressure). Decomposes at 328 °C. Commercial product derived from groundnut (peanut) oil. Used in organic synthesis, lubricating greases, waxes, and plastics. Source of arachidyl alcohol. See also **Vegetable Oils (Edible)**.

ARACHNIDA. A class of the phylum *Arthropoda* including the spiders, mites, ticks, scorpions, pseudoscorpions, whip scorpions, sun spiders and harvestmen. Next to the insects this class is probably the best known among the invertebrates.

Arachnids differ from other members of the phylum in one or more of the following characteristics: (1) the body is usually divided into two regions, a cephalothorax and abdomen; (2) only simple eyes are present; (3) there are no antennae; (4) the thorax bears four pairs of legs in the adult; (5) the abdomen is often unsegmented and bears no appendages; (6) the first pair of appendages are chelate grasping organs, and/or (7) respiration is carried on by tracheae or lung-books. Several arachnids and related forms are shown in Fig. 1.

Arachnids are almost exclusively terrestrial and are predominantly predacious or parasitic, although some of the mites are plant feeders and the harvestmen include vegetable materials among their food.

The development of poison glands is fairly general in the group. Spiders have such glands, opening in the jaws or chelicerae, and scorpions have a special sting at the tip of the abdomen. With the exception of the black-widow spider of the United States and a small scorpion found near Durango, the poison is not known to be harmful to man. There is some

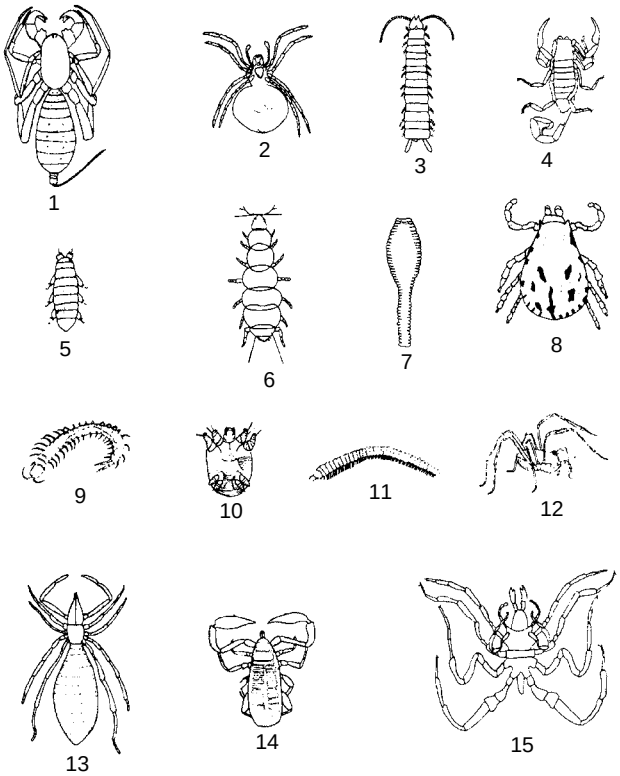

Fig. 1. Arachnids and related forms: (1) Whip scorpion; (2) female black widow spider, *Latrodectus*, ventral view; (3) symphylid; (4) scorpion; (5) tardigrade or water bear; (6) pauropod; (7) linguatulid or tongue worm; (8) tick, *Dermacentor*; (9) centipede; (10) itch mite, *Sarcoptes*; (11) millipede; (12) opilionid; (13) solpugid; (14) pseudoscorpion; (15) pycnogonid or sea spider.

probability that these two species may sometimes inflict wounds that are fatal if untreated.

The secretion of silk by spiders is another salient feature of the group. Silk glands are located in the abdomen, discharging through a group of spinnerets near the posterior end of the body. The silk is used to build webs of various forms for snaring prey, for the construction of cocoons to receive the eggs, as a lining for burrows, and in some cases as a vehicle to carry the animal on currents of air.

The economic importance of arachnids is rather limited. Spider silk has been woven but it is too delicate for extensive use and is valuable only as a source of cross-hairs for optical instruments. Aside from the poisons mentioned above, the principal harm from these animals is derived from the mites and ticks. The ticks do some damage to humans and domestic animals by sucking blood but their greatest damage is due to the transmission of diseases. Texas fever of cattle, Rocky Mountain spotted fever of humans, and other diseases are so conveyed. Mites living in the hair follicles, the sebaceous glands, and the tissues of the skin cause such diseases as scab in sheep and itch in humans. Plant-feeding species of economic importance include the bulb mite, the pear blister mite and various gall mites.

The classification of the arachnids is briefly as follows:

Order *Scorpionida*. The scorpions. Abdomen divided into a pre-abdomen and a slender post-abdomen bearing a claw-like sting at the tip.
Order *Pedipalpi*. The whip-scorpions. Anterior pair of legs slender and antenna-like.
Order *Solpugida*. The sun spiders. Head and thorax separate.
Order *Chelonethida*. Pseudoscorpions. Very small scorpion-like animals; no post-abdomen or sting.
Order *Phalangida*. Harvestmen or daddy longlegs; commonly regarded as spiders but have a segmented abdomen broadly joined to the thorax.
Order *Araneina*. Spiders. Abdomen unsegmented and joined to the thorax by a slender waist.
Order *Acarina*. Mites and ticks. Small to moderate species with a sac-like body showing no well-marked divisions.

ARAGO DISTANCE. See **Meteorology**.

ARAGO, FRANCOIS (1786–1853). Arago was born in Estagel in the Pyrenees. He went to France's Ecole Polytechnique in Paris. After his studies, he went to Spain to work on completing the measurement of a section of a meridian for the French Bureau of Longitudes. When he returned to France, he became a professor of geometry and geodesy at the Ecole Polytechnique.

Arago began his university career by giving lectures on astronomy. However, one of his best contributions to science was his lecturing about scientific discoveries. Over the years, Arago also gained a reputation for developing tools for studying the nature of light, especially for his invention of a polariscope.

With Andre-Marie Ampere, Arago discovered the magnetic field of force around an electric wire and together they invented the solenoid. Later, Faraday used Arago's research to develop the idea of induction.

J. M. I.

ARAGONITE. The mineral aragonite is calcium carbonate, $CaCO_3$, chemically identical with calcite but crystallizing in the orthorhombic system, with acicular crystals. By repeated twinning, pseudo-hexagonal forms result. Aragonite may be columnar or fibrous, occasionally in branching stalactitic forms called flosferri (flowers of iron) from their association with the ores at the Carinthian iron mines. Its hardness is 3.5–4; specific gravity, 2.93–2.95; luster, vitreous to resinous; colors, white, gray, green-yellow or purple; transparent to translucent. Aragonite forms at temperatures of 80–100 °C and is relatively unstable at ordinary temperatures and pressures. It alters to calcite, although very slowly. There are many localities for aragonite in Europe, Bolivia, Pennsylvania, Iowa, Missouri, South Dakota, New Mexico, Arizona and Colorado. Its name is derived from Aragon in Spain. See also **Calcite**.

ARAGO POINT. See **Meteorology**.

ARAUCARIAS. Trees of the family *Araucariaceae*, sometimes referred to as the Chile pine family or Pacific pines. These are evergreen trees of usually large size and heights ranging from 80 to 200 feet (24 to 60 meters) for adult trees. Their leaves are oval, leathery, and spirally arranged. The cones are round or oval. They are most unusual trees of the Southern hemisphere. The Chile pine or monkey puzzle tree (*Araucaria araucana*) rises to a height of about 80 feet (24 meters). The leaves are long, pointed, triangularly shaped and of a yellow-green color. The tree is apparently immune to known diseases and can tolerate all but the wettest or driest of soils. A group of these trees tends to purvey the appearance of a quickly assembled Hollywood set for a jungle movie. The Parana pine or candelabra tree (*A. angustifolia*) is found in southern Brazil and rises to a height of about 110 feet (33 meters). It displays a limited number of branches, has a flat crown, and long hanging branchlets. The leaves possess curved spiny tips and are scaly. The bunya-bunya tree (*A. bidwillii*) occurs in Queensland and attains a height of 150 feet (45 meters). The cones are large, up to 12 inches (30 centimeters) in length. The Norfolk Island pine (*A. excelsa*) rises to a height between 150 and 200 feet (45 and 60 meters). The leaves are small, usually overlapping on older shoots. The cones range from 3 to 4 inches (7.5 to 10 centimeters) in length and are about as broad.

It is postulated by some that a bridge between the aforementioned and most unusual trees and the Giant Sequoias is filled by the Chinese fir (*Cunninghamia lanceolata*) on the one hand and by the cryptomerias or Japanese cedars. The Chinese fir occurs in central and southern China and is a large, spreading, and weeping evergreen that rises to a height of about 150 feet (45 meters). The crytomerias are of several species, including the aforementioned Japanese cedar (*Cryptomeria japonica*), which is a narrow, conical tree (older trees are dome-topped) and rises to a height of about 150 feet (45 meters). The Chinese fir is an important timber tree in China, as is the cryptomeria in Japan.

In the United States, the champion araucaria selected by the American Forests is located in Honolulu, Hawaii. It is a Cunningham (*A. cunninghamii*) tree with the following dimensions: circumference at $4\frac{1}{2}$ ft (1.4 meters) above ground level of 189 in (4.8 meters); and a height of 120 ft (36.6 meters).

ARBER, WERNER (1929–). Werner was born at Gränichen, Switzerland. He studied physics and chemistry at the Eidgenössische Technische Hochschule in Zurich, where he graduated in 1953 with a diploma in

nuclear physics. He then worked on electron microscopy in the biophysics laboratory at the University of Geneva, where he took his doctorate on the phage lambda in 1958. After further studies in genetics and microbiology at the universities of Southern California, Naples and Geneva, he returned to Switzerland in 1971 as Director of the Biocentre at the University of Basel.

Research in the 1960s on radiation damage to cells led Arber and others to realize that some bacteria defended themselves against viruses by using specific 'restriction' enzymes that cut viral DNA into fragments. It followed that these bacteria must somehow simultaneously protect their own DNA from destruction, and Arber showed that this was done by attaching protective enzymes containing methyl groups. These discoveries led Arber to deduce that DNA contains special sites to which restriction and protective enzymes attach, and his assumption was proved experimentally at Johns Hopkins University by the Americans Hamilton Smith and Daniel Nathans. It was quickly realized that DNA fragments could be used to determine the exact sequence of nucleotides in the DNA chain. Arber's work helped to lay the foundations of genetic engineering. He shared the 1978 Nobel Prize in Physiology or Medicine with Nathans and Smith for their joint discovery of the restriction enzymes and their practical application in molecular genetics. His later work has concerned the exchange of genetic materials between organisms. See also **Nathans, Daniel (1928–1999);** and **Smith, Hamilton Othanel (1931–)**.

ARBOR. A shaft or stud, usually cylindrical or conical, on which a cutting tool, a tool holder, or a part to be machined is mounted or held.

ARBORVITAE. Trees and shrubs of the genus *Thuja*, family *Cupressaceae* (cypress family). The thujas include the large eastern white cedar (*Thuja occidentalis*) and the western red cedar (*T. plicata*). Although *T. occidentalis* can attain heights in excess of 100 feet (30 meters), the tree is frequently used in landscape planning and for hedgerows. The leaves are bright green, having overlapping scales. The cones are quite small. The natural range of the species is from southern Labrador to Nova Scotia, and west into Manitoba and Minnesota, and ranging south into Pennsylvania and following the mountains into North Carolina and eastern Tennessee. Specimens in the south are considerably smaller and may be described as small trees or shrubs. The species is quite common in northern New England. Asian thujas include the Japanese arborvitae (*T. standishii*), rare outside of Japan, and the Chinese thuja (*T. orientalis*), a small, often multistemmed tree. The *T. plicata*, also known as the zebra-striped western red cedar, is also used extensively as an ornamental tree.

In the United States, the champion arborvitae selected by the American Forests located in Maryland. It is an oriental (*T. orientalis*) or Chinese thuja with the following dimensions: Circumference at $4\frac{1}{2}$ ft (1.4 meters) above ground level of 100 in (2.5 meters); a height of 59 ft (18 meters); and a spread of 14 ft (4.3 meters).

ARC BACK. This is the occurrence of an arc from anode to cathode in a gaseous rectifier tube. Normally, such a tube has electrons flowing from the cathode to the anode, but under certain conditions excessive heating of the anode, excessive voltage across the tube, or other effects may cause the anode to emit electrons and allow an arc discharge to take place in a direction opposite to the normal direction. Under many circuit conditions this may destroy the tube or it may merely open the protective devices.

ARC CUTTING. Cutting of metal by means of an arc formed between the metal and an electrode. See also arc welding under **Welding**.

ARC (Electrical). A low-voltage, high-current electrical discharge, as contrasted with a spark. The electric arc, so called because of the shape of the "flame," was discovered by Davy about 1808. It is a type of discharge between electrodes in a gas or vapor and is characterized by a relatively low voltage drop and a high current density. The two types of considerable practical importance are the arc in open air and the arc in gases at low pressure. The familiar carbon-arc and the electric-arc furnace are examples of the former. In this type the arc is started by impressing a voltage across the electrodes in contact and then separating them. At the instant of breaking contact the high field and current density initiate the arc. Thereafter, if the current is kept constant, the potential necessary is a linear function of the inter-electrode distance. In its steady state, the arc has an intensely hot cathode, which emits a plentiful supply of electrons. The energy for heating the cathode is obtained from the high current density and from the bombarding positive ions. The arc is thus apparently a thermionic phenomenon. If the carbons are impregnated with a volatile metallic salt, the result is a "flaming arc," useful in producing the arc spectrum of the metal. If a dc carbon arc is placed in parallel with a suitable condenser and an inductance, the circuit so formed may be made to oscillate, as discovered by Duddell, and to serve as a source of undamped electric waves.

The arc is one of the most serious problems in switching electrical circuits, since the separation of the switch or circuit breaker contacts establishes an arc which must be extinguished in order to break the circuit. Many schemes have been developed to accomplish this. See **Circuit Breaker**; and **Electrical Ground Fault Circuit Interrupters (GFCI)**.

The mercury-arc tube is the most important example of an arc in a gas at low pressure. Here the gas is the mercury vapor, the cathode is the mercury pool, and the anode is usually carbon. The arc is initiated by breaking contact between the mercury pool and a starting electrode. In gases at low pressure an arc may be established without breaking contact between the electrodes if the impressed voltage is high enough. If the voltage impressed across the two electrodes separated by a low-pressure gas is gradually increased the current increases slowly at first due to the residual ions and electrons present in the gas. The electrons ionize the gas molecules upon colliding with them, thus giving rise to additional ions and electrons to carry the current and also to produce more ionization by collision. This process continues until suddenly the breakdown voltage is reached, when the current increases very rapidly, even if the voltage is lowered. This is the initiation of the glow discharge. If the circuit resistance does not limit the current the discharge progresses almost instantaneously into an arc discharge having the distinguishing features of the regular arc. The discharge in thyratrons and other gas-filled hot cathode tubes is often called an artificial arc discharge since it is characterized by low voltage and high current density. It is not a true arc however since the cathode heat energy is supplied by an external source and not by the discharge itself.

ARC FURNACE. A furnace heated by an electric arc. The arc may be formed either between an electrode and the metal charge to be heated, or between several arcs placed over the charge.

ARC (Geometry). See **Circle (Geometry)**.

ARCH. An arch is a curved beam or truss made of wood, masonry, concrete or steel, whose supports are able to exert lateral as well as vertical forces to resist the action of any applied loads. These lateral forces are in the nature of thrusts that act inwardly toward the center of the arch span. The curvature of the beam must be in an upward direction in order to develop lateral reaction forces which will act in the required direction. The highest point of the arch is called the crown. The juncture of the arch and its foundation is called the springing.

In an arch, loads induce both bending and direct compressive stress. Although all loads are vertical, arch reactions possess horizontal components. Also, deflections have both horizontal and vertical components.

The masonry arch was used by the Egyptians, Babylonians, Assyrians, and Greeks but received full expression in the bridges and buildings of the Romans. Such arches depended upon the compressive thrust of adjacent blocks, or *vissoirs*, for their stability. That is, the line of pressure, or pressure line, had the same shape as the arch. Under the heavy moving loads of today the pressure line can depart appreciably from the arch axis and thus large tensile forces due to bending can be developed. Masonry is unsuited for such conditions and it is necessary to use reinforced concrete or steel arches. Steel arches are of the solid-rib or trussed type.

These structures may be further classified as fixed or hinged arches. A fixed arch is a structure rigidly connected to its supports in such a manner that they exert vertical and lateral reactions and prevent rotation. A two-hinged arch is one that is free to rotate about its supports, consequently it is able to exert only vertical and lateral reactions. Three-hinged arches have an additional hinge, usually midway between the hinges at the supports. The tied arch is a structure in which the lateral forces are applied by means of a horizontal tension member connecting the ends of the arch.

From the standpoint of structure, an arch is similar to a rigid frame. See Fig. 1. Arches are not commonly precast because stacking for transportation is difficult due to the curvature. However, small spans cast at the site have been used successfully. Prestressing seldom is advantageous because arches are subjected to large compressive forces.

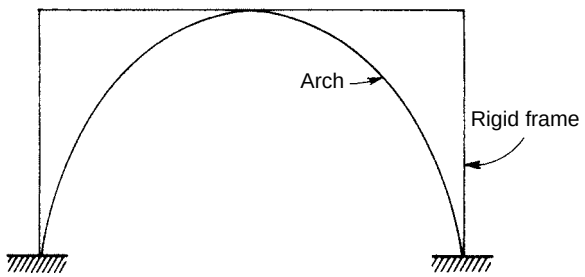

Fig. 1. Comparison of arch with rigid frame.

Arches are frequently used for very long spans and support roofs of such structures as auditoriums, exhibition halls, hangars, stadiums, sporting arenas, and transportation terminals. Typical arch bridges are shown under **Bridge (Structural)**.

One of the most interesting arches is the 630-foot (192-meter) high Gateway Arch, made of stainless steel, situated in downtown St. Louis, Missouri. This catenary arch was designed by Eero Saarinen and is the tallest monument in the United States. See Fig. 2.

Fig. 2. Gateway Arch in Saint Louis, Missouri. Structure is 630 feet (192 meters) high.

ARCHAEA. See **Bacteriology; and Microbiology**.

ARCHAOMETRY. Application of chemical and physical analytical methods to archaeology. Among those used are microanalytical methods, spectroscopic analysis, X-ray, and other types of nondestructive tests. For age determination ^{14}C measurement (chemical dating) is one of the most valuable techniques.

ARCHED SQUALL. See **Meteorology**.

ARCHEGONIATES. Those plants in which the female sex organ is an archegonium are sometimes called Archegoniates.

ARCHEGONIUM. The multicellular female sex organ characteristic of all the *Embryophyta* except the Angiosperms. Those plants in which the female sex organ is an archegonium are sometimes called Archegoniates. The organ consists of a swollen basal portion called the venter, and an elongated neck. The venter may be a single layer of cells, but is often many cells thick. Within the basal portion is contained the single large egg, and a second, somewhat smaller, ventral canal cell, while the elongated neck contains a single row of cells which eventually dissociate, leaving an open canal through which the sperm may pass to reach the egg.

ARCHEOCYTE. Cells of sponges that ingest and digest food, carry the products to other parts of the body, and form reproductive cells. They are amoeboid (see **Amoeba**) and are found in the mesenchyme.

ARCHEOLOGICAL DATING. See **Mass Extinctions**; and **Radioactivity**.

ARCHEOPHYTIC. A paleobotanic division of geologic time. See also **Paleobotany**.

ARCHEOZOIC (Archean). The oldest of the five eras of the earth's history. The rocks of this system are metamorphosed equivalents of all types of sedimentary and igneous rocks, but principally the latter. No undisputed fossils have been found in the Archean. The lower Archean (Keewatin) of North America is composed of a preponderance of metamorphosed, basaltic lava flows and tuffs with some metamorphosed sediments, such as quartzite and slate. The general character of the basal Archean proves that the oldest known rocks do not represent the original crust of the earth. The upper Archean (Laurentian) contains a preponderance of granite, gneisses, and schists in the form of batholiths intruding the Keewatin. The principal areas of Archeozoic rocks are in Canada, Finland, Scandinavia, Australia, Africa and northeastern South America. Many of the formations contain rich ore deposits, especially of gold and silver. Large amounts of graphite suggest the former existence of life. Length of time since the beginning of the Archeozoic is possibly more than 2500 million years. Owing to the lack of fossils, structural complexity, high degree of vulcanism and metamorphism, geologists have found great difficulty in deciphering the history of this earliest recognizable portion of the "crust" of the earth. The structural history of the Archean is therefore not so well known as that of the succeeding periods and intercontinental correlation is particularly difficult. On the other hand, the search for ore deposits has been an important stimulus to the study of the Archean formations, especially in Canada. See Fig. 1

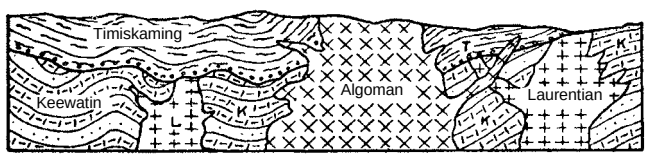

Fig. 1. A highly generalized section, about 25 miles (40 kilometers) long, showing the relations of the Archeozoic group of rocks in the Lake Superior–Lake Huron region of Canada. The Keewatin system was moderately folded and intruded by the Laurentian granite, after which there was deep erosion. Then the Timiskaming rocks were laid down, and later, were strongly folded and intruded by the Algoman granite, after which there was another period of profound erosion, marked by the upper surface.

ARCHIANNELIDA. A class of annelid worms, including small marine species of simple structure.

ARCHIMEDES SPIRAL. A special case of a spiral, represented in polar coordinates by $r = a\theta$. It may be described as the locus of a point moving with uniform velocity along the radius vector, while the radius vector also moves about the pole with constant angular velocity. The evolute of this spiral approaches asymptotically to a circle with radius a. See also **Hyperbolic Spiral**.

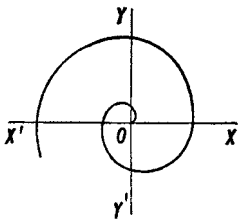

Fig. 1. Spiral of Archimedes.

ARCHIMEDES'S PRINCIPLE. The statement that a net upward or buoyant force, equal in magnitude to the weight of the displaced fluid, acts upon a body either partly or wholly submerged in a fluid at rest under the influence of gravity.

This force is known as the Archimedean buoyant force (or buoyancy), is independent of the shape of the submerged body, and does not depend upon any special properties of the fluid.

ARCHITECT'S SCALE. See **Scale**.

ARC LAMP. The electric-arc lamp has, as its source of illumination, an electric arc struck between two electrodes. In contrast to the incandescent lamp, in which the illumination results from a heated filament, and vapor lamps, in which the illumination is derived from a vapor made luminous by electric current, the light from an arc lamp comes from the highly incandescent crater of one of the electrodes, and from the heated, luminous, ionized gases surrounding the arc. The light from arc lamps is very much more intense than that from the incandescent type lamp. From the standpoint of current consumption, the illumination is produced efficiently. Some arc lamps may not be operated on ac, but all types are adaptable to dc. A constant-current, series type circuit is used to operate street-light arc lamps.

Open-arc type lamps can be divided into: (1) flame arcs; (2) low-intensity projector arcs; and (3) high-intensity projector arcs. The entire arc stream is made luminescent by the addition of flame materials in the flame arc light. This type of lamp is used in photography and related industrial photochemical processes because it produces an essentially continuous radiation and closely approximates natural sunshine. A special coring of rare-earth salts is used. In a special version of the flame-arc lamp, the arc is encased in a glass globe with limited access of air, thus resulting in a nitrogen-rich atmosphere. This enhances the radiation in the violet and near-ultraviolet regions, making the lamp useful in blueprinting and related copying processes.

The incandescent tip of the positive carbon electrode, at or near its sublimation temperature, is the main light source in the low-intensity projector arc. The brightness is uniformly generated over a considerable area. This type of lamp found early use in motion picture, searchlight, and other projector systems requiring a concentrated source of light and the ability to create a well-defined narrow beam.

In the high-intensity carbon arc, rare-earth materials are included in the core of the positive electrode. These materials volatilize into the arc stream as the electrode is consumed. The light from these lamps is well suited to color motion picture photography and projection.

ARC (Mathematics). A segment or piece of a curve. See also **Circle (Geometry)**.

ARC SHOOTING. (1) A method of refraction seismic prospecting in which the variation of travel time with azimuth from a shot point is used to infer geologic structure. (2) A reflection spread placed on a circle or on an arc with the center at the shot point.

ARCTIC CIRCLE. The line of latitude 66°32′N (often taken as $66\frac{1}{2}$ °N). Along this line the sun does not set on the day of the summer solstice, about June 21 and does not rise on the day of the winter solstice, about December 22. From this line the number of annual twenty-four hour periods of continuous day or of continuous night increases northwards to about six months at the North Pole. The area north of the Arctic Circle is known as the *Arctic Zone*.

ARCTIC REGION RESEARCH. See **Polar Research**.

ARCTIC WATERS. Water masses in or associated with the Arctic Ocean, including:

Arctic Deep Water. An ocean water mass with a salinity of about 34.95% and temperature of about −0.85 °C (30.5 °F). Because of its high salinity, it is not believed that it is formed in the Arctic Ocean, but rather it is considered to be the North Atlantic Deep and Bottom Water, flowing north.

Arctic Surface Water. An oceanic water mass of low salinity, averaging from 32.0% to 33.0% in the north, but reaching very low values in summer as the rivers carrying large volumes of fresh water from melting ice decrease the salinity near the surface to values far below 30.0%. As winter approaches, the salinity increases, due to slow mixing with the Arctic Deep Water.

See also **Ocean**.

ARCTIC ZONE. Geographically, the area north of the Arctic Circle (66°32′N).

ARCTURUS *(α Bootes).* Arcturus was probably one of the first stars to be named, most likely receiving its name because of its proximity to the constellation of Ursa Major, thus being called the "watcher of the bear." It is one of the few stars named in the Bible (Job IX), although this reference is evidently to the constellation of Ursa Major rather than to the actual star itself. References to Arcturus are to be found in the writings of many of the ancient poets, including Virgil.

Arcturus is a very interesting star from the astronomical point of view, being what is known as a giant star. In appearance, it is a reddish-yellow, and the spectral type is such as to indicate that its temperature is slightly lower than that of the sun. It is one of the few stars whose diameter has actually been measured with the stellar interferometer. The diameter is about 30 times that of the sun.

Arcturus ranks fourth in apparent brightness among the stars and has a true brightness value of 110 as compared with unity for the sun. Estimated distance from the earth is 36 light years. Arcturus is classified as an orange star of spectral type K. See also **Constellations**; and **Star**.

ARCUS. See **Clouds and Cloud Formation**.

AREA. If a parallelogram has sides denoted by the vectors **A** and **B**, its area is given by the vector product, $\mathbf{C} = \mathbf{A} \times \mathbf{B}$, which is perpendicular to the plane determined by **A** and **B**. The scalar magnitude of **C** equals that of the area and the direction of **C** is arbitrarily taken as the direction of the outward normal to the surface.

In calculus, the area of a surface may be found by integration. If $y = f(x)$ describes a curve, the area bounded by the curve, the X-axis, and the ordinates (a, b) is

$$\int_a^b f(x)\,dx$$

If a surface of revolution is generated by rotating an arc of the curve about the X-axis, its area is given by the integral

$$S = 2\pi \int_a^b y\,ds$$

where $ds^2 = dx^2 + dy^2$.

Formulas for calculating the areas of major surfaces and shapes are given throughout this volume. See **Circle (Geometry)**.

AREA RULE. A prescribed method of design for obtaining minimum zero-lift drag for a given aerodynamic configuration, such as a wing-body configuration, at a given speed.

For a transonic body, the area rule is applied by subtracting from, or adding to, its cross-sectional area distribution normal to the air stream at

various stations so as to make its cross-sectional area distribution approach that of an ideal body of minimum drag; for a supersonic body, the sectional areas are frontal projections of areas intercepted by planes inclined at the Mach angle.

AREA SAMPLING. A method of sampling in which the domain to be examined is divided into small areas some of which are then selected to form the sample. Each area so selected may be fully inspected or may form the basis of sub-sampling. The method is particularly appropriate where no lists are available of the primary units that form the target population, e.g., individuals or dwelling units in developing countries. See also **Sampling (Statistics)**.

ARENACEOUS. A textural term applied to sediments or sedimentary rocks composed of grains of sand. Psammitic has the same meaning.

ARENAVIRUSES. The Arenaviridae are a family of viruses whose members are generally associated with rodent-transmitted disease in humans. Each virus usually is associated with a particular rodent host species in which it is maintained. Arenavirus infections are relatively common in humans in some areas of the world and can cause severe illnesses.

The virus particles are spherical and have an average diameter of 110–130 manometers. All are enveloped in a lipid (fat) membrane. Viewed in cross-section, they show grainy particles that are ribosomes acquired from their host cells. It is this characteristic that gave them their name, derived from the Latin "arena," which means "sandy." Their genome, or genetic material, is composed of RNA only, and although their replication strategy is not completely understood, it is known that new viral particles, called virions, are created by budding from the surface of their hosts' cells.

The first arenavirus, lymphocytic choriomeningitis virus (LCMV), was isolated in 1933 during a study of an epidemic of the St. Louis encephalitis. Although not the cause of the outbreak, LCMV was found to be a cause of aseptic (nonbacterial) meningitis. By the 1960s, several similar viruses had been discovered and they were classified into the new family Arenaviridae. Since the Tacaribe virus was found in 1956, new arenaviruses have been discovered on the average of every one to three years. A number of arenaviruses cause hemorrhagic disease. The Junin virus, isolated in 1958, was the first of these to be recognized. This virus causes Argentine hemorrhagic fever in a limited agricultural area of the pampas in Argentina. Several years later, in 1963, in the remote savannas of the Beni province of Bolivia, the Machupo virus was isolated. The next member of the virus family to be associated with an outbreak of human illness was the Lassa virus in Africa in 1969. Most recently, Guanarito and Sabia viruses were added to this family.

The arenaviruses are divided into two groups: the New World or Tacaribe complex and the Old World or LCM/Lassa complex. Viruses in these groups that cause illness in humans are listed in Table 1.

TABLE 1. ARENAVIRUSES THAT CAUSE ILLNESS IN HUMANS

Virus	Disease
Lypmhocytic choriomeningitis virus	Lymphocytic choriomeningitis
Lassa virus	Lassa fever
Junin virus	Argentine hemorrhagic fever
Machupo virus	Bolivian hemorrhagic fever
Guanarito virus	Venezuelan hemorrhagic fever
Sabia	Unnamed (found in Brazil)

These viruses are zoonotic, meaning that, in nature, they are found in animals. Each virus is associated with either one species or a few closely related rodents, which constitute the virus' natural reservoir. Tacaribe complex viruses are generally associated with the New World rats and mice (family Muridae, subfamily *Sigmodontinae*). The LCM/Lassa complex viruses are associated with the Old World rats and mice (family Muridae, subfamily *Murinae*). Taken together, these types of rodents are located across the greater proportion of the earth's land mass, including Europe, Asia, Africa, and the Americas. One notable exception is the Tacaribe virus, found in Trinidad, which was isolated from a bat.

The rodent hosts of arenaviruses are chronically infected with the viruses; however, the viruses do not appear to cause obvious illness in them. Some Old World arenaviruses appear to be passed from mother rodents to their offspring during pregnancy, and thus remain in the rodent population generation after generation. Some New World arenaviruses are transmitted among adult rodents, likely via fighting and inflicting bites. Only a portion of the rodents in each host species is infected at any one time, and in many cases only in a limited portion of the host's geographical range. The viruses are shed into the environment in the urine or droppings of their infected hosts.

Human infection with arenaviruses is incidental to the natural cycle of the viruses and occurs when an individual comes into contact with the excretions or materials contaminated with the excretions of an infected rodent, such as ingestion of contaminated food, or by direct contact of abraded or broken skin with rodent excrement. Infection can also occur by inhalation of tiny particles soiled with rodent urine or saliva (aerosol transmission). The types of incidental contact depend on the habits of both humans and rodents. For example, where the infected rodent species prefers a field habitat, human infection is associated with agricultural work. In areas where the rodent species' habitat includes human homes or other buildings, infection occurs in domestic settings.

Some arenaviruses, such as Lassa and Machupo viruses, are associated with secondary person-to-person and nosocomial (health-care setting) transmission. This occurs, when a person infected by exposure to the virus from the rodent host spreads the virus to other humans. This may occur in a variety of ways. Person-to-person transmission is associated with direct contact with the blood or other excretions, containing virus particles, of infected individuals. Airborne transmission has also been reported in connection with certain viruses. Contact with objects contaminated with these materials, such as medical equipment, is also associated with transmission. In these situations, use of protective clothing and disinfection procedures (together called barrier nursing) help prevent further spread of illness.

ARES ROCKET. See **Orion Crew Exploration Vehicle**.

ARÊTE. A narrow, jagged, serrate mountain crest, or a narrow, rocky, sharp-edged ridge or spur, commonly present above the snowline in rugged mountains (as the Swiss Alps) sculptured by glaciers, and resulting from the continued backward growth of the walls of adjoining cirques. (*Glossary of Geology*, American Geological Institute).

ARGAND DIAGRAM. A graphical method of representing a function of a complex variable, $z = x + iy$. There are two perpendicular axes, as in the usual rectangular Cartesian coordinate system. The real part of the function is plotted on the real axis, usually the horizontal one, and the imaginary part on the imaginary or vertical axis. Points on the diagram for various values of the number pair (x, y) can then be joined to give a curve for the function of the complex plane. See also **Complex Variable**.

ARGENTITE. The mineral argentite, sometimes called silver glance, is naturally occurring silver sulfide, corresponding to the formula Ag_2S. It crystallizes in the isometric system in cubes, octahedrons and dodecahedrons, or may be massive. Hardness, 2–2.5; sp gr, 7.2–7.34; luster, metallic; streak, gray; color, black, blackish-gray or gray; opaque and sectile to such an extent that it cuts like wax with a knife. Heated upon charcoal it yields a malleable mass of silver. The name is derived from the Latin word for silver, *argentum*.

Localities for fine crystals are Sonora, Mexico, and Freiberg, Saxony; in the United States, at Butte, Montana; Tonopah, Nevada; and Aspen, Colorado.

Argentite is probably the most important primary silver mineral. However, it maintains its cubic (isometric) characteristic only above 179 °C (354 °F). Upon cooling, the inward structure inverts to a non-isometric form, usually orthorhombic, yet retaining its original outward form. It is, therefore, a paramorph after argentite, known as acanthite.

ARGILLACEOUS. This term is used to designate sedimentary rocks composed of fine particles of the nature of clay or mud. Pelitic has the same meaning.

ARGILLITE. A dense, fine-grained, hard, sedimentary rock of various colors (usually white, gray or red). Composed of minute grains of both clay and quartz. Certain types of argillites are easily confused with certain types of fine-grained acid lava flows, such as felsites, unless studied microscopically.

ARGININE. See **Amino Acids**.

ARGON. [CAS: 7440-37-1] Chemical element, symbol Ar, at. no. 18, at. wt. 39.948, periodic table group 18 (inert or noble gases), mp −189.2 °C, bp −185.7 °C, density 1.78 g/cm^3 (solid at −233 °C). Solid argon has a face-centered cubic crystal structure. At standard conditions, argon is a colorless, odorless gas and does not form stable compounds with any other element. Because of its low valence forces, argon is unable to form diatomic molecules, except in discharge tubes. It does form compounds under highly favorable conditions, as excitation in discharge tubes, or pressure in the presence of a powerful dipole. As an example of the first, argon forms amorphous compounds of the type FeA in a discharge tube having iron electrodes. An example of the second is furnished by the hydrates, which argon forms with H_2O at 150 atmospheres and 0 °C. Argon forms compounds, possibly clathrates, with a number of organic substances, such as a compound with hydroquinone containing 9% argon, in which the amount of argon may vary from this proportion. The compounds are made by crystallization of the aqueous solution of the hydroquinone under argon gas pressure on the order of 40 atmospheres.

Argon occurs in the atmosphere to the extent of approximately 0.935%. In terms of abundance, argon does not appear on lists of elements in the earth's crust because it does not exist in stable compounds. However, argon is 2.5× more soluble in H_2O than nitrogen and thus is found in seawater to the extent of approximately 2800 tons per cubic mile (605 metric tons per cubic kilometer). Commercial argon is derived from air by liquefaction and fractional distillation. There are three natural isotopes, ^{36}Ar, ^{38}Ar, and ^{40}Ar, and four radioactive isotopes, ^{35}Ar,^{37} AR, ^{39}Ar, and ^{41}Ar. The lengths of half-lives of the isotopes vary widely, the shortest ^{35}Ar with a half-life of about 2 seconds; the longest ^{39}Ar with a half-life of about 260 years. The first ionization potential of Ar is 15.755 eV; second 27.76 eV; third 40.75 eV. Other important physical characteristics of argon are given under **Chemical Elements**.

The presence of argon in air was suspected by Cavendish as early as 1785, but was not positively identified until 1894 by Lord Rayleigh and Sir William Ramsay. Argon exhibits a characteristic series of lines in the red end of the spectrum. Commercially, argon gas is used in incandescent lamps and fluorescent lamps as an inert gas to minimize vaporization of the filaments and, for this, is preferable to nitrogen. The gas also is used for shielding electrodes in arc welding. A gas of about 99.995% purity is required for lamps. Argon also has found effective use in certain lasers.

Regarding argon in meteorites, see **Krypton**.

Ar Isotopes in Paleochronology. Isotopes of Ar and their ratios have proven useful in geological period dating and thus are of assistance in establishing databases for paleoclimatology and estimating periods of mass extinction on Earth. For example, major changes in Earth's climate are known to have occurred during transition between the Eocene, q.v., and Oligocene, q.v., periods. This was a major transition from the essentially tropical environment of the Mesozoic, q.v., to the start of the galacial world. This is considered the most significant climatic alteration since the prior demise of the dinosaurs. However, it has been difficult to establish the timing of prehistoric events, for lack of evidence.

Since the mid-1960s, ^{40}K–^{40}Ar dates have been used to estimate time periods in terms of Ma (millions of years), and some adjustments were made to prior estimates of the Chadronian boundary (36–32 Ma). Other isotopic data (^{40}Ar, ^{40}Ar/^{39}Ar) and Rb-Sr have been used for time estimating.

As pointed out by Swisher and Prothero (1990) relatively recent advances (1989–1990) in mass spectrometric techniques and the development of laser-fusion ^{40}Ar/^{39}Ar dating techniques have resulted in the ability to date individual volcanic crystals. Multiple analysis and the ability to date single crystals allow the identification of multiple-age components, due to detrital contamination, and thus permit improved precision and accuracy. To date, studies have been directed to North American chronology, notably minerals (biotite, anor, plag) found in Nebraska and Wyoming.

ARGONAUTA *(Mollusca, Cephalopoda).* The genus to which the paper nautilus belongs. This species is not a true nautilus but is more closely related to the octopus.

ARGUMENT. 1. An independent variable; e.g., in looking up a quantity in a table, the number or any of the numbers which identifies the location of the desired value; or in a mathematical function the variable which when a certain value is substituted for it the value of the function is determined. 2. An operand in an operation on one or more variables.

ARGYRIA. Poisoning from the use of silver preparations over too long a period or its absorption during industrial processes, causing a ghastly bluish discoloration of the skin over the entire body.

ARIDITY. The degree to which a climate lacks effective, life-promoting moisture; the opposite of humidity, in the climate sense of the term.

The overall concept of aridity versus humidity is coming to be known as precipitation effectiveness. Two basic approaches have been made. The first, used by W. Köppen and modified by Bailey, does not openly define aridity, but rather assigns delimiting values of annual precipitation (treated with regard to distribution and temperature) to separate a dry climate from other types. The second approach actually prescribes a measure of aridity or precipitation effectiveness and uses these values as a primary parameter of classification. Of this type are Thornthwaite's precipitation- effectiveness index and moisture index, E. de Martonne's index of aridity, W. Gorczyński's aridity coefficient, Lang's moisture factor, and Ångström's humidity coefficient.

ARIDITY COEFFICIENT. A function of precipitation and temperature designed by W. Gorczyński to represent the relative lack of effective moisture (the aridity) of a place.

It is given by (latitude factor) × (temperature range) × (precipitation ratio). The latitude factor is the cosecant of the latitude (taken as 3.0 for 0°–4°). The temperature range is the difference (°F) between the means of the hottest and coldest months. The precipitation ratio is the difference between the highest and lowest annual totals (adjusted to a 50-year record) divided by the average.

The value of this coefficient is about 100 in the middle of the Sahara; in the United States it ranges from 70 at Bagdad, California, to 2 at Eureka, California.

ARIDITY INDEX. See **Meteorology**.

ARIES (the ram). This constellation is far more famous for its classical significance than because of its appearance in the sky. In contains no bright stars and has no conspicuous features. Two thousand years ago, the vernal equinox was located in the constellation of Aries, and the symbol for the vernal equinox is the symbol for the constellation (i.e., the ram's head). Precession has caused the position of the vernal equinox to move backwards into the constellation of Pisces, so that now the "sign of the first of Aries" is to be found in that constellation. (See map accompanying entry on **Constellations**.)

ARIL. In many plants there is formed in the developing fruit an outgrowth from the funiculus, or seed stalk, one which completely or partially surrounds the seed. In the litchi nut it is the thick translucent pulp surrounding the seed; in the nutmeg it is a mesh-like envelope, which when removed and dried is known as mace.

ARISTOTLE (384 BC–322 BC). Aristotle is one of the world's most famous Greek philosophers and mathematicians. He is the author of the scientific system advocating science based on observation. He started his own school, the Lyceum in Athens. At his school there was emphasis on the detailed study of nature. He is known for his important works on logic. He believed logic should be applied to the study of every branch of knowledge. He is remembered for his famous Aristotelian syllogistic, a form of argument consisting of two premises and a conclusion.

J. M. I.

ARITHMETIC. The rules for combination of two or more numbers. The operations involved are addition, subtraction, multiplication, division and the results obtained are, respectively, a sum, difference, product, quotient. Two or more of these operations can be performed successively and the final number obtained is independent of the order of the intermediate steps. Arithmetic, which is the first kind of mathematics normally studied by the beginner, is essentially the art of computation and application of this art.

See also **Progression** for meaning of arithmetic series and progression.

ARITHMETIC CODING. See **Data Compression**.

ARITHMETIC MEAN. The arithmetic mean of a number of observations x_i $(i = 1 \cdot n)$ is the simple average $\Sigma\, x_i/n$. It is commonly referred to simply as the mean.

The arithmetic mean is the most generally useful measure of location. In samples from a normal distribution, the mean is an efficient, and indeed sufficient, estimate of the location parameter, though in other distributions other estimators may be preferable. If $\overline{x}$ is the mean of a sample drawn from a finite population of N members, $N\overline{x}$ is an unbiased estimate of the population total.

A useful generalization of the arithmetic mean is the weighted mean. If each observation x_i has attached to it a weight w_i the weighted mean is given by $\Sigma\, w_i x_i / \Sigma\, w_i$, observations with large weights being given greater influence. If we have a set of estimates x_i of a quantity ξ, and if the variance of x_i is σ^2/w_i with w_i known, the estimate of ξ with least variance is the weighted means of the x_i and the variance of this estimate is $\sigma^2/\Sigma\, w_i$.

ARKOSE. Arkose is a relatively coarse-grained feldspathic sandstone, derived from the rapid disintegration of granite or other feldspathic rock. It is characterized by its content of fresh, unaltered, euhedral feldspar. The term was proposed by Brongiart in 1823, and has been in constant use ever since. Arkose is an important type of sediment, especially in relation to the study of non-conformities, paleoclimatology, and "fossil" soils.

ARM. An extended lobe or appendage of a body. Its most familiar use is in application to the pectoral appendages of vertebrates when freed from the usual functions of support and locomotion, as in humans and the other primates. In anatomy, the term is restricted to the region from the shoulder to the elbow, to distinguish it from the forearm. Some species are still quadrupedal on the ground, but can use their arms to some extent for handling objects.

The radiating lobes of the starfish are called arms or rays and arm is also applied to the branches of the lophophore in brachiopods and to other special structures.

Robots are also said to have arms (also hands, wrists, etc.). See **Robots and Robotics**.

ARMATURE. The armature is one of the two essential parts of the dynamo electric machine. In a generator, the armature is the winding in which electromotive force (emf) is produced by magnetic induction. In the motor armature, conductors carry the input current which, in the presence of a magnetic field, produces a torque and effects the conversion of electrical into mechanical energy. In D.C. machines it is the rotor, but the A.C. armature may be rotor or stator. Larger size synchronous machines always have stationary armatures. The reluctance of the magnetic circuit to the flux which the conductors of the armature must cut in order to generate electric energy, is decreased by providing a core of soft iron or steel, on the surface of which the conductors are embedded in slots suitably provided in the core. The armature windings of a D.C. generator are terminated at the segments of a commutator, by means of which the alternating emf's induced in the armature are rectified and transferred by brushes from the moving rotor to stationary terminals. The conductors must be separately insulated, as must be also the commutator segments, and must be well braced and anchored in their slots to resist the electromagnetic and mechanical forces that tend to displace them.

The term armature is also applied to the moving element of a magnetically actuated relay.

ARMATURE REACTION. This term refers to the reaction of the magnetic field produced by the current flowing in the armature conductors upon the main magnetic field of a dynamo machine. The result is a distortion of the magnetic field, the extent depending upon the reluctance of the magnetic circuit, the arrangement of the armature windings, the type field structure, and the phase angle between the armature voltage and current. In D.C. machines the effect is to increase the flux at some pole tips and decrease it at others, while in A.C. machines the effect depends upon the field structure and the phase angle of the armature current and voltage. The flux may be distorted as in the D.C. machine, it may be changed in magnitude but undistorted in wave form or it may be changed in magnitude and shifted in position with respect to the field windings. Armature reaction is an important factor in the speed and voltage regulation of the machines.

ARMYWORM *(Insecta, Lepidoptera)*. An economically important caterpillar, Cirphis unipuncta, named from its habit of migrating from field to field in large numbers. When severe outbreaks occur these insects completely strip fields of grain of all kinds. When migrating they are trapped in barrier ditches dug around the fields to be protected. They are also killed by poison baits.

The true armyworm develops from a moth (*Pseudaletia unipuncta*) of the moth family *Noctuidae*. It is found in the United States and Canada, east of the Rocky Mountains. The eggs develop on the underside of leaves.

The armyworm is smooth, dark green with long white stripes extending from front to back, and often is fat and up to two inches (5 centimeters) in length.

Occurrence of the armyworm is subject to cycles, not fully understood or predictable. The insect is particularly damaging to maize (corn). In the young corn plants (8 inches (20 centimeters) or less in height), the armyworm devours all or nearly all of the leaves, causing the plant to expire in short order. In taller plants, some or parts of the leaves are left intact, but the insect concentrates on the center of the young stalk and damage is usually fatal to the plant — and once a field is invaded, without immediate control measures at work, all plants in the field are consumed.

The armyworm commences destructive action early in the spring. It is believed that some of these insects winter over as partially developed larvae, but that some may also winter as pupae or adults. This would explain the very early appearance of moths in the northern climes. Depending upon locale, the worms are fully grown by April or May. They pupate just below the groundlevel of the soil. A pupa is dark brown, having a length of about $\frac{3}{4}$-inch (19 millimeters), with a rather blunt head and a sharply tapering tail. The pupa stage lasts for about 2 weeks (longer if weather is unusually cold), from which the insect transforms into a rather drab gray-brown or light-brown moth having a wingspread of about 1.5 inches (about 4 centimeters). The moth can be recognized by a prominent white dot, centered in each front wing. The moth is active only at night. Light, and the odor of decaying fruit, attracts the moth.

The female moth lays her eggs (500 or more) in clusters or rows, preferring to place them on leaves of grasses. Pale green in color, the

young worms tend to "loop" as they move about. These worms may be found by the thousands and tens of thousands in grass and fields of small grain and, frequently, are not detected until their damage has become extensive. The worms feed only at night. When fully grown, the worm is about 1.5 inches in length (4 centimeters). They maintain a green-brown color and have longitudinal stripes. After feasting for several days, the worms enter back into the soil, change to the pupal stage, and re-emerge as moths in from 2 to 4 weeks. In this fashion, there may be two to three generations per year. The larvae of the last generation of the year usually appear between mid-August and mid-September, depending upon locale and weather conditions.

Poison bran is an effective measure, particularly to protect fields that have not yet been attacked. The bran is placed in a line stretching across the probable line of march of the insect once an adjacent field has been decimated. The bait is prepared from bran that is mixed with insecticide. Blackstrap molasses or lubricating oil usually is added to provide sufficient stickiness to keep the insecticide and bran together. The worms also like molasses.

The armyworm is quite similar to the army cutworm, described in the entry on **Cutworm**.

A closely related species is the *fall armyworm (Laphygma frugiperda*, Smith). Although widely distributed, they are notably injurious to crops in the southern United States, particularly during years when there has been a cold and wet spring. Like the armyworm and the cutworm, these insects also prefer small grains, maize (corn), sorghum, and grasses, but they also attack alfalfa, bean, cabbage, groundnut (peanut), cucumber, potato, sweet potato, spinach, and turnip. These worms are particularly fond of lawn grasses and thus are a serious economic pest not only to the food producer, but to the homeowner as well.

Actually, the fall armyworm is considered a tropical insect because it cannot winter over in any area where the soil is frozen hard. Thus, a favorite winter ground is along the Gulf Coast and in southern Florida. Here, during winter, several stages of the insect may be present at the same time. After their number is increased many fold in the spring, they swarm northward, often flying many hundreds of miles before selecting a location for their egg laying. Each female moth lays about 1000 eggs, usually on green plants. The female covers clusters of eggs with hairs from her body. Shortly thereafter, the young larvae descend down through the heart of a plant and continue feeding near ground level until they assume a length of from 1 to 1.5 inches (2.5 to about 4 centimeters). It is at about this time that the insects are noticed as the result of the large amount of damage that becomes apparent. Unlike the armyworm and most cutworms, the worms do not take refuge in the soil during daytime, but rather they cling to parts of plants.

Quite similar in appearance to the true armyworm, the fall armyworm larvae when fully grown are a light-tan to green in color, although sometimes they are black. There are three very narrow white stripes down their back. They can be contrasted with the true armyworm by observing a white inverted "Y" design on the front of the head. Also, the tubercles are more prominent and they have more hair. The marching habit of this worm occurs during the autumn in the northern climes, but can take place in the southern United States any time after the middle of summer and, if weather conditions are ideal for the insect, such marches may occur in early spring. An entire field or garden can be consumed within 36 to 48 hours. The remaining life cycle of the fall armyworm is similar to that of the true armyworm.

Another closely related species is the *beet armyworm (Laphygma exiqua)*. This is a large caterpillar ranging up to $1\frac{1}{4}$-inch (30–32 millimeters) in length when fully mature. It is olive-green with broad light-green striping. Sugarbeet is the favorite target crop of this insect, followed by table beet and a variety of vegetables, citrus, alfalfa, and some wild grasses. This insect, native to the Orient, was first noted in California in the late 1870s and now occurs widely in the Gulf States, and from those states westward into California and northward to Nebraska and Kansas. Its habits are quite similar to those of the fall armyworm. Control is similar.

AROIDS. A large group of monocotyledonous plants, mostly tropical, having a characteristic flower habit. The numerous small inconspicuous flowers are borne on a fleshy stalk or spadix, which is surrounded, more or less completely, by a large, expanded, often brightly colored bract called a spathe. The spadix and spathe together are often but incorrectly considered to be the flower of the plant. The aroids are perennial plants, generally having tubers or rhizomes from which rise large leaves. Many tropical members are climbing plants. Well-known species are the Skunk Cabbage, whose foul-scented flowers appear so early in the spring, the Jack-in-the-Pulpit, and the wild arum, *Calla palustris*, of cold swamps, as well as the *Sweet* Flag, *Acorus calamus*, of the marshes. The cultivated Calla Lilies are all aroids and not lilies at all; some of them are delightfully fragrant. On the other hand, in species of *Amorphophallus*, which are sometimes seen in collections of cultivated plants, the vile odor of the flower structure prevents them from becoming popular; the spathe and spadix of some of them are of gigantic size. In the tropics several species of *Colocasia* are cultivated for the edible rhizomes which appear under the name of dasheen or taro. *Monstera* and several species of *Philodendron* are popular decorative plants in homes and in public buildings.

AROMATIC COMPOUND. An organic compound that incorporates a closed-chain or (ring) nucleus in its structure. This is in contrast with the aliphatic compound, which is comprised of an open-chain structure. The classical example of an aromatic compound is benzene. Aromatic compounds also are sometimes referred to as benzenoids. Some ring-type compounds are not classified as aromatic. These include the cycloparaffins and cycloolefins which are considered to be derivatives of methane. See also **Compound (Chemical)**; and **Organic Chemistry**.

ARRHENIUS-GUZMAN EQUATION. A relation between the viscosity η and temperature T, at constant pressure,

$$\eta = A \exp \frac{B}{RT}$$

where A, B are constants, and R is the gas constant; B may be identified with the *activation energy for liquid flow.*

ARRHENIUS, SVANTE AUGUST (1859–1927). A hundred years ago, Swedish scientist Svante Arrhenius asked the important question "Is the mean temperature of the ground in any way influenced by the presence of the heat-absorbing gases in the atmosphere?" He went on to become the first person to investigate the effect that doubling atmospheric carbon dioxide would have on global climate. The question was debated throughout the early part of the twentieth century and is still a main concern of Earth scientists today.

The son of an estate manager, Arrhenius was born at Wijk near Uppsala, Sweden. Ironically, Arrhenius' education and training were not in climate research, but rather electrochemistry. His doctoral thesis on the chemical theory of electrolytes in 1884 was initially regarded as mediocre by his examination committee, but later was heralded as an important work regarding the theory of affinity. In 1891, Arrhenius was a founder and the first secretary of the Stockholm Physical Society, a group of scientists whose interests included geology, meteorology, and astronomy. His association with this society would later help stimulate his interests in cosmic physics — the physics of the Earth, sea, and atmosphere. In 1903, Arrhenius was awarded the Nobel Prize for Chemistry for his work on the electrolytic theory of dissociation. In the years following his international recognition, Arrhenius lectured throughout Europe and was elected to numerous scientific societies.

Arrhenius did very little research in the fields of climatology and geophysics, and considered any work in these fields a hobby. His basic

approach was to apply knowledge of basic scientific principles to make sense of existing observations, while hypothesizing a theory on the cause of the "Ice Age." Later on, his geophysical work would serve as a catalyst for the work of others.

In 1895, Arrhenius presented a paper to the Stockholm Physical Society titled, "On the Influence of Carbonic Acid in the Air upon the Temperature of the Ground." This article described an energy budget model that considered the radiative effects of carbon dioxide (carbonic acid) and water vapor on the surface temperature of the Earth, and variations in atmospheric carbon dioxide concentrations. In order to proceed with his experiments, Arrhenius relied heavily on the experiments and observations of other scientists, including Josef Stefan, Arvid Gustaf Högbom, Samuel Langley, Leon Teisserenc de Bort, Knut Angstrom, Alexander Buchan, Luigi De Marchi, Joseph Fourier, C.S.M. Pouillet, and John Tyndall.

Arrhenius argued that variations in trace constituents, namely carbon dioxide, of the atmosphere could greatly influence the heat budget of the Earth. Using the best data available to him (and making many assumptions and estimates that were necessary), he performed a series of calculations on the temperature effects of increasing and decreasing amounts of carbon dioxide in the Earth's atmosphere. His calculations showed that the "temperature of the Arctic regions would rise about 8° or 9° Celsius, if the carbonic acid increased 2.5 to 3 times its present value. In order to get the temperature of the ice age between the 40th and 50th parallels, the carbonic acid in the air should sink to 0.62 to 0.55 of present value (lowering the temperature 4° to 5° Celsius)."

During the next ten years, Arrhenius continued his work on the effects of carbon dioxide on climate, and published a two-volume technical book titled *Lehrbuch der kosmischen Physik* in 1903; but this work was not widely read, as it was a textbook for a discipline that did not yet exist. A few years later, Arrhenius published *Worlds in the Making*, a nontechnical book that reached a greater audience. In this book Arrhenius first describes the "hot-house theory" of the atmosphere, stating that the Earth's temperature is about 30° warmer than it would be due to the "heat-protection action of gases contained in the atmosphere," a theory based on ideas developed by Fourier, Pouillet, and (especially) Tyndall. His calculations demonstrated that if the atmosphere had no carbon dioxide, the surface temperature of the Earth would fall about 21° Celsius. This cooler atmosphere would contain less water vapor, resulting in an additional temperature decrease of approximately 10° Celsius. It is important to note that Arrhenius was not very concerned with rising carbon dioxide levels at the time, but rather was attempting to find an explanation for high latitude temperature changes that could be attributed to the onset of the ice ages and interglacial periods.

By 1904, Arrhenius became concerned with rapid increases in anthropogenic carbon emissions and recognized that "the slight percentage of carbonic acid in the atmosphere may, by the advances of industry, be changed to a noticeable degree in the course of a few centuries." He eventually made the suggestion that an increase in atmospheric carbon dioxide due to the burning of fossil fuels could be beneficial, making the Earth's climates "more equable," stimulating plant growth, and providing more food for a larger population. This view differs radically from current concerns over the harmful effects of a global warming caused by industrial emissions and deforestation. Until about 1960, most scientists dismissed the notion as implausible that humans could significantly affect average global temperatures. Today, however, we know that carbon dioxide levels have risen about 25%, a rate much faster than Arrhenius first predicted, and average global temperatures have risen about 0.5° Celsius.

ARRHENIUS VISCOSITY EQUATIONS. (1) Effect of temperature on viscosity, η, of a liquid

$$\frac{d}{dT}\ln(\eta v^{1/3}) = \frac{k_1}{T^2}$$

where v is the specific volume and k_1 is a constant.

(2) Viscosity of solutions, η,

$$\eta/\eta_s = A^x$$

where x is the concentration, η_s is the viscosity of the solvent and A is a constant.

(3) Viscosity of a sol, η,

$$\log \eta/\eta_\infty = kC$$

where η_∞ is the viscosity of the medium and C is the concentration of the sol-forming material.

ARRHYTHMIAS (Cardiac). An arrhythmia is a variation from what is considered normal for a rhythmic phenomenon. An analogy would be an erratic tape recorder whose speed vacillates and differs from that one speed which yields perfectly normal reproduction of music or voice. While the heart has a reasonably wide range in beating rate (pulse rate), depending upon the body's energy requirements (spanning from rest to heavy exertion), the rhythm of heart action is preserved even though rate may be changed. Rhythmic disturbances of the heart are called *cardiac arrhythmias*. Because, as explained in **Heart and Circulatory System (Human)**, the heart is comprised of chambers (sinuses) and valves which are governed by electrical impulses, the impulses in a normal heart are programmed in just the right sequential order and at just the right instant, the timing of which is on the order of milliseconds. A crude analogy is the firing order of a multi-cylinder internal combustion engine.

Some authorities classify cardiac arrhythmias as *passive* and *active*. In some cases, both passive and active arrhythmias may be simultaneously present. The detailed etiology of these conditions is beyond the scope of this encyclopedia. The principal tool available to the physician in the analysis and diagnosis of cardiac arrhythmias is the electrocardiogram. *Bradycardia* is the term usually used to describe an abnormal slowness of the pulse rate. *Tachycardia* is the term used to describe excessive rapidity of heart action. *Heart block* is a term that signifies the interruption of muscular connection between the atrium and ventricle so that they beat independently of each other. Since there are numerous electrically conductive pathways within the heart, there are several specifically named heart blocks. These include: *arborization* heart block, in which there is interference with the fine terminal subendocardial fibers of the *Purkinje system* (specialized sino-atrioventricular conduction system); *atrio-ventricular* heart block; *auriculo-ventricular* heart block; *bundle-branch* heart block, in which the two ventricles contract independently of each other; *complete heart block*, a situation in which the functional relation between the parts of the *bundle of His* (a muscular band connecting the auricles with the ventricles of the heart) is destroyed by a lesion, so that the auricles and ventricles act independently of each other; *inter-ventricular* heart block; and *sino-auricular* heart block, in which the blocking is located between the auricles and the mouths of the great veins and coronary sinus. See Fig. 1 in entry on **Heart and Circulatory System (Physiology)**.

Because of the several pathways of conduction, a pair of conducting leads to the electrocardiograph does not suffice. A standard arrangement of twelve leads to the instrument is commonly used. The physician will evaluate with maximum possible accuracy the risk posed by an arrhythmia, particularly a tachyarrhythmia and the urgency of attempting to terminate it. Although normal hearts may tolerate tachyarrhythmia for extensive periods, when there is marked underlying heart disease, such arrhythmia may cause hypotension (low blood pressure), congestive heart failure, or coronary insufficiency. Tachyarrhythmia are prone to degenerate into the more serious ventricular arrhythmia. In addition to general cardiac health, the physician will take into consideration the heart rate, the duration of the episodes of arrhythmia, and whether the arrhythmia is regular or irregular.

Passive Arrythmias

Particularly in individuals who are quite physically active, *sinus bradycardia* may be present. This is defined as a resting heart (adult) which

beats fewer than 60 times per minute. The rates of long-distance runners, for example, may range between 40 and 50 beats per minute. A number of conditions, however, may cause an abnormally slow discharge rate of the sinus node. This occurs during severe pain and can be induced by increased vagal tone caused by various drugs (parasympathomimetic), such as endrophonium and neostigmine, and by a number of tranquilizing drugs. Increased vagal tone also can be associated with acute myocardial infarction. A number of physiologic situations will slow the sinus node, including hypothyroidism and high fever. There is also what is known as *hypersensitive carotid sinus reflex*. (The carotid artery is located in the region of the neck, face, and skull.) The carotid sinus becomes increasingly sensitive with age and a type of syncope (sudden suspension of consciousness) can be caused by twisting the neck or wearing a tight collar. See also **Syncope**.

In some patients, particularly the elderly, presenting sinus bradycardia, there may be a condition known as the *sick sinus syndrome.* The bradycardia may be punctuated by episodies of tachycardia (*bradycardia-tachycardia syndrome*). A form of sick sinus syndrome has explained some sudden deaths of young athletes, who at autopsy have exhibited an idiopathic (cause not known) obliterative disease of the artery to the sinus node.

A slow heart beat (bradycardia) may be a factor in development of congestive heart failure with patients who have myocardial disease. See also **Congestive Heart Failure (CHF)**.

Active Arrythmias

Some authorities place active arrythmias into two fundamental categories — supraventricular and ventricular. Representative of *supraventricular arrythmias* are atrial premature beats and junctional premature beats; sinus tachycardia; paroxysmal supraventricular tachycardia; paroxysmal atrial tachycardia; paroxysmal (AV) atrioventricular junctional tachycardia; paroxysmal atrial tachycardia with block; multifocal atrial tachycardia; atrial flutter; and atrial fibrillation. Representative of ventricular arrythmias are ventricular premature beats, ventricular tachycardia, accelerated idioventricular rhythm, and ventricular fibrillation.

Ventricular Fibrillation. This condition may be described as an irregular twitching of the muscles in the wall of the ventricle of the heart. About two-thirds of the deaths due to heart attack are attributed to uncontrolled ventricular fibrillation (VF) which kills many patients before they reach a hospital. The probability of VF increases with the size of the dead tissue (infarct) that results when the blood flow to a portion of the heart is drastically reduced by blockage of one or more of the arteries. This is a primary motivation for finding treatments to limit infarct size. The presence of dead tissue from prior milder heart attacks will contribute to VF in a major attack. Thus, in persons with a history of heart problems, surgery to eliminate abnormal tissues that may give rise to the arrhythmia is sometimes suggested as a preventive measure. When a patient lives to reach a hospital, continuous monitoring of the heart will reveal any abnormal rhythms that presage VF and thus can be treated as soon as they occur.

Various communities have instituted emergency procedures that provide *cardiopulmonary resuscitation* (CPR), including mouth-to-mouth resuscitation and external heart massage. Therapy must be commenced within 5 minutes to prevent irreversible brain damage when the supply of blood to the brain is blocked. A major role of CPR is to identify VF and the immediate use of drug therapy. Currently, successful CPR programs require a nearly ideal environment to operate successfully: a large number of trained personnel and sufficient units to reach a heart attack victim within 5 minutes or less; prompt rudimentary measures taken by bystanders (if attack occurs in public places), by family (in the home), by fellow office and factory workers, etc., and, above all, telephone for an emergency unit; adequate instrumentation, including the ability to transmit instrumental data as well as voiced observations, in the emergency vehicle; excellent radio communication between vehicle personnel and hospital medical staff (a physician immediately available at all times) who can advise the most appropriate emergency procedures. The objective is to extend as much as possible the skills and means of the hospital to the patient before arrival at a hospital.

Pre-excitation Syndromes. These conditions occur when all or a portion of the ventricle is activated by atrial impulses earlier than would be the case were the impulses reaching the ventricles via the normal conduction pathways. One such condition is known as the *Wolff-Parkinson-White* syndrome and is believed to result from congenital cardiac defects, frequently involving the tricuspid valve (*Ebstein's anomaly*). Recent research indicates that pre-excitation syndrome can occur by a number of different pathways. Sometimes involved are the Kent bundles, the James fibers, and the septal fibers of Mahaim. Although the arrythmias (usually sporadic) associated with pre-excitation syndrome can be tolerated by some patients (even at rates of 250–300 beats per minute), this tolerance is usually limited to young persons with otherwise normal hearts. In contrast, in some patients, the arrythmias can be disabling.

Pacemakers

In cases of complete or bifascicular heart block, an implanted pacemaker may be used. In the early years of pacemaker use, there were numerous problems with failures arising from electrode displacement or breakage, premature battery depletion, or faulty pulse generators. Today, the reliability of the units has markedly increased, but precaution must be exercised in selecting an instrument from the several types available. Two techniques have been used in pacemaker implantation — insertion of an electrode through (1) a cephalic vein or (2) the external jugular vein into the apex of the right ventricle. The power source is placed subcutaneously just inferior to the clavicle; or direct epicardial electrodes are attached to the ventricle through a small midline thoracotomy. The pulse generator is placed subcutaneously in the epigastric region. In the *demand type* of pacemaker, the unit will not compete with the patient's own rhythm if the AV conduction should return, or with ventricular premature beats should they be present. The pacemaker can be designed and implanted in accordance with the particular problems of the patient.

Over a half-million patients in the United States live with the aid of a permanent cardiac system to ensure a dependable cardiac rhythm, with the number increasing by several thousand each year. The latest available systems take advantage of the advancements in microelectronics. Such advancements have led to complex multiprogrammable single- and dual-chamber arrangements for pulse generation. But, as pointed out by Ludmer and Goldschlager (see reference), the large number of available pacing systems has complicated the understanding of newer generator functions and pacemaker electrocardiography, and thus the ability to diagnose normal and abnormal pacemaker function. The proper methods and techniques of outpatient follow-up also have been complicated.

The modern pacemaker generator is a hermetically sealed metal can weighing from 30 to 130 grams, powered by a lithium battery projected to last 2 to 15 years. The modern unit is non-invasively (transcutaneously) programmable in more than 42 million possible setting combinations. Noninvasive programming, by which certain pulse-generator functions can be transiently and reversibly changed, has revolutionized the pacemaker industry and avoids re-operation in up to 20% of patients.

The parameters that are reprogrammable in many modern pacemakers include: (1) rate, (2) energy output, (3) refractory period, (4) sensitivity, (5) hysteresis, (6) mode of function, (7) lower rate limit, (8) atrioventricular delay, and (9) upper rate limit. The refractory period of a pacemaker generator may be defined as the time after either a paced complex (pacing refractory period) or a sensed spontaneous complex (sensing refractory period) during which the generator is unreceptive to incoming signals. In some pacemakers, pacing and sensing refractory periods are equal, whereas in others, the refractory period after a paced complex is longer than that after a spontaneous complex.

The complex technology of pacemakers tends to rival the sophisticated instrumental techniques applied in controlling a complex chemical plant and thus suggests that those physicians who specify pacemakers today must understand and appreciate the relevant sophistication of these devices. For the patient who has interests along these lines, the Ludmer/Goldschlager reference should be "must" reading. Because of these complexities, this is an area of medical specialization where a second opinion may be highly justifiable. Two causes of problems with all pacing systems are the inability to sense electrical signals of borderline quality (undersensing) and the capability of sensing unwanted electrical signals originating from outside the heart (oversensing). Irrelevant signals may include those of a physiological nature, electromagnetic interference emanating from any other medical aids of an electrical nature, or from devices encountered at home or at work, such as radio and television transmitters and arc-welding equipment; still another source of signals may be generated within the pacing system itself, caused by inactive leads or electrode parts of the pacing device.

In another excellent reference (Phibbs/Marriott), the overall importance of the pacemaker in relieving patients of symptoms and in saving lives is fully acknowledged. The researchers also stress, however, that it would be wrong to pretend that the implementation of permanent pacing is not without some risk. Medical complications fall into three principal categories: (1) thrombosis and embolism, (2) infection, and (3) less common complications, including pacemaker-generated arrhythmias, myocardial perforation, and tamponade. The risk of serious thrombotic or embolic complications is estimated at approximately 2% of cases. A relatively benign form of thrombosis of the veins of the upper arm and shoulder may be expected in about 30% of patients with transvenous pacemakers. Thrombosis of the axillary and subclavian veins is much more serious, possibly requiring anticoagulant and thrombolytic therapy. Pulmonary embolism, often fatal, has been the subject of numerous case reports. Pulmonary embolism in a patient with a pacemaker should always arouse the suspicion of thrombosis on the pacing wire as the source. The dimensions of the problem have not been fully defined. Infection from pacemaker implantation can be expected in from 1 to 7% of cases, usually taking the form of septicemia or as endocarditis. Phibbs and Marriott report that patients with pacemakers encounter major difficulty in obtaining life and health insurance. Psychological problems associated with pacemaker patients are also reported.

Statistics have shown that many pacemakers in the past have been implanted needlessly in patients, as for example the use of a pacemaker to correct for a situation that was of a transient nature with little prospect of recurrence. Studies along these lines have been conducted at major hospitals and medical centers. Phibbs/Marriott report that in a few localities as many as 75% of pacemaker implantations were found unjustifiable by any reasonable standards after review by several disinterested experts. The total figure for larger areas is certainly much lower, but in some regions and states it approximates 30%. Causes for misdiagnosis and incorrect recommendation of a pacemaker include transient situations as previously mentioned, hypothyroidism, simple misinterpretation of an electrocardiogram and, among less obvious situations, the effects of various drugs on cardiac arrhythmias. Drug-induced depression of atrioventricular conduction is often confused with intrinsic dysfunction or disease.

It is further observed that there are impelling medical and legal reasons for total removal of *unnecessary* pacing equipment. Approximately 50% of the older types of electrodes used and practically all of the newer, long-tined electrodes will become permanently entrapped. "In the large percentage of these patients in whom the pacemaker is entrapped, removal will require cardiopulmonary bypass, with major morbidity and possible death. Failing to attempt to remove an electrode as soon as it is found unnecessary could reasonably be construed as falling below an acceptable level of practice, since such failure may expose the patient to a life-threatening intervention."

Antiarrhythmic Agents

Some of the drugs used in the control of ventricular and atrial tachyarrhythmias include:

- *Quinidine* — important in the control of ventricular and atrial tachyarrhythmias. The drug decreases automaticity, excitability, and conduction velocity. It prolongs effective refractory period and action potential duration. Although quinidine is essentially metabolized in the liver, several instances of drug interactions involving quinidine have been observed.
- *Procainamide* — similar in action to quinidine. The drug is as effective as quinidine for treatment of ventricular tachyarrhythmias, but is not very effective in treatment of atrial tachyarrhythmias. Most common early noncardiac manifestations of procainamide toxicity include gastrointestinal disturbance, anorexia, nausea, and vomiting. The drug also can cause drug fever or allergic rash.
- *Propranolol* — decreases conduction through the atrioventricular node. Often an effective agent for slowing the ventricular response in patients with atrial fibrillation or atrial flutter. The major toxic effects are related to its beta-blocking activity, which may precipitate excessive sinus bradycardia, congestive heart failure, or in patients with bronchospastic disease, bronchial asthma.
- *Lidocaine* — effective in treatment of ventricular arrhythmias. Not effective in treatment of supraventricular tachyarrhythmias. Cardiac toxicity is observed as negligible at therapeutic levels. Major toxic effects are neurologic, including confusion, seizures, and (rarely) respiratory arrest and coma.
- *Mexiletine* — a lidocaine derivative that provides oral therapy for ventricular tachyarrhythmias due to many causes. Side-effects may include epigastric burning and constipation. Neurologic toxicity may include tremulousness, diplopia, dizziness, and (infrequently) slurred speech.
- *Tocainide* — a lidocaine derivative that provides oral therapy for ventricular tachyarrhythmias due to many causes. Side effects include nausea and vomiting.
- *Digitalis* — stabilizes atrial electrical activity and assists in preventing atrial tachyarrhythmias. Particularly useful, in combination with diuretics, in treatment of ventricular arrhythmias arising from congestive heart failure and enlarged heart.
- *Verapamil* — the first of the calcium antagonist drugs to be approved for clinical use in the United States, although previously used in other countries for several years in the treatment of arrhythmias and angina. The calcium antagonists inhibit the flux of calcium across the slow channels of vascular smooth muscle cells and cardiac cells. Adverse reactions have been reported when verapamil and propanolol are given intravenously (simultaneously).
- *Amiodarone* — a benzofuran derivative with reported effective use for treatment of supraventricular and ventricular tachyarrhythmias. The drug has been used for a number of years in countries other than the United States. The drug, with a long half-life, may persist in the body for over two months after therapy has ceased. Amiodarone interacts with other drugs, potentiating the anticoagulant properties of warfarin and increasing the serum concentration of several other drugs. Side-effects from long-term therapy are considered mild, including skin reactions, photosensitivity, mild gastrointestinal effects. As with all drugs, there are uncommon manifestations.

ARROW WORM. Small marine animals sometimes classified with the annelid worms but more often included in the separate phylum *Chaetognatha*.

ARROYO. This term is applied to dry stream channels with nearly vertical walls and flat bottoms which are characteristic of semi-arid regions. They may suddenly become filled with torrential waters after heavy rains. The word arroyo is of Spanish origin.

ARSENIC. [CAS: 2440-38-2] Chemical element, symbol As, at. no. 33, at. wt. 74.9216, periodic table group 15, mp 817 °C (24 atmospheres), sublimes at 613 °C, density 5.72 g/cm^3. One naturally-occurring stable isotope: ^{75}As. Various studies indicate that arsenic exists in several allotropic forms. The metallic form has a steel-gray color in the crystalline form and is brittle. Although the red form of arsenic sulfide As_2S_2 was observed by Aristotle as early as 400 B.C., the first attempt to isolate the metal was not made until 1250 by Albert Magnus. Later documentation on the preparation of the element was given by J. Schroder and N. Lémery in the 1600s. First ionization potential 9.8 eV; second 18.63 eV; third 28.34 eV; fourth 50.1 eV; fifth 62.5 eV. Oxidation potentials $AsH_3 \rightarrow As + 3H^+ + 3e^-$, 0.54 V; $As + 2H_2O \rightarrow HAsO_2 + 3H^+ + 3e^-$, −0.2475 V; $HAsO_2 + 2H_2O \rightarrow H_3AsO_4 + 2H^+ + 2e^-$, −0.559 V;

$AsO_2^- + 4OH^- \rightarrow AsO_4^{3-} + 2H_2O + 2e^-$, 0.71 V; $As + 4OH^- \rightarrow AsO_2^- + 2H_2O + 3e^-$, 0.68 V. Other important physical properties of arsenic are given under **Chemical Elements**.

Gray or metallic arsenic, density 5.73 g/cm^3, which sublimes on heating, and has the vapor composition As_4, becoming As_2 at higher temperatures, is the ordinary variety. On rapid cooling, the vapor condenses to yellow arsenic, density 1.97 g/cm^3, which reverts to the gray variety on warming. An intermediate form in the transition is black amorphous β arsenic, density 4.6–5.2, also obtained by the thermal decomposition of arsine. Brown arsenic, density 3.7–4.2, obtained by reduction of acid solutions of trivalent arsenic, is probably a finely divided form of black arsenic.

Arsenic sublimes on heating and is unchanged in dry air, but a film of oxide is formed in moist air; heated in air at 180 °C, arsenic forms arsenic trioxide of the odor of garlic, poisonous; insoluble in HCl but soluble in concentrated HNO_3 or concentrated H_2SO_4 to form arsenic acid; soluble in hot NaOH solution; heated with chlorine forms arsenic trichloride; heated with metals forms metallic arsenides. When arsenic is heated in a tube and the vapor cooled (1) slowly (that is, in the hot part of the tube) black arsenic is formed, and this form is converted into the gray at 360 °C, (2) rapidly (that is, in the cold part of the tube) yellow arsenic is formed, and this form is quickly converted into the gray by the action of light. Yellow arsenic is soluble in CS_2.

Arsenic occurs in nature as the arsenide of iron, cobalt, nickel, and as the mineral sulfides, *realgar* (arsenic monosulfide, AsS), red colored; *orpiment* (arsenic trisulfide, As_2S_3), yellow colored — these two minerals when powdered once were used as paint pigments — *arsenopyrite*, *mispickel* (iron arsenosulfide, FeAsS); *enargite*, Cu_3AsS_4; and *tennantite*, $Cu_8As_2S_7$.

The primary arsenic-containing material is arsenious oxide obtained by separation from roaster or smelter flue gases. Metallic arsenic is obtained as sublimate by heating the oxide with carbon.

Arsine. AsH_3, is formed by hydrolysis of arsenides, or reduction (by zinc and HCl or aluminum and NaOH) of arsenic compounds, as in the Gutzeit test. It reacts with metals at higher temperatures or in solution to give the arsenides. Diarsine, As_2H_4, is produced by reduction of arsenic trichloride, $AsCl_3$, by lithium aluminum hydride, $LiAlH_4$ in ether at −190 °C. It melts below −50 °C, but begins to decompose into AsH_3 and brown polymeric $(AsH)_x$ about −100 °C. It is more stable in the gas phase than in the solid or liquid phases.

Arsenides. These are prepared by fusion from the elements. Their properties vary across the periodic table, those of the alkalies and alkaline earths being readily hydrolyzed by H_2O or acids and are stoichiometric, while the arsenides of the other metals show an increasingly intermetallic character and resist hydrolysis.

Gallium Arsenide. Devices using gallium arsenide are extremely important in contemporary electronic equipment. For example, some of the fastest digital integrated circuits built to date are made of gallium arsenide. They are biphase clock flip-flops configured to perform frequency division. They operate at frequencies up to 5.77 GHz, which is about the highest division speed yet reported for integrated circuits operating at room temperature. These circuits have been fabricated by electron-beam lithography to produce gate lengths of 0.5 micrometer in the MESFET (metal-semiconductor field-effect transistor) switching transistors. Gallium arsenide devices can be used in very-high-frequency signal processing or as interfaces to more complex chips, including VHSIC (very high speed integrated circuits). (*Note*: This and the following two paragraphs were prepared by staff.)

In special tests carried out by several research groups (AT&T Bell Laboratories, IBM, Arizona State University, and Japanese investigators) on gallium arsenide devices, experimental evidence indicates that possibly electrons can travel through a semiconductor without being slowed by collisions, that is, ballistically. As pointed out by Robinson (January 1986), at least in theory, the faster the electrons travel through a transistor, the faster the device can switch on and off. Although, to date, there has been no demonstration of how to take advantage of ballistic transport in a practical transistor, the concept does excite visions of ballistic electrons traveling at nearly the speed of light and providing the basis for transistors that can switch trillions of times per second.

Gallium arsenide and silicon transistors each have their own specific advantages. GaAs transistors switch faster than Si transistors and they also emit near-infrared and visible light, a property of value when both optical and electrical functions are combined in one chip. In many other respects, the GaAs devices are inferior to their silicon counterparts. Researchers have recently found how to effect epitaxial growth of crystalline GaAs layers on silicon wafers and thus combine the properties of both semiconductors, particularly in the manufacture of high-speed microelectronic chips.

The potential of GaAs and other III-V semiconductors are well portrayed by Yablonovitch (see list).

See also **Microelectronics**; **Semiconductor**; and **Transistor (Invention and Development)**.

Trihalides. The trifluoride and trichloride, AsF_3 and $AsCl_3$, are liquids at room temperature and the tribromide and triiodide, $AsBr_3$ and AsI_3 are solids, although the former melts at 31 °C. Like the analogous phosphorus compounds, they have pyramidal structures. Their hydrolysis in aqueous solution is not quite complete, consistent with their greater ionic character (than the phosphorus halides), as is the fact that As^{3+} is precipitated from their solutions as the sulfide. The only stable binary pentahalogen compound of arsenic is the pentafluoride, AsF_5, a colorless gas, which like the trihalides, is less readily hydrolyzed than the corresponding phosphorus compound. A very unstable pentachloride, $AsCl_5$, has been reported. The mixed halide AsF_3Cl_2 can be made by passing chlorine into ice-cold arsenic trifluoride.

Arsenic (III) Oxide. As_4O_6, exists as tetraarsenic hexoxide in the solid state and in the vapor to above 800 °C, where dissociation to As_2O_3 commences. It is somewhat soluble in H_2O (about 20 g/l at 25 °C), and its solutions have some acidic properties, although the acid has not been isolated and its formula is probably not $As(OH)_3$, the form used for convenience in writing reactions. It is an amphiprotic substance, since, as stated above, As^{3+} is precipitated by H_2S from acid solutions as the sulfide, while the salts, the arsenites (containing the ion AsO_3^{3-}), are readily formed. Their solubility in H_2O varies across the periodic table, those of the alkali metals being very soluble, those of the alkaline earth metals less so, and those of the heavy metals essentially insoluble. Arsenite ion probably exists as $As(OH)_4^-$ in solution.

Arsenic (V) Oxide. As_4O_{10} is a white solid, decomposes at 315 °C, isomorphous with phosphorus pentoxide, P_2O_5, but not produced by a simple oxidation of As_2O_3. It is made by dehydration of arsenic acid or $As_4O_{10}{\cdot}4H_2O$. It hydrates to give arsenic acid, $H_3AsO_4{\cdot}\frac{1}{2}H_2O$. This acid is only slightly weaker than phosphoric acid, which it resembles in forming a wide variety of polyacids. It also forms primary, secondary, and tertiary (ortho) arsenates. Raman spectral studies of concentrated arsenic acid solutions in H_2O have a strong band assigned to the — OH group, whence it is inferred that the acid is present in different forms in concentrated and dilute solutions. Many arsenates are converted by ignition into pyro-arsenates, e.g., calcium pyroarsenate, $Ca_2As_2O_7$, and meta-arsenates are also known.

Direct fusion of the elements yields a number of arsenic sulfides, including As_4S_3, As_4S_4, As_2S_3, and As_2S_5, the last two being obtained also by precipitation from arsenic (III) and arsenic (V) solutions, respectively. The trisulfide dissolves in alkali sulfide solutions to form thio-arsenites:

$$As_2S_3 + 3S_2^{2-} \longrightarrow 2AsS_3^{3-} + S$$

while with polysulfides it forms thioarsenates:

$$As_2S_3 + 2S_2^{2-} + S \longrightarrow 2AsS_4^{2-}$$

Organoarsenic Compounds. The largest group of organic arsenic-containing compounds is the arsenic acids $RAsO(OH)_2$, where the R may be alkyl, aryl, or heterocyclic groups and their salts. In addition to specific compounds mentioned under the uses of arsenic, some organo-arsenic compounds include methylarsine CH_3AsH_2; methylarsenic tetrachloride CH_3AsCl_4; diphenylarsenic peroxide $(C_6H_5)_2$ AsOOAs $(C_6H_5)_2$; triphenylarsenic dihydroxide

$$(C_6H_5)_3As(OH)_2;$$

dimethylarsine borane $(CH_3)_2AsHBH_3$; and ethoxydichloroarsine $C_2H_5OAsCl_2$.

Uses. Future production of As_2O_3 will be influenced by the ability to handle ores in compliance with environmental restrictions. As_2O_3 is available in two grades: (1) crude, 95% As_2O_3; and (2) refined arsenic, 99% As_2O_3. Domestic supplies of the United States are supplemented by imports from Sweden, France, and Mexico. Commercial arsenic metal is produced chiefly by the United States and Sweden.

Arsenic trioxide finds major use in the preparation of other compounds, notably those used in agricultural applications. The compounds

monosodium methylarsonate, disodium methylarsonate, methane arsenic acid (cacodylic acid) are used for weed control, while arsenic acid, H_3AsO_4, is used as a desiccant for the defoliation of cotton crops. Other compounds once widely used in agriculture are calcium arsenate for control of boll weevils, lead arsenate as a pesticide for fruit crops, and sodium arsenite as a herbicide and for cattle and sheep dip. In some areas, arsenilic acid has been used as a feed additive for swine and poultry. Restrictions on these compounds vary from one country and region to the next.

Refined arsenic trioxide is used both as a fining and decolorizing agent in glass. As_2O_5 and arsenic acid are used in the manufacture of chromated copper arsenate, which is used extensively as a wood preservative.

Indium arsenide, gallium arsenide, and gallium arsenide phosphide find use as semiconductors. For these materials, the starting arsenic source must be extremely pure. Arsenic trichloride and arsenic hydride (very high purity) find application in the production of epitaxial gallium arsenide. Also, in various combinations with iodine, germanium, selenium, sulfur, tellurium, and thallium, arsenic will form a group of glasses with very low melting points.

The applications of arsenic as a metal are quite limited. Metallurgically, it is used mainly as an additive. The addition of from $\frac{1}{2}$ to 2% of arsenic improves the sphericity of lead shot. Arsenic in small quantities improves the properties of lead-base bearing alloys for high-temperature operation. Improvements in hardness of lead-base battery grid metal and cable-sheathing alloys can be obtained by slight additions of arsenic. Very small additions (0.02–0.05%) of arsenic to brass reduce dezincification.

Toxicity. Although metallic arsenic and arsenic trisulfide may be handled, as in the case of most arsenical compounds, skin contact should be avoided. Arsine requires extreme caution in handling because of its very high toxicity. In handling arsenic and its compounds, reducing conditions should be avoided because these may give rise to the undesired formation of arsine. Wherever arsenic and its compounds are present as dusts or vapors, proper ventilation and respirators are mandatory. Good housekeeping and appropriate hygienic practices should also be observed.

Arsenic is commonly found in small amounts in the tissues of plants and animals. A human body may contain as much as 20 mg (As_2O_3). No role in natural biological phenomena has been found for As. Although the element may be present in seawater to the extent of 0.006–0.03 ppm, it may be ten times as high in estuaries. Shellfish tend to accumulate the arsenic from the large amount of seawater with which they come in contact. Oysters may contain 3–10 ppm. However, shellfish of the same species grown in different localities show wide variations in arsenic content, suggesting that it is an accidental constituent, which the organisms learn to tolerate. Its lack of function in the human body is suggested by the fact that it tends to accumulate in the hair and nails, which are essentially nonliving.

As and Gene Amplification. Research by Te-Chang Lee and associated scientists have reported that arsenic acts specifically in the progression phase of carcinogenicity. Findings indicate that arsenic may be related to its ability to cause gene amplification, but not gene mutations. Data collected regarding humans occupationally exposed to arsenic indicates that exposure to As appears to act at a late stage in the carcinogenic process. Thus, the scientists postulate that amplification of an altered or activated oncogene may be a late stage in neoplastic progression. The hypothesis would explain why arsenic is not an effective complete carcinogen, initiator, or tumor promotor. There may be other substances, in addition to As, that act in this manner.

ARSENOPYRITE. The mineral arsenopyrite is a sulfarsenide of iron corresponding to the formula FeAsS. A variety in which some of the iron is replaced by cobalt is known as danaite. It crystallizes in the monoclinic system but twinning produces pseudo-orthorhombic crystals. Its hardness is 5.5–6; sp gr, 6.07; luster, metallic color, silvery-white to steel gray, but usually with a yellow to gray tarnish; streak, black. Arsenopyrite is a common mineral with tin and lead ores and in pegmatites, probably having been deposited by action of both vapors and hydrothermal solutions. It is a widespread mineral, well-known deposits occurring in Austria, Saxony, Switzerland, Sweden, Norway; Cornwall and Devonshire, England; Bolivia; in the United States at Roxbury, Connecticut; Franklin, New Jersey; Paris, Maine; Emery, Montana; and Leadville, Colorado. Danaite was first found in Franconia, New Hampshire, by J.D. Dana, for whom it was later named. Arsenopyrite also is known as *mispickel*, an old German term whose exact derivation is unknown.

ARTEMISIA. Genus of the family *Carduaceae* (aster or thistle family). Many of the nearly 300 species of *Artemisia* have been cultivated. Southernwood, *Artemisia abrotanum*, is cultivated in gardens for its delicate foliage and aromatic odor. Another and a homely species, *Artemisia vulgaris* or mugwort, is also frequently cultivated, as is *Artemisia absinthium*, a native European perennial plant. All contain volatile oils. That from *Artemisia absinthium*, oil of wormwood, is a powerful drug, capable of causing violent convulsions when taken even in small doses. It is used to flavor the alcoholic beverage absinthe, a liquor capable of producing much the same effects as the drug. The sage brushes of the western United States are all species of *Artemisia*; like other species they contain an abundance of aromatic oil. From *Artemisia dracunculus*, tarragon is obtained. This is used as a condiment, and for flavoring vinegar and mustard.

ARTERIES AND VEINS (Vascular System). Malfunctioning blood vessels predispose several of the major fatal and disabling diseases. These include *cardiovascular diseases*, as typified by ischemic heart disease — angina pectoris and acute myocardial infarction; and *cerebrovascular diseases*, as represented by cerebral thrombosis and cerebral hemorrhage. A general description of the blood circulatory system is given in the entry on **Heart and Circulatory System (Human)**.

Blood vessels fail, fully or partially, in several ways. Particularly in connection with the arteries, a process known as *atherogenesis* may occur. This is a slow process and progresses with the age of the individual. Over a period of time, plaque-like lesions form in the arterial walls, reducing both the elasticity and useful diameter of the vessel. This, in turn, diminishes the amount of blood that can be conveyed by a given artery to the organ it is supplying and also affects the manner in which the artery must respond in concert with the actions of the heart. Arteries so damaged are more prone to obstructing the flow of blood when thrombi or emboli are present, causing heart damage that may terminate in death (heart attack); or causing brain damage that also may terminate in death or in severe paralysis and mental degradation (stroke). Blood vessels also may leak or rupture, particularly if aneurysm is present, causing damage to surrounding tissue.

In describing vascular disorders, certain terms are frequently used. These include:

Thrombus — a blood clot formed within the heart, or in a blood vessel, remaining at its site of origin. Once a thrombus migrates by way of the bloodstream to a different site and when two or more thrombi agglomerate, the term *embolism* may be used. Thrombi and emboli also are sometimes called occlusions — as in coronary occlusion.

Spasm — coronary artery spasms are described in entry on **Ischemic Heart Disease**.

Embolism — the obstruction of a blood vessel by an embolus, often a migrated blood clot or other debris. If not absorbed, once detached from its

place of origin, an embolus may circulate freely in the bloodstream until it finally reaches a vessel through which it cannot pass. An embolus on the arterial side of the heart, such as may originate in chronic valvular disease, will lodge in one of the systemic arteries of the body. On the venous side, an embolus, usually arising in some area of infection, will pass into the heart and thence to the arteries of the lungs. In either situation, the consequences are similar — the blood supply to the region is cut off and, unless adequate alternative channels are available, death or grave debility will result. In the case of the large arteries to such organs as kidneys, brain, and heart, there is only limited possibility of collateral circulation from the outset, and infarction results. An infarct is defined as an area of necrosis in a tissue caused by obstruction of circulation to the affected area. Myocardial infarction is defined as the death of an area of tissue in the heart muscle, caused by decreased blood supply to the heart. In the case of emboli in other parts of the body, unless treated, the final consequence may be gangrene.

Embolism may be caused by means other than blood clotting. Fat embolism is seen in severe bone injury, where fat globules released from the pulped bone marrow may occlude arteries in the brain and/or lungs. Air embolism may form when air is accidentally aspirated into the veins, especially those of the neck. Fragments of tumors may be carried as emboli in the circulation to distant parts. These may be too small to cause immediate effects of emboli, but instead they may form the nucleus for secondary growths at some distance from the primary tumor.

Aneurysm — a sac or pouch filled with blood that protrudes from the wall of an artery, a vein, or the heart. In a *true* aneurysm, the wall of the sac consists of at least one of the layers of tissue that make up the wall of the blood vessel. In a *false* aneurysm, all layers of the artery have ruptured, but blood is retained in connective tissue surrounding the artery. See also **Aneurysm**.

Hemorrhage — the escape of blood from a ruptured vessel. This may vary from seepage to a massive flow. See **Hemorrhage**.

Arteries

The arteries are complex, composite tubes that carry blood from the heart to the capillaries. In the adult, the largest of the arteries, the aorta and pulmonary artery, are indeed quite large — up to 1.2 inch (3 centimeters) in diameter. Likening an artery to a pipe or hose is a gross oversimplification because an artery is a dynamic structure that incorporates functions that go far beyond the simple task of a conduit. For example, the elastic properties of an artery, unlike a rigid pipe, make it possible for the artery to accommodate large and cyclic changes in blood flow that are characteristic of normal heart pumping action. With the capability of continuously changing the orifice (channel for transporting the blood), the artery assists in the outward distribution of blood from the heart through what might be called a squeezing action. Further, the action of the artery varies the resistance to flow of blood and thus the back pressure on the heart; the pliable nature of the artery resists rupturing. The muscular tissue of the artery is generously supplied with nerve fibers (*vasomotor nerves*), which in essence act as a control over the relative or effective pliability of the artery.

The normal, healthy artery is composed of three coats, each of which is made up of additional layers and thus is quite unlike and much more complex than what one may envision when thinking of a pipe or tube. (1) The *inner coat (tunica intima)* consists of three layers — (a) endothelial cells: (b) connective tissue, which occurs only in the larger arteries; and (c) elastic fibers with microscopic perforations (*fenestrated membrane*). (2) The *middle coat (tunica media)* consists of muscular and elastic tissue. This middle coat provides the artery with extensible and elastic properties. These characteristics enable the artery to expand upon receiving blood at each contraction of the heart and, in turn, to squeeze the blood forward as the orifice is adjusted to receive more blood at another contraction of the heart. (3) An *external coat (tunica externa or adventita)* consists of areolar connective tissue made up of smooth muscle cells, either scattered or in the form of longitudinally arranged bundles.

When empty, the arteries do not collapse; the orifice for carrying the blood remains open. However, when an artery is cut, as from an injury, the muscular coat does contract to some extent, thus narrowing the opening of the wound and permitting a clot to form to close (plug) the orifice, an action that is mandatory to the halting of hemorrhage. In the body, a majority of the arteries are accompanied by one or more veins which are contained within a protective sheath of connective material for providing support to these vessels. Some authorities classify arteries as (1) *elastic arteries*, which are the larger vessels that carry blood from the heart to arteries of lesser diameter. The property of elasticity is a prominent feature of these vessels; and (2) *muscular arteries*, which are of smaller diameter, that distribute blood to specific organs. The muscular characteristics of these vessels provide ability to reduce (by contraction) or expand (by relaxation) the blood flow in accordance with the specific demands of the organs being supplied. Arteries also have their own blood supply because of energy requirements. The arteries, capillaries, and veins so involved are identified as *vasa vasorum*. As with other blood vessels, the arteries divide and subdivide in a complex branching system. The smallest of these branches are called *arterioles*, and it is at the distal ends of these tiny arterioles that the capillaries begin. As the arteries become smaller, the proportion of smooth muscle to elastic tissue increases.

Arteriosclerosis and Atherosclerosis

Commonly referred to as *hardening of the arteries*, this is a condition that exists when the walls of the blood vessels thicken and become infiltrated with excessive amounts of mineral and fatty materials. Arteriosclerosis occurs in all races and among people living in all climates. The disorder tends to progress with the age of the patient and is sometimes considered a disease of the middle-aged and elderly, but it should be quickly observed that coronary artery disease is responsible for nearly one-third of the deaths of persons between the ages of 35 and 65. The disorder has been known for centuries, although it was not even partially understood until the last half of the 1800s, when the first hypotheses as to its etiology were proposed. The complex and still only partially understood process which causes arteriosclerosis is called *atherogenesis*, particularly as the process applies to the major arteries, such as the coronary arteries. "Hardening" of the major arteries is commonly referred to as *atherosclerosis*. Because of the great importance of this disease as a predisposing condition for heart attack and stroke, intensive research into the etiology, diagnosis, treatment, and prevention of atherosclerosis is being conducted worldwide. Although considerable progress has been made in recent years, the etiology of the disease has not been fully explained and, in fact, there are several viewpoints on this topic. See also **Ischemic Heart Disease**; and **Cerebrovascular Diseases**.

Familial Hypercholesterolemia. In terms of the biological knowledge of the arteries, there is one exception to the foregoing statement, namely, the discovery of the genetic mechanism that is responsible for familial hypercholesterolemia (FH). For their discovery of the LDL (low density lipoprotein) concept and the biological pathways involved in FH, Michael S. Brown and Joseph L. Goldstein (University of Texas) received the Nobel Prize in Physiology or Medicine in 1985. The work of these researchers commenced in 1972. As acknowledged by Brown and Goldstein in their acceptance address, their work was buttressed by the findings of earlier investigators.[1] Rather than directing their efforts to a general relationship between cholesterol and cardiac disease, as had been the case of numerous statistical studies over recent years, Brown and Goldstein concentrated their attention on FH, a disease in which the concentration of cholesterol in the blood is elevated many times above normal and heart attacks occur early in life. The researchers postulated that this dominantly inherited disease was the result of a failure of end-product repression of cholesterol synthesis. Brown and Goldstein used the techniques of cell culture to explain the postulated regulatory defect in FH. Such investigations led to the discovery of a cell surface receptor for a plasma cholesterol transport protein (LDL) and to the explanation of the mechanism by which the receptor mediates feedback control of cholesterol synthesis. The gene encoding for the LDL receptor was shown to be defective in the case of individuals with FH. These defects were shown to disrupt the normal control of cholesterol metabolism. Further study of the LDL receptor led to an understanding of receptor-mediated *endocytosis* (process by which cells communicate with each other through internalization of regulatory and nutritional molecules). This process differs from

[1] In 1901, after studying a patient with black urine, Garrod, a physician, suggested that a simple mutant gene can produce a discrete block in a biochemical pathway, which Garrod called an "inborn error of metabolism." Garrod's exceptional insight preceded by some forty years the "one-gene-one-enzyme" concept of Beadle and Tatum. Later the Nobel Prize winning Linus Pauling and a physician, Vernan Ingram, through studies of patients with sickle cell anemia, showed that mutant genes alter the amino acid sequences of proteins.

previously described biochemical pathways because it depends on the continuous and highly controlled movement of membrane-embedded proteins from one cell organelle to another (a process now termed *receptor recycling*). It was learned that many of the mutations in the LDL receptor (of the type occurring in FH patients) disrupt the movement of the receptor between organelles. Brown and Goldstein concluded that these mutations define a new type of cellular defect that has broad implications for normal and deranged human physiology.[2]

Familial hypercholesterolemia was first described by Carl Müller (1938) who referred to its cause as an "inborn error of metabolism." Two forms of the disease (heterozygous and homozygous) were first noted by Khachadurian and by Fredrickson and Levy. The heterozygous form is the less severe of the two types and is present in persons who carry a single copy of a mutant LDL-receptor gene, numbering one person in 500 persons worldwide. Such individuals have a twofold increase in the number of LDL particles in plasma at birth and heart attacks become commonplace at ages 30 to 40 years. These individuals are 25 times more prone to suffer myocardial infarctions by age 60 than are members of the general population. Fewer persons (about 1 in 1 million) inherit two mutant genes at the LDL receptor locus, one from each parent. Needless to say, this form of the disease is much more serious than the heterozygous form. At birth, these persons have 6 to 10 times the normal concentrations of plasma LDL at birth and frequently suffer heart attacks during childhood. These findings in connection with FH indicate proof that high levels of plasma cholesterol can produce atherosclerosis in humans. However, the cause of heart attacks among the general populace, as related to cholesterol levels, still lacks the biological explanation and proof that some experts would like to see. As of the late 1980s, such proofs remained to be found, although there is voluminous statistical information to support the cholesterol connection. This is covered later in this article.

Traditional Concepts of Atherogenesis. In the late 1980s, the German physiologist, Rudolf Virchow, suggested that atherogenesis is a process involving the deposition of cholesterol and other lipids in the arterial wall, resulting from an abnormally high concentration of lipids in the blood. Virchow further suggested that endothelial cell injury initiated atherogenesis. During the intervening years, much clinical and experimental evidence has been collected to support the hypothesis and, in fact, during the first half of the present century, Virchow's hypothesis served as the basis for preventive cardiology. In more recent years, several other hypotheses have been proposed, but as of the late 1980s a fully satisfactory resolution of these various scientific viewpoints had not occurred.

From research on laboratory animals and human autopsies, much has been learned, when diseased arteries are examined, concerning the arterial deposits (plaques) and the structural and compositional changes that have occurred. Since atherogenesis is a slow process, and non-invasive instrumental methods for observing living tissues over a long period are limited, a fully satisfactory step-by-step description of the total process, including the initiating event or events, remains to be delineated.

Multiple-Risk or Risk-Factor Hypothesis

Beginning in the early 1980s, essentially by consensus among many scientists rather than by a bank of convincing scientific evidence and in lieu of a better understanding of the etiology of atherosclerosis, a multifaceted approach to the disease was considered the most practical guideline for professionals in the field. This hypothesis continues as the most influential concept in preventive cardiology. The risk factors include:

1. High serum concentration of blood lipids (hyperlipidemia), including the role of cholesterol.
2. Hypertension.
3. Cigarette smoking.
4. Insufficient exercise.
5. Certain genetic disorders.
6. Excessive intake of animal proteins, among others.

All of the listed risk factors appear to be predisposing factors for arteriosclerosis in susceptible individuals.

[2] As an aside, it is interesting to note that since it was first isolated from gallstones (1784), cholesterol has been of fascinating interest to scientists. Thirteen Nobel Prizes have been awarded to scientists who devoted most of their careers to studying cholesterol.

Hyperlipidemia — Role of Cholesterol. Numerous studies (see listed references) have provided statistical evidence to demonstrate the correlation of high levels of cholesterol with high levels of serum cholesterol. The linkage to cholesterol, in addition to the previously reported studies of Brown and Goldstein, is largely based upon the observation that atherosclerotic plaques contain large deposits of cholesterol and upon data from epidemiological studies.

Cholesterol is a steroid bearing an alcohol group. It is unstable in water and essentially all of it is carried in the blood as lipoproteins. Some cholesterol is required by the body as a precursor for the manufacture of certain steroids, such as bile acids and several hormones. Many investigators insist that the amount of cholesterol produced is governed in some way by the dietary intake of cholesterol and there is much statistical information to support this view.

Lipoproteins are large, complex polar molecules. Carried on the inside are the non-polar molecules, such as the triglycerides (esters of glycerol and three long-chain fatty acids) and esters of cholesterol. It has been estimated that much of the cholesterol is carried in ester form. The remainder exists as non-esterified cholesterol contained on the surface of the lipoproteins. Currently, the lipoproteins are categorized as:

LDL (low-density lipoprotein or beta fraction) — rich in cholesterol, but poor in triglycerides. Identified by Brown and Goldstein in connection with HF disease, as previously mentioned.

VLDL (very-low density lipoprotein or pre-beta fraction) — rich in triglycerides and contains substantial cholesterol.

HDL (high-density lipoprotein or alpha fraction) — normally contains 20–25% of the total cholesterol, but appears to exert a protective effect. It has been suggested that HDL inhibits cholesterol uptake by smooth muscle cells, or by transporting cholesterol out of smooth muscle cells to its site of metabolism in the liver.

The aforementioned ratio of total cholesterol to HDL cholesterol has been found to be a useful predictor of coronary artery disease and a more reliable indicator than the level of either fraction alone. A favorable ratio is 4.5:1 or lower.

Investigators have found that the LDLs carry much of the cholesterol found in the blood and play a major role in cholesterol metabolism (in cells other than the liver) and participate in the formation of atherosclerotic lesions. The function of the HDLs appears to be that of transporting cholesterol from the peripheral tissues to the liver. Although the HDLs may be incorporated into LDLs or VLDLs and recycled to the peripheral tissues, some investigators believe that the HDLs may provide a means for removal of cholesterol from the tissues and thus decrease the probability of its terminal deposition as atherosclerotic plaques.

It has been found that specific receptors for the HDLs are contained in human fibroblasts and certain other cells. The interaction of the HDLs with receptors is considered by some researchers as an initial step prior to the degradation of cholesterol and thus suppresses cholesterol synthesis in these cells.

As research continues, the explanations of the lipoproteins multiply, but currently with no common denominator within view. It is apparent that once a key is found, this will be the foundation of preventive measures. Although it is possible that such a key may be diametrically opposed to current preventive procedures, most practitioners are staying with the treatment of hyperlipidemia. Hyperlipidemia is treated primarily by dietary restriction, an approach that seems effective when elevations of both cholesterol and triglyceride levels are secondary to obesity and do not reflect a primary genetically determined form of hyperlipidemia. It has been found that weight reduction, achieved by restriction of food calories and alcohol intake, is the principal cause of the decrease in serum lipids in patients who respond to such therapy. Serum cholesterol can be reduced modestly by diets that are low in cholesterol or that substitute polyunsaturated fats (largely of vegetable origin) for saturated fats (largely of animal origin).

One of the most recent findings, described shortly, is the apparent relationship between fish consumption and coronary heart disease.

It has been a general practice of many cardiologists to treat high serum cholesterol levels either by dietary control, by drugs, or by a combination of the two. Cholestyramine is a high-molecular-weight resin that binds bile acids in the gastrointestinal tract and has been used quite extensively even though in some patients it has discomforting side-effects and is relatively costly.

A suggested regimen for dieting followed by many cardiologists is:

1. Avoid overweight by balancing caloric intake with exercise-mediated energy expenditure.
2. Reduce overall fat intake from about 40% to about 30% of total calories.
3. Reduce intake of saturated fat so that saturated fat and unsaturated fat each accounts for about 10% of caloric intake.
4. Reduce cholesterol intake to about 300 mg per day.
5. Reduce consumption of refined and processed sugars by about 45% so that such sugars account for about 10% of total calories; increase consumption of complex and unrefined carbohydrates from about 28% to about 48% of caloric intake.
6. Limit sodium intake to about 5 grams per day.

This diet, of course, is not exclusively directed to reducing cholesterol levels, but to accommodate other heart disease risks as well.

Hypertension as a Risk Factor. The risk of hypertension in coronary disease probably rises from the increasing physical stress placed on the arterial wall, thus enhancing the process of arterial wall injury. One hypothesis stresses how factors such as variations in intra-arterial pressure and uneven flow patterns account for the distribution of atherosclerotic plaques. A difference in arterial pressure and its effect on plaque formation is demonstrated by the fact that high-pressure systemic arteries display much more damage than that found in the low-pressure pulmonary arteries. See entry on **Hypertension**.

Smoking as a Risk Factor. It has been established that smoking enhances platelet stickiness and causes coronary vasoconstriction produced by nicotine and hypoxemia induced by inhalation of carbon monoxide. In contrast with the risk of smoking (cumulative) in lung cancer, the risk in coronary disease appears to be reversible upon discontinuation of smoking.

Lack of Exercise as a Risk Factor. The popularity and broad acceptance of the importance of exercise in preventing coronary artery disease greatly exceeds the scientific evidence. For example, there is no evidence that coronary collateral vessels develop or that atheromatous changes regress as a result of exercise. Exercise as a factor in weight reduction can lead to a reduction in serum lipid levels, but as previously described, lipid levels remain a topic of controversy. **It should be noted here that the importance of exercise for the rehabilitation of patients who have had a clinical coronary disease, recently or remotely, had different goals and techniques than a program designed for a healthy person as a preventive measure**.

Although stress, personality, and behavior patterns as causative factors in coronary artery disease have received wide public recognition and recognition by some physicians as well, relatively little attention has been given to this topic by pathologists and epidemiologists, largely because these factors are difficult to study.

Response-to-Injury Hypothesis. The role of injury to endothelial cells, part of Virchow's original hypothesis on atherogenesis, has been revived in recent years and current findings are based largely upon studies of lesions of animal arteries. The present version states that plaques form in response to frequently recurring injuries to arterial walls. It has been noted that nearly any type of chronic injury to animal arteries will progress to the formation of lesions that are much like the plaques found in human arteriosclerosis. This hypothesis suggests that injury to the endothelium, causing desquamation (shedding of superficial cells), is the primary event. Smooth muscle cells then migrate from the media into the intima through fenestrae in the internal elastic lamina and there undergo active proliferation within the intima. The adherence of platelets to exposed connective tissue may cause the formation of platelet aggregates, or microthrombi. As the lesion progresses, fibrosis, lipid deposition, and calcification may ensue, thus yielding the type of complex plaque noted in diseased arteries.

Based largely upon this hypothesis, platelet-inhibiting drugs, such as aspirin, are in use.

A Genetic Approach to Heart Disease

The risk-factor hypothesis previously described is, in a way, an "after the fact" approach to minimizing heart disease, requiring ambitious public awareness programs to alert the population of the risks (high blood pressure, high levels of serum cholesterol, smoking, etc.) and thus, by altering the habits of society, ultimately reducing the risk of heart disease. In another approach, some authorities believe that rather than targeting programs that intervene with societal habits (and thus meet with very slow acceptance), the principal effort should be directed toward determining well in advance those persons who are most likely to be naturally prone to heart disease. One very obvious way to do this is to turn the problem over to molecular biology. At a conference of the American Heart Association (Sarasota, Florida, January 1986), an approach taken by California Biotechnology, Inc. (Mountain View, California) was described. This group is seeking genetic markers near the sites of genes that are known to be involved with lipid metabolism and with blood pressure regulation. The target, of course, is to develop highly accurate predictive tests for identifying persons at risk. One spokesman for the group expressed that a test of 90% accuracy for predicting persons who will get cardiovascular diseases will be relatively easy to attain and that a level of nearly 100% accuracy may be possible. Some genetic proof for this approach rests in the fact that there are numerous examples of where heart disease has a familial connection. Specialists in the field predict that genetic markers for heart disease may become as common and as well accepted as those which currently apply to Huntington's disease and muscular dystrophy, among other well known diseases with a hereditary nature.

Buerger's Disease

This is an arterial disease (*thromboangitis obliterans*) which also may involve the veins. This is an inflammatory disease followed by obliteration of the lamina. This results in impairment of the circulation to the extremities, manifested by coldness, cyanosis, pain, and, if untreated and uncontrolled, eventually gangrene of the affected part. Treatment is directed toward improving the circulation of the extremities by special exercises, elevation of the affected part, drug therapy, and occasionally surgical measures that remove vessel-constricting impulses by interfering with their nervous pathways.

Aortic Aneurysms — Synthetic Grafts

The presence of aneurysms in any segment of the ascending aorta often occur, resulting from prior aortic dissection, atherosclerosis, and uncommonly aortitis, syphilis, and trauma. The ascending aorta is also subject to diffuse fusiform dilatation, which is associated with aortic valvular regurgitation, a condition called *annuloaortic ectasia*. Effective treatment often involves synthetic graft replacement of the ascending aorta, sometimes also requiring replacement of the aortic valve. Atherosclerotic aneurysms of the descending thoracic aorta are usually asymptomatic and have little tendency to rupture or to cause pressure symptoms. They are seldom removed unless large (greater than 10 cm), or progressively enlarging and causing symptoms.

Aneurysms are found more often in the abdominal aorta, usually an atherosclerotic lesion most frequently found in men over 60 years old. Noninvasive techniques are reliable for detecting these aneurysms. Although not usually required, angiography is sometimes used prior to surgery. The usual procedure is resection of the aneurysm and replacement with a prosthetic graft. Mortality of the procedure ranges from 2 to 5%, death usually caused by myocardial infarction. Patients considered of possible high risk are evaluated thoroughly prior to the final decision for surgery. Such clinical evaluation may include treadmill exercise testing, radionuclide scanning, and coronary arteriography. In the case of a ruptured aneurysm, emergency surgery is required, which involves an operative mortality risk of 25 to 50%.

The occurrence and treatment of acute peripheral arterial occlusive disease and chronic occlusive arterial disease is beyond the scope of this encyclopedia.

Other diseases of the arteries include *aortitis*, which is an inflammatory condition sometimes defined as a nonspecific form of pathologic change that represents a final common effect of many disorders arising from such underlying causes as syphilis and bacterial infection. Aortitis also may be associated with rheumatoid arthritis, lupus erythematosus, scleroderma, psoriasis, ulcerative colitis, and Crohn's disease. Important forms of primary aortitis are the ideopathic diseases known as *Takayasu's aortitis* and *giant cell arteritis*. Takayasu's aortitis (also known as pulseless disease) principally affects young women and is mainly seen in Asia. Giant cell arteritis is characterized by an accumulation of multinucleated giant cells in the arterial walls. Usually found in the elderly, giant cell arteritis can be treated effectively with corticosteroids.

Venous Disorders

Varicose Veins. These are veins that have lost their elasticity and, as a consequence, are irregularly enlarged and swollen. They have a dilated, lumpy, twisted and tortuous appearance. The overlying skin may be affected with ulcers. Varicose veins are most often seen in the legs of middle-aged and older persons, although certain conditions, such as pregnancy, may cause them to appear in younger adults. The dilation of the veins results from the inability of the weakened venous walls to withstand the pressure of the blood within the veins.

If the veins were simply continuous tubes running from the legs to the heart, the weight of a column of blood carried this high would press out on the leg veins when the individual stood erect. Normally, the column of blood is broken by the presence of valves that prevent the full weight of the blood from causing undue pressure on the veins in the leg. See Fig. 1. If a vein loses its elasticity, it will become distended, and the valves will fail to close completely. The weight of the blood in that vein then presses out on the walls of the vein, causing even more distention; and a reversal of flow of blood in that vein may occur. The veins also may become swollen when a venous constriction prevents the normal emptying of the blood.

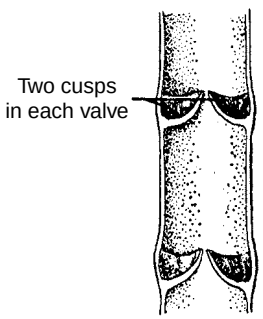

Fig. 1. Large vein, showing how valves composed of two cusps occur along the vein and prevent the back flow of blood in these vessels.

The classical sign of varicose veins is the actual appearance in the legs of swollen, tortuous, blue veins. The enlargement may affect a short segment of a single vein, or nearly all of the veins in the entire leg. When a systemic disease is responsible for the disorder, it usually appears in both legs to an approximately equal degree. *Phlebitis* (inflammation of a vein), constriction, injury, or obstruction in the veins in one leg, however, will affect only the one leg. Aside from disfiguration, varicose veins cause appreciable physical discomfort. Both dull and stabbing pains may be noted, and the entire limb may become quite swollen. When the condition has existed for some time, the veins sometimes become toughened and thick, so that they feel firm to the touch. More often, however, they are soft and elastic, except at the hard knotty swellings that occur in the regions of the valves. Ulceration and bleeding may leave large black and blue areas beneath the skin. In men, a type of varicosity may occur in which the veins in the scrotum are affected. In this condition, known as *varicocele*, the scrotum contains a soft, tumor-like mass of swollen venous materials. Similarly, varicosity of the veins in the rectum is known as *hemorrhoids* (piles).

In severe cases of varicose veins, it may be necessary to surgically remove portions of a vein that are particularly bothersome, or strip out the entire varicose vein. In milder cases, merely tying off (ligate) the varicose veins to relieve pressure may suffice. Occasionally, a combination of an operative procedure and sclerosing solutions which close off small veins may be required.

Raynaud's Disease. A vascular disorder characterized by paroxysmal cyanosis of the fingers in response to cold or to emotional stimuli. Toes, ears, chin, may also be affected. The disease appears most commonly in women in the third decade of life, and familial connections have been described. The cyanosis is due to interference with the blood supply through constriction of the vessels (vasospasm) resulting from abnormalities of the nervous control of the vessel walls.

Venous Thrombosis. Two forms of venous thrombosis are presented: (1) Lesions in *superficial veins* may be caused by tightly adherent thrombi. There may be significant inflammation and in some cases cellulitis, but these thrombi rarely penetrate to deep veins to cause pulmonary emboli. Treatment includes application of local heat and possibly administration of antibiotics where infection is suspected. (2) *Deep venous thrombi* may lead to pulmonary embolism, the latter being a life-threatening situation. Some physicians describe deep venous thrombi as "silent" because they may not be detected by routine clinical examination. In fact, the primary site may be difficult to fix even after the diagnosis of pulmonary embolism. However, when present, clinical signs include distended veins, localized areas of tenderness over venous structures and, in the calf, notation of increased heat, edema, and sometimes discoloration. Some conditions mimic the symptoms of deep venous thrombi, including rupture of calf muscle fibers or of synovial cysts involving the knee. Procedures for diagnosis of deep venous thrombi include venography, which will reveal any filling defects. This procedure is used with discretion because the invasion necessary for venography can in itself induce venous thrombosis. Although not applicable to the calf, noninvasive diagnostic measures include impedance plethysmography and ultrasonography. Radionuclide scanning is useful in connection with the calves, but not in the thighs. The treatment of deep vein thrombosis is the prompt administration of intravenous heparin. This drug acts rapidly in preventing further thrombus formation and prevents the release of serotonin and thromboxane A_2 from platelets adherent to those thrombi that embolize to the lungs. See **Anticoagulants**.

Pulmonary Embolism. The formation of emboli is the major consequence that is feared from deep venous thrombi. Although pulmonary emboli are sometimes overdiagnosed, statistics also show that in a high percentage of fatal cases, the disease has gone on unsuspected for quite a period of time. The usual symptoms are apprehension, weakness, faintness or syncope, dyspnea, and a substernal pain that is not distinguishable from that of myocardial infarction. Lung examination may indicate wheezes. To assist in diagnosis, the physician will order blood gases analysis and frequently an emergency perfusion lung scan. However, a number of conditions also alter pulmonary blood flow and such scans are not fully definitive. In recent years, pulmonary arteriography has become the reference standard for the diagnosis of pulmonary embolism. However, the procedure is undertaken with discretion because of risks associated with it. Other diagnostic tools include chest x-ray, electrocardiography, and serum enzyme levels. Treatment of pulmonary embolism includes drugs, such as morphine sulfate or meperidine, to relieve pain and the institution of intravenous heparin therapy. After several days, the patient may be switched to oral anticoagulants, a treatment which in some cases may extend over a year.

Massive Pulmonary Embolism. In this case, large emboli occlude the proximal pulmonary arterial circulation, producing symptoms much like those of myocardial infarction. Usually, electrocardiography will distinguish between the two conditions. Massive pulmonary embolism causes many deaths and, in any case, must be considered a life-threatening emergency. Upon diagnosis, large doses of intravenous heparin are given, along with morphine and oxygen. If there is persistence of shock for over 30 minutes, an immediate pulmonary arteriogram should be done. However, this requires the equipment and skills of an open-heart surgery facility. In severe instances and where massive pulmonary emboli are confirmed, surgery to remove the embolism may be elected to save the life of the patient.

In the management of massive pulmonary embolism and severe deep venous thrombosis, thrombolytic therapy has been relatively recently available. This involves the use of streptokinase and urokinase, agents which hasten the dissolution of thrombus. Thrombolytic agents cannot be given concurrently with anticoagulants and they do have a number of side effects. Several years of additional experience will probably be required to assess the values and risks of thrombolytic agents.

ARTESIAN WATER. Artesian water is groundwater that flows freely at the surface from an artesian bore or well. The name artesian comes from the flowing wells constructed in the twelfth century at the Carthusian monastery near Lilliers in the northeastern French province of Artois.

The term "artesian" has also been extended to refer to artesian aquifers, in which the groundwater is under a sufficient pressure head to flow at the surface, and to artesian basins, sedimentary basins that may contain artesian aquifers. The term subartesian refers to the situation where the water level rises above the top of the aquifer but is below ground surface.

The artesian condition is, however, an accident of topography, not necessarily a property of the water, the bore, or the aquifer. For this reason, it is preferable now to use the term 'confined' to refer to the aquifer. 'Confined' implies the presence of a low permeability confining bed above the confined aquifer, which allows a positive (above ground) hydraulic head to be maintained. Rarely, flowing water can be obtained from an unconfined aquifer without a confining bed, provided there is a sufficient upward head gradient.

Artesian water is common in sedimentary basins, where there are extensive aquifers overlain by confining beds. The classic artesian basin is shaped like a saucer; the aquifer crops out around the elevated margins of the basin, where it can be recharged by rainfall or stream flow. See Fig. 1. The cities of London and Paris lie at the centers of their basins and were among the first cities to exploit artesian water on a large scale. The Great Artesian Basin in eastern Australia is one of the largest examples; it is 1,500 km (932 miles) across. However, artesian conditions can occur in other geological formations.

The phenomenon of free-flowing groundwater was first documented sometime in the first millennium B.C. at Dakhla Oasis in the western desert of Egypt, during the course of progressively deepening hand-dug wells. The first to explain the correct nature of artesian wells were Mahammad Karaji (died 1016) and al Biruni (973–1048), but in Europe, the explanation had to await an understanding of the hydrologic cycle. In 1691, Bernadino Ramazzini (1633–1714) described the artesian wells that were commonplace in the Italian city of Modena. He drew a geologic section, although it appears he envisaged underground rivers rather than porous strata as the water source. In 1715, Antonio Vallisnieri (1661–1730), President of the University of Padua, reasoned that rainfall on the mountains was the source of the artesian water at Modena and

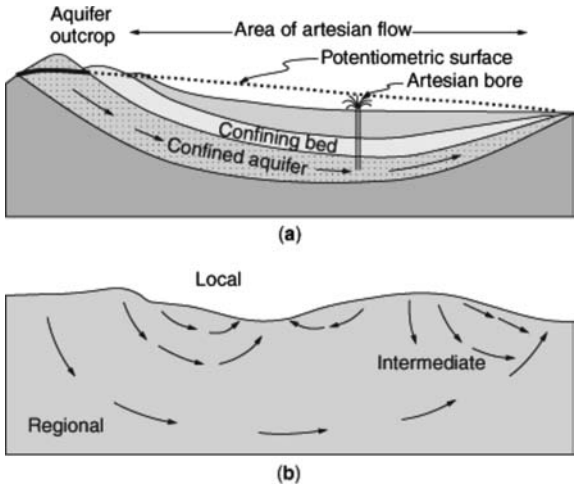

Fig. 1. Groundwater flow in a classical artesian basin (**a**) contrasting with cross-formational flow in local, intermediate, and regional flow systems in a nonclassical basin (**b**).

illustrated his work with geologic sketches of the Alps made by Johann Scheuchzer.

The existence of artesian water began to be widely appreciated in Europe in the early 1800s, after French engineers introduced Chinese drilling technology. The success of the Grenelle artesian bore near Paris, in which water rose to a height of 33 meters and flowed at the rate of 4000 cubic meters per day stimulated the development of artesian water. In the absence of suitable pumps, the availability of free-flowing water was an important economic factor in opening up new lands for agriculture and pastoral use in the Americas and Australia. The existence of the Great Artesian Basin in Eastern Australia was postulated in 1881. Proved by drilling in 1887, it rapidly led to pastoral development. The recognition of waterborne diseases and the contamination of shallow water supplies in cities was also an incentive to developing artesian supplies of clean drinking water in the Eastern United States, Europe, and Australia by the turn of the century.

Such was the impact of free-flowing water on the public that drilling for artesian water was often carried out in geologically unfavorable places (and despite professional advice); the perception was widely held that artesian water would be encountered, providing the boring was deep enough.

Geologic textbooks of the mid- to late 1800s illustrated the structure of classical artesian basins such as the Paris and London Basins, although it was recognized by the end of the century that flowing wells could also occur under different conditions. A series of papers by U.S. Geological Survey authors provided detailed explanations of artesian water. Thomas Chamberlin's classic paper (1), which is recognized as the beginning of the science of hydrogeology in North America, systematically laid down the conditions under which artesian flows would be obtained: the presence of a pervious stratum, impermeable beds above and below, an inclination of the beds so that the edge is higher than the surface at the well, and adequate rainfall.

Chamberlin's observations can now be qualified somewhat. Few, if any, confining beds are now considered completely impermeable, and in many places, the confining beds yield significant amounts of water by leakage to adjacent artesian aquifers. Tóth has drawn together ideas on regional hydraulic continuity, recognizing cross-formational flow in which it is not necessary to have inclined beds to produce artesian conditions. In many artesian basins, the water is of great antiquity, a million and a half years in the case of the discharge from the Australian Great Artesian Basin, although current rainfall is necessary to maintain the hydraulic head in recharge areas.

In 1928, Oscar Meinzer's paper on the elasticity of artesian aquifers drew together much of the work from the intervening period, demonstrating the concept of elastic storage, whereby flowing water is released by the reduction in hydraulic head and compressibility of the aquifer matrix.

However, there were many who denied the conventional theory (held in the main by Geological Surveys) that the origin of the water was meteoric and that the pressure was related to the elevation of the water table in outcrop areas of artesian aquifers. In Australia, distinguished academic geologists such as J. W. Gregory (1906) and Alexander du Toit (1917)

invoked juvenile and connate water, rock pressure, and gas bubbling to explain the origin of water and pressure. These ideas were supported by American geologists whose oil-field experience led to the concept of closed and hydraulically isolated systems.

There is still debate surrounding the explanation for the origin of artesian pressure, stimulated by studies of nonclassical basins such as the Hungarian Basin, and this has led to a better understanding of basin hydrodynamics.

Studies of the Great Artesian Basin clearly show the hydraulic continuity of aquifers over large distances and the observed potentiometric heads that decline gently away from the recharge areas. Furthermore, isotopic age dating using chlorine-36 indicates a transit time across the basin of 1.5 million years that correlates with hydrodynamic modeling.

Artesian water is released from elastic storage, and as the pressure is reduced, the aquifer matrix bears more of the hydrostatic pressure. Thus, subsidence occurs in most situations where the compressibility of the aquifer is much greater than that of water itself. Artesian flows may also lead to irreversible consolidation of aquifers, particularly in geologically recent environments that are not fully consolidated. In large artesian systems such as the Great Artesian Basin, free-flowing water is effectively mined from elastic storage, as there is little potential to induce more recharge on the timescale of abstraction. Maintenance of artesian head is the priority for management, given the economic consequences once bores cease to flow. In the Great Artesian Basin, a program is underway to cap and control the flow of artesian bores to maintain the aboveground pressure and to prevent the waste of water, which had been allowed to flow many kilometers in open 'bore drains' to water livestock.

Owing to the great depths from which it may come, artesian water is often much warmer than the shallow groundwater and may have to be cooled before use. A feature of artesian bores is that the head of water varies according to the temperature. A bore may cease to flow after the water is shut in and the water column cools. Artesian flows may also cease after degassing in a shut-in bore. Artesian flows are also affected by barometric pressure changes.

Artesian water may also be relatively highly mineralized, owing to the long travel time, and contain gases and dissolved iron, which may precipitate at the surface. The words may, therefore, have a bad connotation in terms of drinking water.

ARTHRITIS (Infectious). An inflammatory joint disease caused by pyogenic (pus-forming) bacteria, mycobacteria, or fungi.

Acute Bacterial Arthritis. The *acute* form of the disease is usually caused by pyogenic bacteria, of which the most common cause is *Neisseria gonorrhoeae*. Of the remaining cases, caused by nongonococcal bacteria, *Staphylococcus aureus*, *Streptococcus pneumoniae*, and other strep microorganisms are involved. A wide variety of infections which cause bacteremia may predispose acute bacterial arthritis — pneumococcal pneumonia, endocarditis, skin infections, and cholangitis, among others. The condition may develop as the result of joint surgery. As reported by Goldenberg and Reed (see reference), septic arthritis complicating prosthetic-joint surgery has become a serious medical problem since the late 1970s. Early accounts of prosthetic-joint surgery reported a 5 to 8% rate of infection (1972). Later reports indicated a 1 to 4% infection rate. However, a 1984 report indicated that the infection rate can be as high as 30% in surgical revision of prosthetic joints. In most studies of prosthetic-joint infections, the cases have been divided into *early* (occurring in the first postoperative year) and *late* infections. Intraoperative wound contamination is considered a likely source of some early infections, whereas late infections are most likely to be hematogeneously acquired. Staphylococci are the most common pathogen. *Staph, epidermidis* accounts for 40% of prosthetic-joint infections, and *Staph, aureus* for 20%. Multiple organisms and anaerobic bacteria also are often involved. About 12% of cases of acute bacterial arthritis are attributed to gram-negative bacili. An infection of this type is sometimes called *acute septic arthritis*. Related or predisposing factors include urinary or biliary tract infection, neoplastic (tumor-forming) diseases, diabetes mellitus, intravenous heroin abuse, and certain antibiotics and immuno-suppressive drugs. In about 20% of cases, *Salmonellae* are implicated; *Pseudomonas* and *Serratia* species are usually involved in cases of septic arthritis in narcotic addicts. *Haemophilius* influenzae is an uncommon agent in adults, but is a frequent cause of the disease in children. At one time, prior to tight health controls over milk and milk products, brucellosis was a major cause of spinal infectious arthritis.

Bacteria may invade the joint cavities by way of the bloodstream or they may spread from a contiguous focus of osteomyelitis. Purulent discharge may damage articular cartilage, joint capsule, and subchondral bone.

Symptoms of bacterial arthritis are hot, swollen, and painful joints. Onset may be abrupt, particularly in the presence of systemic illness. Fever of a transient or low-grade level may be present. Most frequently involved joints are the knees, followed by hips and shoulders. Symmetry is not usually present, an advantage in terms of diagnosis.

Precise diagnosis usually requires examination and culture of joint fluid. In early phases of the disease, x-rays are of little help. There are several disorders with similar symptoms and the diagnosis may be complex. Early diagnosis, however, is extremely important if recovery without permanent joint damage is to be achieved. Choice of most effective antimicrobial and antibiotic therapy hinges on accurate diagnosis. Drainage of the affected joint is also important to reduce pressure and to remove cartilage-destroying enzymes present in the pus. Aspiration at intervals over several days may be required. Moderate movement of the joint after the initial phase is encouraged to maintain mobility of the joint. The affected joint should not be subject to weight bearing, however, until inflammation has subsided. With early diagnosis and prompt therapy, full recovery without joint damage can be expected.

Tuberculosis Arthritis. This is uncommon. The disease is caused by the presence of *Mycobacterium tuberculosis*. The joints most often involved are hips and knees in children and vertebral joints in adults. Predisposing factors include diabetes mellitus, lupus erythematosus, narcotic addiction, and intra-articular injections of corticosteroids. Often present for a long period without notice by the patient, the disease can result in serious, permanent joint damage. Diagnosis may require an open synovial biopsy. Therapy includes resting the joint and use of antimicrobial drugs, such as isoniazid and ethambutol.

Fungal Arthritis. This relatively uncommon type of infectious arthritis results from invasion by mycotic agents and varies considerably with geographical location. For example, the disease may be associated with coccidiomycosis in the southwestern United States and with blastomycosis in the southeastern United States. Amphotericin B therapy is usually indicated.

Syphilitic Arthritis. This may occur in congenital, secondary, or tertiary syphilis. It is most commonly seen in infants and very small children with congenital syphilis. In these instances it may lead to destructive osteochondritis. A more moderate form of the disease may develop in older children and adolescents with congenital syphilis. Penicillin therapy is usually indicated.

Lyme Arthritis. This relatively recently recognized disease is attributed to a virus. The disease can result in chronic joint destruction, but in most cases is self-limiting. See also **Lyme Disease**.

ARTHRITIS (Rheumatoid). See **Rheumatoid Arthritis**.

ARTHROPODA (Arthropods). Arthropods generally exhibit ecdysozoan features such as the presence of a cuticle, reduction or absence of locomotory cilia and a cuticular moulting cycle regulated by ecdysteroids. Arthropods (or panarthropods) nevertheless share derived morphological characteristics that distinguish them from other ecdysozoa, for instance, compound eyes and a segmented, jointed and hardened exoskeleton, which has internal musculature. Arthropod segments usually arise by teloblastic growth; each segment primitively bears a pair of jointed limbs and exhibits other typical arthropod features (Fig. 1). Segments tend to be grouped into body regions or tagmata and specialized in this regard. Major groups of arthropods exhibit a characteristic tagmosis (Fig. 2a,b); for instance, insects and crustaceans have three tagmata–head, thorax and abdomen–with a characteristic number of segments comprising the head. Subsidiary taxa of these major groups may have a characteristic number of segments in the thorax and abdomen as well. Considerable debate exists concerning the homology of head segments in different groups of arthropods. For instance,

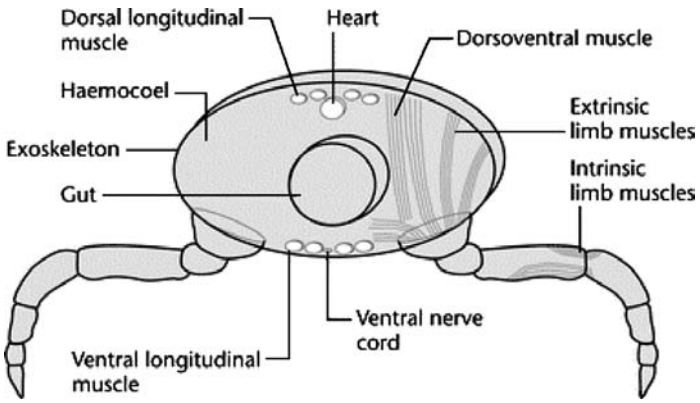

Fig. 1. A cross-section of a typical arthropod segment showing basic characteristics. All arthropods are built from many such segments, which may be modified in various ways.

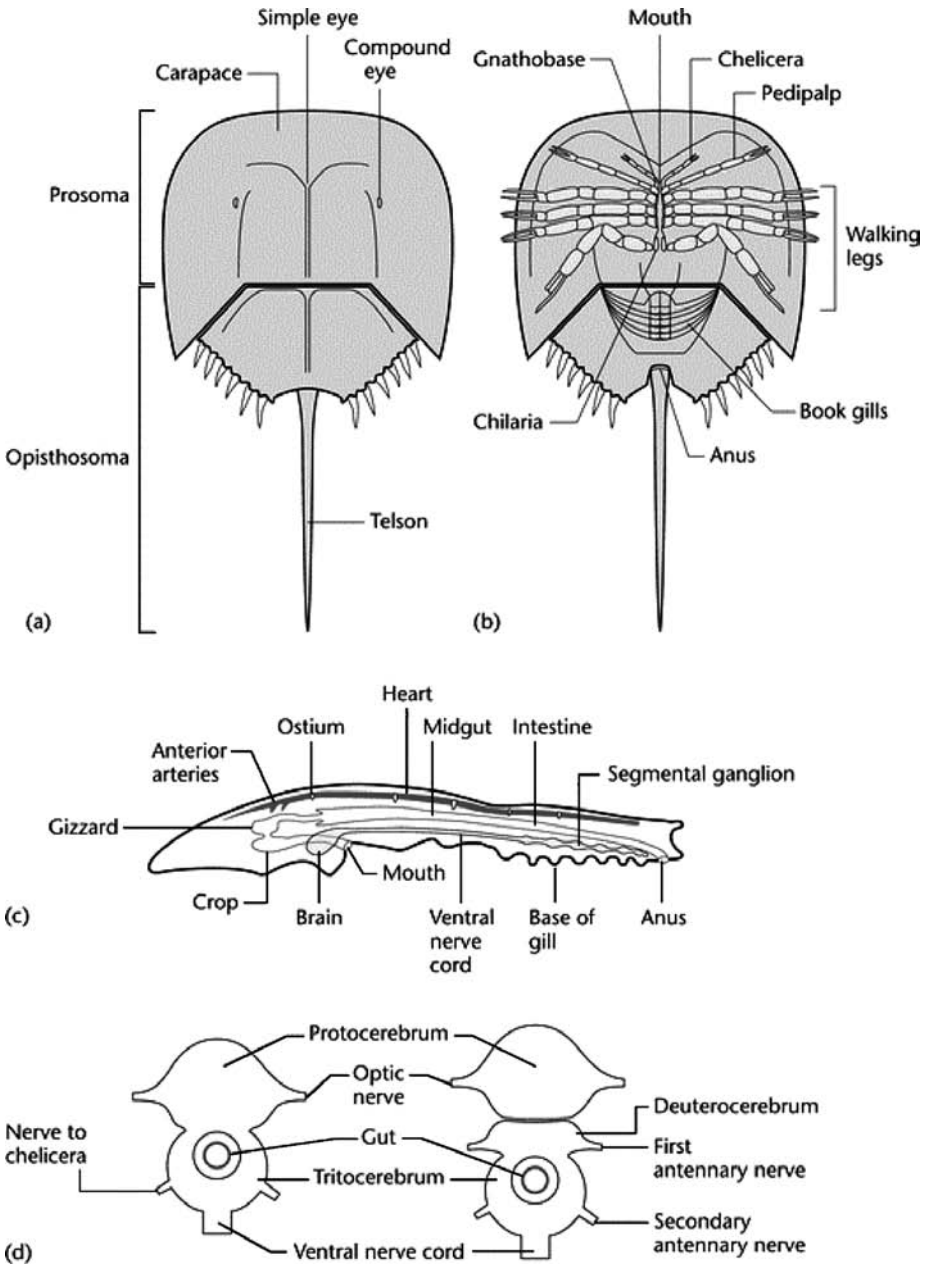

Fig. 2. Dorsal (**a**) and ventral (**b**) views of *Limulus polyphemus*, the common horseshoe crab of Atlantic and Gulf coasts of North America. This xiphosuran chelicerate shows many typical arthropod features both externally and internally, (**c**) comparison of the structure of the arthropod brain, e.g. that of *L. polyphemus* and a crustacean and (**d**) might suggest that the chelicerae of the former are homologous to the second antennae of the latter, but this is far from clear.

the structure of the arthropod brain (Fig. 2d) might suggest homologies between head segments in chelicerates and crustaceans, but this is far from clear. Arthropod limbs exhibit two forms: uniramous (one branch) and biramous (two branched). Generally chelicerates, myriapods and insects have uniramous limbs, while crustaceans and trilobites have biramous limbs. Limbs of major groups of arthropods also show characteristic numbers, morphologies and functions. Antennae, mouthparts, chelicerae, walking legs, grasping and swimming appendages are all derived from the basic arthropod limb (Figs. 1 and 2). Arthropods also include the only invertebrate group to evolve flight. Internal features (Figs. 1 and 2) include a reduced coelom, an open circulatory system with a dorsal, ostiate heart, a complete gut, a dorsal brain and paired ganglionated, ventral nerve cords. See also **Crustacea**; **Crustaceans**; and **Insect**.

Diversity and Abundance

At least 75% of all animal species so far described belong to the phylum Arthropoda, and millions of species, particularly of insects, probably remain to be described. Insects, spiders, scorpions, horseshoe crabs, centipedes, millipedes and crustaceans are all arthropods; together these arthropods are not only abundant and diverse, but also play vital roles in all ecosystems. This dominance of arthropods has continued since the earliest beginnings of animal life, although different groups of arthropods have been predominant at different times in the history of life. Initially, the now-extinct trilobites were the most prominent group; later, the now largely extinct merostomates (horseshoe crabs and water scorpions) achieved prominence. Today, arachnids (scorpions, spiders, mites and ticks), crustaceans (barnacles, copepods, amphipods, shrimps, lobsters and crabs), myriapods (centipedes and millipedes) and insects (beetles, flies, butterflies, moths, ants, wasps and bees) are the major components of arthropod diversity. Notably, two of these modern groups–crustaceans and particularly insects–have evolved eusociality, a form of colonial, group-living in which only some of the participating individuals carry out reproductive functions. See also **Arachnids**; **Centipede**; **Crustacea**; **Crustaceans**; **Insect**; **Mite**; **Scorpion**; **Spider**; and **Trilobita (Trilobites)**.

Habits and Habitats

The diversity of arthropods corresponds to the diversity of the habitats that they occupy. Remarkably, arthropods have been enormously successful in marine, freshwater and terrestrial environments. The exclusively marine trilobites exploited a variety of habitats. Most were benthic, crawling over the bottom or ploughing through the upper layers of sediments. Larvae and even adults of some small species may have been planktonic. Merostomates include the giant (up to 3 meter (9.8 feet) long) water scorpions, which occupied marine and freshwater environments and may have even been more or less terrestrial. Scorpions are among the most ancient terrestrial arthropods, inhabiting a variety of terrestrial environments, particularly deserts and tropical forests. Spiders are one of the most abundant types of terrestrial animals. They inhabit virtually every terrestrial habitat as well as freshwater and intertidal marine habitats. The ability of spiders to produce silk and fashion it into webs and other devices has allowed them in some sense to construct and modify the habitats that they occupy. Arachnids are also unusual in that they lack compound eyes. Pycnogonids (sea spiders) are widely distributed in marine environments, functioning largely as slow-moving, "sit and wait" predators. Myriapods are terrestrial, functioning as active, aggressive — and poisonous — predators (centipedes) or herbivores (millipedes). Insects are spectacularly diverse in freshwater and particularly terrestrial habitats, and less commonly inhabit the fringes of the ocean itself. The success of insects is largely because of their intimate, extensive and long-standing relationships with angiosperms, the flowering plants–feeding on them, pollinating them, engaging in symbioses with them. The capacity of many insects for flight has further opened a range of habitats for them. Crustaceans, on the other hand, are predominantly oceanic and are found at all depths in every marine, brackish and freshwater habitat. Isopods (pill bugs) are one of the few groups of crustaceans that are truly terrestrial.

The Arthropod Cuticle

The characteristic hardened exoskeleton of arthropods in part explains their success as a group. This exoskeleton or cuticle is a complex layered structure secreted by the underlying epidermal cells (Fig. 3). While the cuticle has been most extensively studied in decapod crustaceans and insects, many of its features appear to be shared by all arthropods.

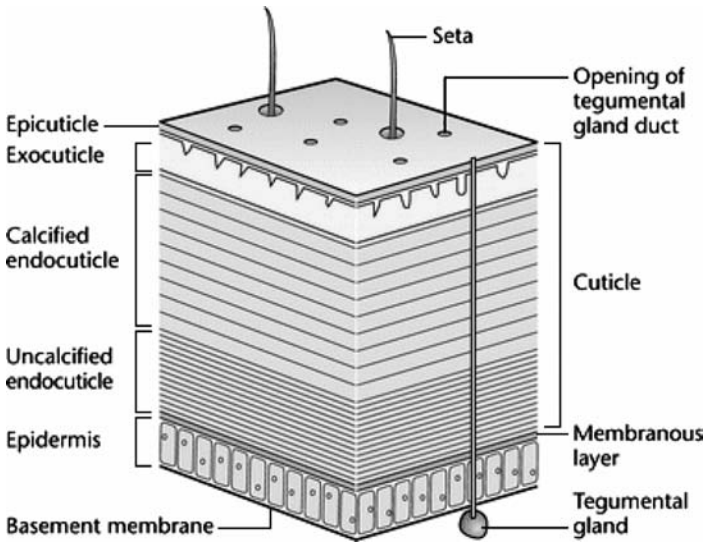

Fig. 3. The cuticle and epidermis of a crustacean.

The outermost layer (the epicuticle) consists of a protective layer of lipoprotein overlying the waxy layer. The waxy layer is particularly well developed in terrestrial insects and arachnids; it contains various long-chain hydrocarbons and fatty acids and serves to make the epicuticle both relatively water-impermeable and an effective barrier against pathogens. The innermost layer of the epicuticle consists of the cuticulin layer, which is made up of proteins. While the epicuticle is functionally important, it is also quite thin, consisting of only about 3% of the exoskeleton's total thickness.

The bulk of the cuticle consists of the procuticle, formed from layers of protein and chitin. The procuticle is sometimes divided into an exocuticle and an endocuticle. The procuticle is tough, but not necessarily rigid. Two processes produce a hardened, inflexible procuticle: mineralization and sclerotization. The former process involves the deposition of calcium carbonate and is common in crustaceans inhabiting mineral-rich seawater. The latter process involves "tanning" of the protein component by the formation of *o*-quinone crossbond linkages. Tanning probably occurs to some extent in all arthropods, but it is particularly common in terrestrial forms such as insects and arachnids.

The underlying epidermis or hypoepidermis is responsible for the secretion of the cuticle. In addition to epithelial cells, this tissue contains various unicellular glands, which may have ducts to the surface of the cuticle. Beneath the epidermis lies a distinct basement membrane, which forms the outer boundary of the main body cavity or hemocoel.

Arthropod Physiology

Arthropod physiology is in large part dictated by two features of the cuticle: first that it is relatively impermeable, and second that it usually cannot stretch or contract. Since a muscular, flexible body wall cannot be used to enhance blood flow, a muscular, pumping heart is necessary for circulation. On the other hand, since there are no closed coelomic spaces, an open circulatory system with a hemocoel is possible. Respiratory pigments, particularly hemocyanin, are common in larger forms. With regard to excretion, nephridia with open nephrostomes are not feasible–the blood of the hemocoel cannot be directly drained to the outside! Excretory structures must be internally closed and are often coelomic remnants associated with particular segments, although the identity of these segments may vary between different taxa, e.g. excretory structures are found on head segments in crustaceans and leg segments in arachnids. These efficient mechanisms of osmoregulation, coupled with the impermeable cuticle, contribute to the success of arthropods in freshwater and terrestrial environments. On the other hand, except perhaps in tiny arthropods with high surface-to-volume ratios, the largely impermeable cuticle does not allow gas exchange through the body wall so specialized structures have been developed. These structures take very different forms in marine and aquatic versus terrestrial groups. Larger marine and aquatic forms usually possess blood-filled, thin-walled cuticular evaginations that serve as gills. Terrestrial forms, on the other hand, have cuticular invaginations of various types, which allow oxygen to enter solution without excessive water loss.

The characteristic arthropod cuticle has its most dramatic effects on mechanisms of growth. A rigid exoskeleton precludes gradual changes in body size; consequently, growth takes place episodically by means of the process of molting or ecdysis. Many features of this process may be shared derived features of the ecdysozoa; certainly, because of the elaborate structure and function of the arthropod cuticle, these moulting cycles dominate the biology of arthropods. Actual tissue growth occurs during the intermolt stages (instars). When the exoskeleton is "filled" by this cell multiplication, the arthropod enters the premolt stage (proecdysis). Certain epidermal glands secrete enzymes that digest the old endocuticle, and the epidermis begins to separate from the exoskeleton. Beneath the old exoskeleton the epidermis secretes a new, soft cuticle. Subsequent to these events, actual ecdysis occurs. The old cuticle splits, usually in a characteristic manner for particular taxa, and the freshly molted arthropod pulls itself out. Immediately, this individual swells by the rapid uptake of water or air. The postmolt stage (postecdysis) commences with the hardening of the new exoskeleton by mineralization, or sclerotization, or both. It should be apparent that the many advantages of the exoskeleton are lost until the new exoskeleton has hardened; for example, even locomotion is difficult. Natural selection has no doubt streamlined the physiology of arthropod moulting. Nevertheless, as fossils in the Burgess Shale attest, the first arthropods appear to have molted much as modern ones do.

Since the moulting process involves the synchronization of various organism-wide physiological processes, it is no surprise that this process is hormonally controlled. Ecdysone is responsible for the initiation of proecdysis. At least in crustaceans, the secretion of this hormone is controlled in turn by molt-inhibiting hormone (MIH), which is produced by neurosecretory cells during intermolt stages. Sensory input from the nervous system mediates external (e.g. tidal cycles) or internal (e.g. soft tissue growth) stimuli and downregulates MIH, leading to the secretion of ecdysone and the initiation of active moulting.

While compound eyes occur in some lophotrochozoan groups (e.g. annelids and mollusks), these are probably independently derived from similar structures in arthropods. Indeed, studies of ostracods suggest that even among arthropods, compound eyes may have been independently derived. Certainly, the physiology of these eyes is a major topic in the study of arthropods. As their name implies, compound eyes include several or many distinct photoreceptive units, the ommatidia. Each ommatidium has its own field of vision, and each is supplied with its own nerve fibers that lead to the optic nerve. The visual fields of the ommatidia overlap to some degree. Thus the image that is formed by a compound eye differs greatly from that produced by a complex camera-type eye such as that found in cephalopods and vertebrates. In particular, compound eyes are useful for detecting and analyzing movement, because a shift in the position of an observed object causes changes in the nervous impulses from several ommatidia.

The Impact of Arthropods in the Modern World

Arthropods are inescapable in modern human life–as food, as pests, as carriers of disease and as 'model systems' in modern biology.

Drosophila melanogaster, the fruit fly, is one of the principal "model systems" of modern biology. Much insight into biology in general and human biomedicine in particular has been and will continue to be provided by *D. melanogaster*. For instance, the homeobox, a sequence of 60 amino acids that forms a helix-turn-helix motif and binds to deoxyribonucleic acid (DNA), was first discovered in *D. melanogaster*. This sequence characterizes a group of regulatory genes that has now been found to be widespread in animals. These genes act as "master switches" in a number of developmental processes. Notably, *D. melanogaster* and the nematode *Caenorhabditis elegans* represent the first metazoa to have their entire genomes sequenced. The study of these two creatures will no doubt continue to enhance our understanding of genetic mechanisms; nevertheless, the general applicability of these two model systems may be limited by their close relationship as ecdysozoa.

Insects are carriers of many human diseases. Mosquitoes in particular are vectors for malaria, yellow fever, viral encephalitis, dengue and other serious illnesses. Malaria, one of the most widespread human diseases, illustrates the sometimes complex process of disease transmission. When a female *Anopheles* mosquito feeds on human blood, she releases an immature stage of the protist *Plasmodium*. These protists multiply and mature within the human liver and blood. Mosquitoes feeding on humans now pick up mature *Plasmodium*, which then mate in the gut of the mosquito. Immature forms are produced within the mosquito, thus completing the life cycle and leading to subsequent human infection. Now that the genomes of both the protist parasite and the mosquito vector have been sequenced, a more complete understanding of the biology of these organisms should lead to progress in stopping malaria. See also **Malaria**.

Roughly 10,000 years ago as human agriculture developed in several parts of the world, one of the goals of these first plant breeders was probably to improve the production and palatability of these first crops. Inadvertently, in the process, the first conflicts between humans and insects were begun, in that selection for improved production and palatability also rendered these crops more vulnerable to insect herbivores, or "pests." This early human–insect conflict is manifest even in the Bible (e.g. the plague of locusts in Exodus). In the modern world, billions of dollars are spent annually to protect human crops. It is simply impossible for humans to grow food without protecting it from insects either with extrinsic pesticide use (e.g. dichlorodiphenyltrichloroethane (DDT)) or with intrinsic pesticides, or usually with both. Intrinsic pesticides, i.e. those produced directly and "naturally" by plants themselves may pose serious health risks for humans. It is estimated that humans ingest roughly 10000 different kinds of these 'natural' pesticides and their breakdown products. For instance, when cabbage is eaten, 49 natural pesticides are ingested, including glucosinolates, indoles, isothiocyanates, cyanides, terpenes and phenols. These and other compounds are widespread in domestic crops, and function largely to repel insect herbivores. Presently, there is considerable debate about the use of genetically modified crops, which also intrinsically produce toxins to repel insect herbivores (e.g. *Bt* corn). Environmental pollution related to pesticide use, human disease caused by natural and synthetic dietary pesticides, and social conflicts over genetically modified food all are ultimately due to the battle between humans and insects over food. It is of note that despite the best human efforts, insects consume roughly one-third of human harvests or potential harvests annually. See also **Plant Breeding and Crop Production**.

On a more positive note, honeybees alone pollinate billions of dollars of crops annually, not to mention producing millions of dollars worth of honey. Also, since humans do not directly farm the ocean for crops, and since crustaceans are largely marine, this group of arthropods is a major source of food for humans. Human fisheries of crustacean species abound, for instance, for crabs (e.g. snow and tanner crabs), crab-like species (the Alaska king crab and the South American centolla), shrimp and their relatives, and lobster. In the case of the American lobster, *Homarus americanus*, record catch amounts have occurred in recent years. Although the reasons for this are obscure, the over fishing of predatory fish species may be a contributing factor. Other fisheries have precipitously declined, for example, that of the red Alaskan king crab (*Paralithodes camtschatica*). In some areas, "farming" of freshwater shrimp is occurring, sometimes with detrimental environmental effects. Some human fisheries of nonarthropods are indirectly based on crustaceans, for instance, those of krill-eating whales, squid and fish in the ocean surrounding the Antarctic. While clearly the bulk of human diet is derived from land-based agriculture, direct and indirect fisheries of crustaceans have an impact disproportionate to their size because they provide high-quality protein. Given the 10% rule of ecological efficiency, replacing these fisheries with additional land-based agriculture would be essentially impossible. See also **Aquaculture**.

Fossil History

It is not merely in the present day that arthropods are the most abundant and diverse multicellular organisms; rather, the dominance of arthropods can be seen throughout the history of animal life, beginning with well-preserved fossil assemblages from the Cambrian. For instance, the Burgess Shale preserves the fauna from an ancient marine reef about 525 million years ago, near the dawn of abundant large-scale animal life. As with other Cambrian assemblages, trilobites such as Olenoides are common. Modern arthropods are also represented. Crustaceans appear in the form of Canadaspis, chelicerates as Sanctacaris, and onychophorans as Aysheaia. Nevertheless, there are also many arthropods, including the most abundant fossil Marrella, which do not so clearly fit into any of these (or other) groups of arthropods. In fact, one of the liveliest recent scientific debates focuses on these diverse Burgess Shale arthropods, their phylogenetic affinities, their morphological disparity, and their general significance in terms of organismal evolution. See also **Burgess Shale**.

While trilobites, in part because of their well-mineralized exoskeleton, dominate other Cambrian and Ordovician marine fossil beds, by the later

Paleozoic trilobites are less common, eventually becoming extinct in the end-Permian mass extinction about 250 million years ago. Merostomates (xiphosurans and eurypterids) are known from Ordovician marine deposits and flourished in the Silurian and Devonian. Eurypterids, the water scorpions, were often quite large and in some cases were common in freshwater and possibly terrestrial environments. While the eurypterids became entirely extinct in the Permian, a few species of xiphosurans are still extant (Fig. 2). See also **Trilobita (Trilobites)**.

Scorpions, perhaps a sister group of the eurypterids, are among the most ancient terrestrial arthropods, invading land prior to the Carboniferous. Insects also invaded terrestrial habitats at this time, although Devonian insect fossils are rare. Winged insects are common as Carboniferous fossils, suggesting that wings arose soon after insects' colonized land. Indeed, much of the success of insects is attributable to their wings. Early insect fossils do not elucidate the structure that wings evolved from, although studies of developmental regulatory mechanisms in modern insects suggest that they may have evolved from the basic limb structure. Generally, insect diversity coevolved with terrestrial plants, particularly angiosperms. Perhaps appropriately, amber is a major source of exquisitely preserved fossil insects. While there has been considerable popular and scientific interest in obtaining ancient DNA from insects in amber, initial reports were overly optimistic concerning the likelihood of success in this regard.

As with insects and their wings, the number, morphology and function of body segments and limbs have reflected the diversification of the arthropods throughout the Phanerozoic. With marine forms this was particularly apparent during the Mesozoic. At this time, marine crustaceans and their prey radiated extensively. Various crustacean groups (e.g. stomatopods and decapods) developed characteristic appendages that allowed them to become much more sophisticated in subduing their prey. In turn, groups of prey such as mollusks developed better antipredator defenses, e.g. in features of their shells such as thickness and sculpture. See also **Mollusca**; and **Mollusks**.

Phylogenetic Controversy — One Group or Many?

Discussions of the evolution of arthropods have been tied to the premise that annelids and panarthropods (Arthropoda + Tardigrada + Onychophora) are sister taxa within the larger "Articulata" taxon. A plausible stem lineage for these sister taxa would be a segmented, soft-bodied, worm-like creature with serially arranged coelomic spaces and well-developed circular and longitudinal muscles. If such a creature derived the major arthropod feature–a hard, jointed exoskeleton–a number of structural and functional correlates would have to evolve simultaneously. Circular and longitudinal muscles would no longer be useful in locomotion and would be lost, while striated muscles organized as intersegmental bands would evolve (Fig. 1). The coelom could no longer be used as a hydrostatic skeleton and would be lost, while an open circulatory system and a hemocoel would evolve. The latter would require a muscular heart and a closed excretory system. Moulting or ecdysis of the rigid exoskeleton would be required for growth. Adaptations for coping with osmotic and ionic stress, and for gas exchange, would evolve as appropriate. The evolution of these features collectively has been termed "arthropodization," and the controversy over arthropod monophyly has focused on the very real possibility that this evolutionary scenario may have occurred more than once, i.e. that this suite of functionally interconnected traits might be evolved independently in different groups of arthropods.

This controversy has a long history, and numerous specific hypotheses of arthropod polyphyly have been proposed. For instance, some have argued for a Myriapoda + Hexapoda + Onychophora clade ("Uniramia") with another clade comprising the trilobites, crustaceans and chelicerates. Other phylogenetic hypotheses describe a paraphyletic Arthropoda.

Nevertheless, the controversy over arthropod systematics has been completely recast by the recent "ecdysozoan hypothesis," i.e. panarthropods and annelids are not sister taxa, but belong to distinct clades of metazoa, presently termed Ecdysozoa and Lophotrochozoa. Within the Ecdysozoa, the sister group of the panarthropods now appears to be the clade containing the nematodes and the nematomorphs. By this hypothesis, evolutionary scenarios deriving arthropods from annelid-like ancestors via the process of "arthropodization" would be untenable. The ecdysozoan hypothesis nevertheless remains controversial (see the next section). See also **Nematodes**.

Modern Phylogeny

In what some have characterized as a debate between "molecules and morphology," nucleotide sequence data, particularly of 18S ribosomal DNA (rDNA), suggest that the relationship between annelids and panarthropods is unlikely to be close. Rather, these molecular data indicate that arthropods and allied taxa form the Ecdysozoa, a clade including other moulting animals. In particular, the Ecdysozoa emerges when rapidly evolving nematode sequences (which can lead to long-branch attraction and an apparent basal position for the nematodes) are removed from the phylogenetic analysis. Nevertheless, some careful morphological analyses have also raised questions about the close relationship between panarthropods and annelids, while at the same time sequence data from a number of genes neither supports nor contradicts the ecdysozoan hypothesis. In terms of relationships within the arthropods, morphological analyses have never reached a general consensus, and again molecular data have been and will continue to be crucial. The classification shown here (Table 1) will probably be further modified as additional genomic data become available and additional analyses are performed. At this time sequence data are not providing entirely clear subphyletic groupings, and other kinds of evidence (e.g. that of development) can contribute to this synthesis.

TABLE 1. A CLASSIFICATION OF THE PHYLUM ARTHROPODA AND THEIR CLOSE RELATIVE

Panarthropoda
Tardigrada
Onychophora
Arthropoda
Trilobita
Chelicerata
Merostomata
Arachnida
Pycnogonida
Mandibulata
Myriapoda
Hexapoda
Crustacea

Glossary

"Ten Per Cent" Rule of Ecological Efficiency — Roughly 10% of the energy at one trophic level is available to the next trophic level.

Amber — Fossil resin usually from coniferous trees.

Benthic — Bottom dwelling.

Clade — A group of organisms that includes the most recent common ancestor and all the descendants of that ancestor.

Coelom — An internal, fluid-filled body cavity that lies between the gut and the body wall and is lined with embryonically derived mesodermal tissue.

DDT — Dichlorodiphenyltrichloroethane, a synthetic chemical pesticide.

Ecdysozoan — An animal belonging to the clade containing arthropods, onychophorans, tardigrades, nematodes, nematomorphs, chaetognaths and kinorhynchs.

Ecdysteroids — Steroid hormones used in signaling ecdysis or moulting.

Hemocoel — A blood-filled cavity that bathes the internal organs.

Hydrostatic Skeleton — A fluid-filled cavity constrained by muscular body walls.

Intertidal — An area covered by the sea at high tide, while exposed at low tide.

Krill — Huge schools formed by gregarious euphausiaceans.

Long-branch Attraction — The tendency of parsimony-based methods to group long-branch taxa together.

Lophotrochozoan — An animal belonging to the clade containing lophophorates, annelids, mollusks, echiurans and sipunculids.

Monophyletic Group — A group of species that includes their single, common ancestor and all of this ancestor's descendants.

Nephridia — Structures used in excretion and osmoregulation.

Osmoregulation — Regulation of water and ion balance.

Ostiate Heart — A heart with pores to permit the entrance of blood from the hemocoel.

Panarthropods — Animals belonging to the clade containing arthropods, tardigrades and onychophorans.

Paraphyletic Group — A group of species that includes their single, common ancestor but not all of this ancestor's descendants.

Polyphyletic Group — A group of species that does not include their single, common ancestor.

Sister Taxa — The closest possible phylogenetic relatives, two taxa with a stem lineage common to them alone.

Stem Lineage — If a species becomes the stem species of a clade through splitting, its lineage becomes the stem lineage of the clade.

Symbiosis — An intimate association between different species, including parasitism, commensalism and mutualism.

Tagmosis/tagmata — Regional specialization of the body.

Teloblastic Growth — New segments arise during development from a specific budding zone at the rear of the animal.

ARTHROPOD-BORNE VIRUSES. Arboviruses (*ar*thropod–*bo*rne *viruses*) are those maintained in nature in cycles involving haematophagous arthropod vectors and susceptible vertebrate hosts. These viruses replicate in the arthropod host and transmit them biologically, not simply by mechanical means such as by contamination of the mouth part of an arthropod that has recently taken a blood meal from an infected vertebrate. Infected arthropods are able to transmit arboviruses to vertebrates from which they are ingesting blood. The vertebrate host becomes infected and may develop viraemia of sufficient level and duration to allow infection of subsequently feeding arthropods, thus continuing the vector–host–vector cycle. When the vertebrate host does not produce sufficient viraemia to serve as a reservoir for subsequently feeding arthropods, that vertebrate is considered a "dead-end" host. In any case, the term *arbovirus* is an ecological one. Viruses that are naturally transmitted by arthropods include those of many virus families and are not necessarily related one to another. Arboviral diseases are among the most common in the world: arboviruses cause a wide variety of illnesses in humans, livestock and wildlife.

Mosquitoes are the principal vectors for most recognized arboviruses, possibly due to intentional bias in collecting and processing; however, some arboviruses are transmitted exclusively by other biting flies or by ticks. Among mosquitoes, the female is the blood feeder, requiring specific blood proteins to produce eggs. This explains why arboviruses are usually isolated only from female mosquitoes in field studies. The rare isolation of virus from larval mosquitoes is taken as evidence of transovarial infection; isolations from male mosquitoes is evidence that the virus was acquired either transovarially or venereally from an infected female. Infection of the vector has been considered to be lifelong, with no observable pathological changes or untoward effects on the arthropod; some exceptions may occur. In sum, an uninfected mosquito takes a blood meal from a virus-infected vertebrate and becomes infected itself. After an extrinsic period of incubation in the mosquito, virus can be found in the salivary glands, from which it is released while taking a subsequent blood meal, thereby infecting the next host on which it feeds.

Classification

There are more than 500 recognized arboviruses and, because there are so many species of arthropods and vertebrates, there probably are many more than that. Included among the arboviruses of importance to humans, livestock and wild vertebrates are Rift Valley fever, LaCrosse, eastern equine encephalitis, yellow fever and dengue viruses. As noted above, arboviruses do not all belong to a single taxon. The term *arbovirus* is an ecological description. Molecular analyses have substantiated previous antigenic classification schemes. Genetic descriptions and taxonomy have substantially replaced the antigenic classification used in the past. Differences in antigenic, morphological, biochemical and genetic characteristics are used to separate arboviruses into families, genera and species, replacing the terms serogroups, antigenic complexes, viruses, subtypes and varieties, which reflect their decreasing order of relatedness.

Venezuelan equine encephalitis virus was discovered in 1939. Its geographic distribution, antigenic characteristics and epidemiology indicated that it was distinct from the two other equine encephalitis viruses recognized at that time, *Western equine encephalitis virus* and *Eastern equine encephalitis virus*. Results of classic antigenic studies, using both hemagglutination-inhibition and neutralization, demonstrated that these three viruses were related but distinct. Because some of these viruses were interrelated while others were also related to but distinct from those of the first group, it was suggested that the viruses related to *Venezuelan equine encephalitis virus* be considered members of a newly established group A arboviruses, to distinguish them from Japanese encephalitis, West Nile, yellow fever, St Louis encephalitis, and other viruses, the group B arboviruses. Conclusions from meticulous electron microscopic, physicochemical and genetic studies indicated the placement of the group A and group B arboviruses in the virus family *Togaviridae*; however, differences in replication mechanisms of these viruses required further division and the genus *Alphavirus* was formed from the former group A arboviruses, while the family *Flaviviridae* and the genus *Flavivirus* were formed from the former group B arboviruses. The rapid discovery of many viruses, variously related to each other, allowed the formation of "groups". It became clear that using letters for group names would soon be inadequate. In addition, certain viruses in some groups shared antigens with certain viruses in other groups. This conundrum was solved when it was recognized that many groups of viruses were similar morphologically and genetically and these viruses were then placed in "supergroups", now called *genera*. Arboviruses have now been placed in many virus families, including not only *Togaviridae* and *Flaviviridae* but also *Bunyaviridae*, *Rhabdoviridae*, *Reoviridae* and *Orthomyxoviridae*. Additional subdivision into genera within these families has been possible with some of the arboviruses. For example, viruses of the family *Bunyaviridae* have been placed in the genera *Bunyavirus*, *Nairovirus*, *Phlebovirus*, *Hantavirus* and *Tospovirus*, reflecting the remarkable variation among them. Mosquitoes transmit most bunyaviruses (viruses of the genus *Bunyavirus*); ticks transmit most nairoviruses; some of the phleboviruses are transmitted by mosquitoes, some by ticks and others by other insects. Hantaviruses, although included in the family based on molecular and morphological analyses, are transmitted exclusively from rodent to rodent and sometimes from rodent to human (usually a dead-end host) and are therefore not arboviruses. Tospoviruses (*to*mato *spo*tted wilt-related *viruses*) are transmitted between certain plants by plant-feeding insects, such as thrips. See also **Thrips (Insecta, Thysanoptera)**. Although arthropod-borne, they are not considered arboviruses because they are not transmitted by blood-feeding arthropods to vertebrates. Clearly, the arboviruses comprise a diverse assemblage of closely and distantly related viruses as well as viruses unrelated to them. Just as clearly, this diversity makes for challenges and provides interest. See also **Flaviviruses** and **Hantaviruses**.

Replication

The genetic code of all arboviruses is based on ribonucleic acid (RNA), not deoxyribonucleic acid (DNA). Because RNA viruses do not have the proofreading capabilities of DNA viruses, mutations (errors in the genome) are much more common among RNA viruses than among DNA viruses. Therefore, the rate of mutation of RNA viruses leads to greater variation among them and allows evolution of the viruses to move at a relatively rapid rate. This is advantageous for the viruses, in that they can continuously avoid antiviral responses of the hosts and adapt to new conditions. The versatility of arboviruses is apparent from their ability to replicate in such diverse hosts as insects, humans, rabbits, birds, reptiles and more. Viral versatility, however, is a disadvantage to the vertebrate host, in that it cannot develop a single system with which to fight infections with these viruses.

The genomes of flaviviruses and togaviruses consist of a single strand of positive-sense RNA. That is the RNA itself serves as the messenger RNA (mRNA), the carrier of the genetic message. The RNA genome of flaviviruses is approximately 11 000 nucleotides in length and is the only mRNA. The genome is capped at the 5′ end but has no poly(A) tract at the 3′ end. The complementary sequence of the 5′ end is similar to the 3′ terminal region of the plus strand, suggesting that these sites may be important for viral replicase recognition in initiation of RNA synthesis. Flavivirus RNAs have conserved noncoding sequences at the extreme 5′ and 3′ ends that may be important for virus replication and encapsidation. The genomic mRNA encodes a single polyprotein that is cleaved co- and posttranslationally by host signalases (a class of enzymes) and viral-encoded proteases to generate 10 viral proteins. The RNA genome of togaviruses comprises approximately 12 000 nucleotides. Togaviruses differ from flaviviruses both in gene arrangement and in the number of viral mRNAs. The 5′ two-thirds of the genomic mRNA of togaviruses encodes the replication and transcription machinery of the virus. A viral transcriptase is translated from the genomic mRNA early during infection and synthesizes a full-length negative-sense RNA. This negative-sense RNA serves as a template for replication of the genome and transcription of a subgenomic mRNA. The subgenomic mRNA is colinear with the 3′ two-thirds of the genome and encodes a single polyprotein that is posttranslationally cleaved to form the structural proteins of the virus. The mRNAs of togaviruses are capped at the 5′ end and have a poly(A) tract at the 3′ end.

The replication of bunyaviruses, orthomyxoviruses and rhabdoviruses is consistent with their having single-stranded, negative-sense RNA genomes. The first step after entry of the virus and uncoating of the viral negative-sense genome is to transcribe mRNA. Because the infected cell lacks the appropriate viral enzymes, all negative-strand RNA viruses package a transcriptase with the viral genome in the mature virion. Bunyaviruses have a tripartite negative-sense genome that consists of large (L), medium (M) and small (S) RNA species. The viral nucleocapsids are circular in configuration because of hydrogen bonding of conserved RNA sequences with inverted complementarity at the 3′ and 5′ termini. The S RNA segment codes for the nucleocapsid (N) protein and a nonstructural protein NS_s, which are translated from overlapping reading frames in the viral complementary sequence. The M RNA codes for a polyprotein that is posttranslationally processed, yielding the G1 and G2 glycoproteins and a nonstructural protein NS_m. The L RNA codes for the RNA polymerase. The S RNA of some bunyaviruses (genus *Phlebovirus*) is ambisense, meaning that the S RNA is both positive and negative sense. Orthomyxoviruses, such as the tick-borne Dhori and Thogoto viruses, have six or seven negative-sense RNA genome segments. These viruses are morphologically similar to influenza viruses. The RNA segments have 3′ ends similar to viruses in the family *Orthomyxoviridae*. Based on nucleotide sequences that have been compared to those of Influenza A, B and C viruses, segments 4, 5 and 6 of *Dhori virus* have been predicted to code for the single glycoprotein (521 amino acids), the nucleoprotein (474 amino acids) and the matrix protein (270 amino acids), respectively. As do bunyaviruses, orthomyxoviruses cap their 5′ terminus by scavenging cap sequences from host mRNAs. Also like bunyaviruses, orthomyxoviruses can increase their evolutionary potential by reassorting their genomes following superinfection of susceptible cells. In contrast, the rhabdovirus genome is a single negative-sense RNA comprising approximately 11 000 nucleotides. Five viral mRNAs are transcribed from the genome and each mRNA encodes a single viral protein. See also **Rhabdoviruses**.

Orbiviruses (family *Reoviridae*) possess linear, double-stranded RNA (dsRNA) genomes comprised of 10 segments. *Colorado tick fever virus* (genus *Coltivirus*; family *Reoviridae*) contains 12 dsRNA genome segments. The RNA segments and proteins of these viruses can be readily distinguished by their migration patterns in polyacrylamide gels and by their electrophoretic heterogeneities. Unlike the other arboviruses discussed previously, orbiviruses and coltiviruses do not possess envelopes. These viruses must also package a transcriptase in the mature virion to initiate transcription in the infected cell. Transcription of orbiviruses and coltiviruses is conservative and only the negative-sense dsRNA strand acts as a template for mRNA synthesis. As can other arboviruses with segmented genomes, orbiviruses and coltiviruses can potentially reassort their genomes in cells infected with more than one genetically similar virus. See also **Coltiviruses**; and **Reoviruses**.

No matter how many RNA segments, whether the segment(s) is positive-sense or negative-sense and whether the virion has a transcriptase or synthesizes one after it infects the cell, all these viruses enter the cell (different viruses have different mechanisms for this), direct their own replication (RNA, proteins and other constituents), the constituents self-assemble into whole, infectious virions and the cell releases these virions (different viruses have different mechanisms for this as well), which are then capable of beginning the cycle anew.

When cells are simultaneously infected with two very closely related viruses having multiple genome segments, reassortment of these segments can occur. Lifelong infection of the vector provides substantial opportunity for bunyaviruses and other viruses to evolve by genetic drift and, under suitable circumstances (i.e. mixed infection), by segment reassortment.

Epidemiology

Viruses evolve by a variety of genetic mechanisms: (1) substitution of single nucleotides by point mutation; (2) deletion of one or more nucleotides; (3) duplication of existing sequences; (4) insertions of nucleotides; (5) substitution of nucleotides, termed recombination when the genome is nonsegmented; (6) reassortment of segmented genomes; and (7) rearrangement of nucleotides. When any of these changes takes place, genetic variation, a potentially powerful tool for evolution, is generated. Such changes can be silent, in that they have no effect on virus replication and survival; they can be lethal to the virus, in that they eliminate a function critical to the ability of the virus to replicate; they can change the ability of the virus to replicate or confer on it a new ability, such as to extend its host range or to cross phyla, replicate at higher or lower temperatures, escape the effects of the immune system of the host, or otherwise become more competitive than before.

Both the evolution and the epidemiology of arboviruses can, at least in part, be attributed to their vectors, to their vertebrate hosts and to the viruses themselves. Because arboviruses are so diverse with regard to the number of their RNA segments, modes of replication, protein content and characteristics, arthropods and vertebrate hosts infected and other attributes, it is not surprising that the epidemiologies of these viruses are distinct, family to family, genus to genus and even virus to virus. Viruses from each of several families will be used as examples of these fascinating and important differences.

Family Togaviridae, Genus Alphavirus, Western Equine Encephalitis Virus (WEEV). The first comprehensive studies in the USA of an arbovirus causing human illness were begun in California. In the summer of 1930, Meyer and coworkers investigated an extensive epizootic of equine encephalitis in the San Joaquin Valley and isolated a virus from the brain of a sick horse. They wondered whether this same disease might account for a polioencephalomyelitis concurrently being noted in some people of the region. The next summer, the disease reappeared in epizootic form in the San Joaquin Valley and spread to other areas of California. It recurred in the summer of 1932 throughout much of California and in most western states. In each of those years the outbreaks ceased with the onset of cool weather. This finding, and that of high-level viraemias in acutely infected horses, led to the suspicion that the virus was arthropod-borne. Occurrence of a similar illness in humans in the same areas as the sick horses suggested that Meyer's earlier hunch was correct and stimulated further studies of the aetiologic agent, WEEV, which Meyer had isolated in 1930. Subsequently, the virus was shown in the laboratory to replicate in, and be transmitted by, *Aedes aegypti* mosquitoes and serological surveys indicated widespread infection of birds and a variety of other animals in the wild. The detailed clinical studies, epidemiological investigations and data analyses are classics in the history of both arbovirology and of virology in general and did much to establish arbovirology as a significant field of research. In 1938, WEEV was isolated from the brain of a child who had died from encephalitis and in 1941 it was isolated from naturally infected *Culex tarsalis* mosquitoes, first in the Yakima Valley of Washington and later in the San Joaquin Valley of California, where it had all begun. In sum, WEEV has been found mostly in the western USA and western Canada, replicates in arthropod and vertebrate cells (birds, horses, humans and others), is transmitted between wild birds by *Cx. tarsalis* mosquitoes and may be inapparent for many months or years, only to reappear when conditions are suitable. The exact nature of those conditions has not been determined but a great deal of information about the ecology of WEEV is available.

Family Togaviridae, Genus Alphavirus, Eastern Equine Encephalitis Virus (EEEV). EEEV cycles between wild birds, transmitted by *Culiseta melanura* mosquitoes, mainly in the states along the eastern seaboard of the

USA. In well-studied areas of New York, New Jersey and Massachusetts, it has been shown that *Cs. melanura* mosquitoes are the enzootic (epidemiologically unremarkable infections of nonhuman animals) vectors, transmitting EEEV between passerine birds, rarely from birds to equids or humans. Equids and humans may be dead-end hosts but the level of viraemia in some horses exceeds the minimal titre considered necessary to infect mosquitoes subsequently feeding on them. Epizootics (outbreaks in nonhuman animals) begin in swampy habitats and move outward when viraemic birds move: locally migrating viraemic birds may move virus to adjacent areas; and distantly migrating viraemic birds may disperse virus to areas further away.

A pivotal phase of the natural cycle of EEEV is the transfer of virus from enzootic to epizootic vectors and, from that point, epidemic extension. Considerable field evidence indicates that *Cs. melanura* mosquitoes, which are found in all enzootic foci in North America and which feed principally on birds, do not serve as epidemic vectors. This role is played by mosquitoes such as *Coquillettidia perturbans*, *Aedes vexans*, *Ae. canadensis* and *Ae. sollicitans*, which more commonly feed on mammals than do *Cs. melanura* mosquitoes. Recent studies in New Jersey have thrown considerable light on the dynamics of transfer of EEEV from coastal habitats, such as freshwater swamps and adjacent salt marshes, to more inland areas. Using banding, radiotelemetry and color marking, it has been shown that glossy ibis (*Plegadis falcinellus*), which feed in small flocks in fresh- or saltwater marshes, are often found in proximity to mosquitoes carrying EEEV. These birds roost in trees in freshwater swamps where *Cs. melanura* mosquitoes are abundant and spend the days feeding in salt-marsh areas where the potential epidemic vector *Ae. sollicitans* is abundant. The veterinary literature suggests that eastern equine encephalomyelitis has existed in New Jersey for at least 90 years but was not recognized in humans until about 1959 when the glossy ibis was introduced there and when New Jersey experienced its first epidemic. It may be that EEEV existed in enzootic cycles previous to the introduction of the glossy ibis but that changes in the ecology and the fauna in New Jersey have brought about the current situation.

As can WEEV, EEEV can infect and cause disease in horses and humans. Outbreaks of these two viruses are taken seriously by public health authorities because of the devastating nature of the illnesses they cause. Other alphaviruses, including VEEV and Ross River, Barmah Forest, chikungunya, o'nyong nyong, Mayaro, Sindbis, Semliki Forest viruses, and others, are known to cause a variety of illnesses, including uncomplicated fevers, encephalitis, fever with rash, fever with arthralgias (joint pains) and fever with rash and polyarthritis. As is true with the vast majority of all virus infections, infection with any of the 27 alphaviruses may result in no illness.

Family Flaviviridae, Genus Flavivirus, St Louis Encephalitis Virus (SLEV). SLEV was first recognized as causing a human encephalitic disease during an outbreak in Paris, Illinois in 1932. The virus was isolated the following year from human brain tissue in a similar but larger epidemic in St Louis, Missouri. Since its discovery, SLEV has been responsible for more than 1000 deaths, at least 10 000 severe illnesses and no fewer than a million mild or subclinical infections. In September 1933, the US Surgeon General, H. S. Cumming, detailed L. L. Lumsden, a Public Health Service field officer, to study the epidemiology of the ongoing St Louis outbreak. Lumsden reported that the epidemiologic characteristics indicated that mosquito transmission was involved and he provided evidence that *Cx. pipiens* mosquitoes, breeding in sewage ditches, was the species involved. Other investigators felt that the data were insufficient to support such a hypothesis and favored the idea of person-to-person transmission instead. Lumsden's report was shelved at the time, but his conclusions were corroborated by later studies. See also **Flaviviruses**.

In 1941, in the same Yakima Valley studies in which WEEV was first isolated from *Cx. tarsalis* mosquitoes, SLEV was obtained from this same mosquito species. Pathological and clinical characteristics of St Louis encephalitis in human cases were made, the incubation period was defined, laboratory animal host systems were developed, studies of disease epidemiology were begun and the geographic distribution was demarcated. Work indicated that *Cx. tarsalis* was to SLEV in the western environment what *Cx. pipiens* was to this virus in the east. SLEV was subsequently shown to be a member of the group B arboviruses (see above), now known as the flaviviruses. SLEV has been shown to occur from Canada to Argentina and to cause human disease wherever it occurs. Many strains and varieties have been recognized and isolates of SLEV have been obtained from rodents as well as birds (the natural vertebrate host), humans and other species. The natural cycle of this virus involves *Culex* species mosquitoes and birds and, as with WEEV, and EEEV, is recognized only when sufficient virus build-up in the natural hosts (mosquitoes and birds) allows "spillover" into humans.

In addition to SLEV, among the 68 recognized flaviviruses are those that, in the aggregate, cause hundreds of thousands of illnesses and immeasurable human misery each year around the world. Included are the viruses that cause dengue. This is usually a relatively mild illness characterized by fever, headache and rash, sometimes with severe joint pains and skin that is sensitive to touch. Four distinct viruses can cause this disease and they are distributed around the world in tropical and subtropical areas. These viruses are transmitted by the peridomestic mosquito *Ae. aegypti* or by *Ae. albopictus* mosquitoes. Outbreaks are explosive because these viruses are transmitted by these mosquitoes from human to human without the need for an intervening wild vertebrate host. However, uncomplicated dengue can set the stage for a more complicated and deadly disease, dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS). Although individual strains of dengue viruses may themselves cause these complications, it is more likely to be a combination of a unique individual dengue virus causing secondary dengue (an infection with a dengue virus subsequent to infection with another dengue virus), which results in DHF/DSS. It appears that the primary infection, which stimulates production of antibodies against that dengue virus, also predisposes the patient to the more severe form of the disease via what is known as antibody-dependent enhancement; that is, a small amount of antibody to the first dengue virus somehow sensitizes the body to the second dengue infection and, when such an infection occurs, immune complexes (antigen–antibody combinations) precipitate and cause blood vessels to leak, leading to pooling of blood and shock. Hypothetically, it is relatively simple to prevent dengue or to control outbreaks when they begin because all one need do is: (1) kill all the mosquitoes; (2) isolate patients so that they cannot be fed upon by questing mosquitoes; or (3) vaccinate people against these viruses. In practice, this is impossible. Further discussion of diagnosis and control of dengue can be found below. See also **Dengue Fever and Dengue Hemorrhagic Fever**; and **Hemorrhagic Fever Viruses**.

Japanese Encephalitis Virus (JEV). JEV is transmitted between birds and pigs principally by *Cx. tritaeniorhynchus* mosquitoes. People are at risk of acquiring infection with JEV if they are fed upon by infected mosquitoes. JEV is found in Asia, where it is the leading cause of viral encephalitis, with 30 000–50 000 cases per year (central nervous system (CNS) infections only, not including mild illnesses) with a case-fatality rate of 0.3–60%, depending on the quality of care the patients receive. Humans are only incidentally infected and are probably dead-end hosts for this virus.

West Nile Viruses (WNV). As are so many of the flaviviruses, the natural cycle of *West Nile virus* (WNV) comprises mosquito transmission between birds. *Culex* species mosquitoes become infected by feeding on birds infected with the virus, and these infected mosquitoes then can transmit the virus to humans and animals while they are blood-feeding. This virus also replicates in ticks but the role of ticks in transmission of WNV is unclear. This virus occurs rather commonly in Africa, some parts of Europe, western Asia and the Middle East but had not been detected in the western hemisphere until the summer of 1999, when it caused an outbreak of encephalitis in New York City. The overall case-fatality rate in West Nile virus encephalitis is 3–15% but is highest among elderly patients. Probably because wild birds in the USA have had no prior experience with this virus, individuals of many species of birds, particularly crows, die when infected with WNV; horses may become sick and develop encephalitis after WNV infection. As with other mosquito-borne viruses, seasonal peaks in virus prevalence and infections of vertebrates occur when mosquito populations are at their highest. See also **West Nile Virus**.

Yellow Fever Virus (YFV). The King of Terrors, Yellow Jack, the Saffron Scourge and other much more colorful and descriptive terms have been used to describe yellow fever, caused by *Yellow fever virus* (YFV), another flavivirus. This disease is endemic and occasionally epidemic in some areas of Africa and South America. The virus that causes it is carried by mosquitoes; in urban African epidemics *Ae. aegypti* or *Ae. africanus* is usually responsible. These peridomestic mosquitoes become infected by feeding on a viraemic human who has returned to a populated area from an area in which YFV was circulating, such as in a rainforest.

The nonepidemic, natural circulation of YFV in rural or forested areas is called *sylvatic yellow fever* and is transferred from the principal natural vertebrate hosts, usually monkeys, by tree-hole-breeding mosquitoes, in Africa usually *Ae. africanus* but sometimes *Ae. simpsoni* mosquitoes, in South America by *Hemagogus* species mosquitoes. Sylvatic yellow fever is usually sporadic, but can serve as the source of urban yellow fever. In Africa, *Ae. furcifer* and *Ae. luteocephalus* are the most commonly involved species of mosquitoes transmitting YFV in the sylvatic setting. African monkeys do not become ill when infected with YFV, and sylvatic mosquitoes will take a blood meal from humans who enter forested areas and from humans in villages at the forest edge, the "zone of emergence."

Yellow fever epidemics have been documented in Africa since 1778, causing hundreds of thousands of cases and tens of thousands of deaths. Massive vaccination campaigns, first begun in francophone West Africa, prevented epidemics there for many years; however, the disease has reappeared in countries where vaccination programs were abandoned and the impact of outbreaks has fallen on unimmunized young people. For the past 20 years, West Africa has been the major geographic focus of yellow fever epidemics on the continent, but regional outbreaks returned to East Africa during the 1990s. Many African countries have experienced yellow fever outbreaks and epidemics in recent years. All these outbreaks had two things in common: failure to maintain adequate levels of immunization in an at-risk population; and lack of will and capability to rapidly detect and respond to an outbreak. Recurrence of yellow fever in many areas is expected to continue.

Because the epidemiology of yellow fever is known, it is possible to determine the degree of risk that a particular area will have an epidemic. Factors to be considered include whether: (1) the area has a history of yellow fever epidemics; (2) people who live there visit or work in forested areas where sylvatic YFV is likely to occur; (3) people come to the area from places where there is yellow fever; (4) mosquitoes that transmit YFV are present; (5) the area has a long rainy season; and (6) there is a nearby forested area with monkeys. Nonetheless, predicting yellow fever epidemics is an inexact science but it is clear that environmental factors, those that most affect the vector mosquitoes and the vertebrate hosts, are critical. The amount of rainfall and the availability of mosquito-breeding sites are both important. Heavy rainfall contributes to the development of large mosquito populations. In areas that are continually dry, storing water close to homes provides breeding sites for *Ae. aegypti* and other peridomestic mosquitoes. Mosquito larvae need relatively still water to develop, whether it is in a tree hole, a water-storage jar or a tin can in a garbage dump. Not all mosquitoes can transmit YFV. Some that can transmit the virus neither seek humans on which to feed, nor fly far from the forest but they will feed on humans who enter the forest.

A person's immune status is the most important host factor. People become immune after being vaccinated or after natural infection with YFV or with a closely related flavivirus. In some areas many flaviviruses occur. This "hyperendemic" condition decreases the susceptibility to YFV but complicates laboratory diagnostic efforts because it is extremely difficult to distinguish between antibody to the current infection and antibody to infections with related viruses in the past. In populations that have experienced epidemics in the past, or where vaccination has been erratic, the highest attack rates will occur in people belonging to younger age groups. In populations that have not been exposed to either vaccine or natural virus, the attack rates and the severity of disease are the same for all people in all age groups and males and females are equally affected.

Social and cultural host factors also influence who becomes infected. For example, if transmission is sylvatic (in the forest) and males spend more time hunting or working in forested areas, then males may have higher attack rates. If the transmission pattern is urban, women and children spending more time near their houses (where the vector mosquitoes are) may have higher attack rates. In sum, YFV is transmitted between monkeys (infected monkey $\longrightarrow$ mosquito $\longrightarrow$ susceptible monkey) in natural sylvatic cycles, from monkey to humans via mosquitoes (infected monkey $\longrightarrow$ mosquito $\longrightarrow$ susceptible human) in sylvatic settings, and from human to human (infected human $\longrightarrow$ mosquito $\longrightarrow$ susceptible human) in urban settings. Thus, while it is essentially impossible to break the cycle of sylvatic transmission, all that needs to be done to break the urban cycle is to eliminate the vector mosquitoes and isolate the patients. Of course, it would be easier simply to vaccinate everyone at risk but many countries where yellow fever occurs have neither the political will, the funds, nor the required knowledge and technology. Yellow fever today is a preventable disease that is not being prevented.

Other Significant Viruses. Other important flaviviruses, such as the tick-borne encephalitis viruses (*Central European encephalitis virus, Russian Spring–Summer encephalitis virus* and *Powassan virus*, to name a few), *Japanese encephalitis virus* and *West Nile virus* (which invaded the USA in the summer of 1999 and was responsible for the deaths of several people and illnesses in scores more) periodically cause outbreaks or epidemics in areas where the viruses cycle in nature. The tick-borne flaviviruses replicate in ticks, which transmit these viruses when questing for a blood meal, which they require in order to mature to the next stage of their own development. These viruses are restricted to the ranges of their tick hosts, *Ixodes ricinus* (the vector of *Central European encephalitis virus*) in far eastern Europe to western Europe; *I. persulcatus* (the vector of *Russian Spring–Summer encephalitis virus*) in far eastern Siberia to eastern Europe; and *I. cookei* (the vector of *Powassan virus*) in Canada and the northern USA. Transmission of these viruses occurs when tick populations are at their highest and the ticks are questing, usually in spring and autumn.

The epidemiologies of bunyaviruses, rhabdoviruses and orthomyxoviruses are no less fascinating than those of togaviruses and flaviviruses and the reader is directed to the Further Reading list for details regarding these and other viruses and the diseases they cause. Nonetheless, it can be said that these viruses are transmitted by hematophagous arthropods and that the geographic distributions of the viruses are consistent with the geographic distributions of the arthropod vectors of those viruses. Members of the family *Bunyaviridae*, including *La Crosse, Akabane, Oropouche, Rift Valley fever, Sandfly fever Naples* and *Sandfly fever Sicilian, Crimean–Congo haemorrhagic fever*, and *Nairobi sheep disease viruses*, and other viruses of lesser significance to humans and livestock, cause diseases that range from uncomplicated febrile illnesses, fevers with rash, to encephalitis, abortion storms in herd cattle, retinitis and severe hemorrhagic illness.

Clinical Features

The spectrum of clinical illnesses caused by arboviruses is a wide one. As noted above, these viruses can infect but cause no illness (subclinical infections) or cause illnesses characterized by fever, fever with rash, hemorrhagic fever, headache, arthralgias and polyarthritis. Most arbovirus infections, when clinically apparent, result in febrile illnesses (illnesses with fever). Invasion of the CNS can lead to aseptic meningitis or encephalitis, a life-threatening result with serious implications for final outcome. Sequelae (evidence of residual damage) are not uncommon, particularly in children, so that these infections are to be avoided.

WEEV can be used as an example of the pathogenesis of an alphavirus. Onset is sudden and accompanied by a constellation of fever, headache, chills, nausea, vomiting or, occasionally, respiratory symptoms. Symptoms and signs indicative of CNS infection follow within several days and may include lethargy, drowsiness, rigidity of the neck muscles, photophobia and vertigo. The patient drifts into stupor or coma in severe cases. In particular, infants under 2 months old are irritable and have focal or generalized convulsions, and tremors. These signs appear in 90% of patients under 1 year old and decreasingly in patients of greater age. Confirmed or probable *in utero* infections were observed in five infants infected with WEEV near term. They survived acute encephalitic illnesses but three had severe neurological sequelae. Also seen are various pathological reflexes, which vary from patient to patient and appear to depend on the stage of illness. Weakness and poor reflexes are common and children often display rigidity of the muscles, involuntary movements and paralysis. Cerebrospinal fluid (CSF) pressure may be mildly elevated and CSF contains normal glucose, normal or mildly elevated protein and elevated leucocyte counts. Early in infection, polymorphonuclear cells predominate but mononuclear cells predominate later. After about 10 days, patients begin gradual convalescence. Patients who die usually do so within a week after onset of illness. At autopsy, the significant primary findings are in the CNS. The brain is usually oedematous. Multiple necrotic foci, often without white cells infiltrating them, are found in striatum, globus pallidus, substantia nigra, cerebral cortex, thalamus and pons. Widespread perivascular cuffing and meningeal reaction are often observed. Pathological findings in a 75-year-old woman with focal neurological signs due to WEEV encephalitis were perivascular infiltration and multifocal necrosis in the deep grey matter. Similar findings in the basal ganglia and spinal cord corresponded to the focal clinical signs.

Sequelae of western equine encephalomyelitis include fatigue, irritability, headache and tremors for as long as 2 years. The overall case fatality

rate is 3–4% but adults usually recover completely. A minority display motor damage, intellectual impairment, emotional lability, or seizures. Of infants and children with CNS involvement, 56% under 1 month old, 16% under 2 months old and 11% 2–3 months old have severe motor damage or intellectual deficits and often require permanent institutionalization or comprehensive home care. Only occasionally are serious sequelae seen in pediatric patients over 1 year old, but 25–33% of children with convulsions during the acute illness will have subsequent seizures, some beginning 18–24 months after the acute phase.

Yellow fever will be used here as an extreme example of an arbovirus infection. Illness caused by YFV may range from an undifferentiated febrile illness to death. Patients with classic yellow fever have fever, vomiting, stomach pain, prostration, dehydration, yellowing of the white of the eye, gastrointestinal bleeding leading to "black vomitus," and abnormal kidney function. Between 20 and 50% of patients with classic symptoms die; with deepening scleral icterus, hemorrhages, shock, encephalopathy and renal failure. The death rates during epidemics and the consequent social and economic disruption can be enormous. There is no specific treatment for yellow fever, such that, as with all arbovirus infections, treatment is simply symptomatic and the results of such treatment depend as much on the constitution of the patient as on the medical practitioner. This is the reason that prevention (mosquito control, vaccination of at-risk people and education) is more important than are curative efforts.

La Crosse virus (LACV) may be the best-studied virus of the family *Bunyaviridae* with respect to virus ecology, disease aetiology and pathogenesis. Most La Crosse virus infections are subclinical but, when illness occurs, onset is abrupt. Patients present with fever, chills and headache with or without photophobia; abdominal pain and upper respiratory symptoms, with or without sore throat and cough, may occur. Progression to more serious illnesses is usually predicted or defined by one or more of the following symptoms: vomiting, nuchal rigidity, lethargy and coma. Most patients have fevers $>37\,^{\circ}C$ ($>98.6\,^{\circ}F$) and 40% have fevers $>39\,^{\circ}C$ ($>104\,^{\circ}F$). Illnesses may be classified as: (1) no seizures during the acute illness (58%); (2) seizures occurring only during the acute illness (33%); or (3) seizures occurring after the acute illness (9%). LACV produces an acute encephalitis that begins as a mild febrile illness lasting 1–3 days and sometimes for a week or more. In CNS infections, subsequent signs and symptoms usually subside after a few more days. Difficulty in walking, learning disabilities and other cognitive deficits occur in no more than 2% of those with CNS infections due to LACV. Learning efficiency and behavior of most recovered patients do not differ from control groups in the same communities.

Diagnosis

Because there are no pathognomonic profiles, no specific symptom or array of signs and symptoms, no physical findings, laboratory abnormality, radiographic or electroencephalographic features useful in defining any of the diseases discussed here, a differential diagnosis on clinical grounds is usually impossible. However, a thorough knowledge of both the illnesses arboviruses cause and of the epidemiological aspects of the natural cycles of these viruses can enable an attentive clinician to make a reasonable differential diagnosis. Most patients recover without significant sequelae and require only supportive therapy during the acute illness. The critical initial task of the clinician is to eliminate the possibility of a treatable illness when one of the possibilities is a presumptive viral encephalitis. Albeit nonspecific, leucopenia can be a first and simple tool to provide initial information in forming a clinical impression. Slow-wave background activity by electroencephalogram (EEG) and a mild lymphocytic pleocytosis in the CSF are indicators of encephalitis, rather than the less worrisome, but still serious, aseptic meningitis.

Patient age, seasonality of the disease, location of exposure (if not in the immediate area of residence), occurrence of similar cases in the community and other epidemiological features must all be taken into consideration. The possibility of strokes, brain tumors and other noninfectious CNS disorders must also be excluded, as must herpes, mumps, influenza, adenovirus, respiratory syncytial, lymphocytic choriomeningitis, encephalomyocarditis, hepatitis viral encephalitides, Lyme disease, acquired immune deficiency syndrome (AIDS) encephalopathy, Creutzfeldt–Jakob disease, Alzheimer disease, long-term alcohol abuse, other dementias with other aetiologies, Reye syndrome and treatable bacterial, mycobacterial and fungal infections in otherwise healthy and in immunocompromised individuals.

Control

Strategies for surveillance, prevention and control are now available and being applied but methods of prediction of outbreaks are still imprecise. Well-organized, well-funded, routine mosquito abatement remains the most effective method of preventing human infections caused by mosquito-borne viruses, although emergency methods are employed when outbreaks are imminent or in progress.

Expanded education programs can promote changes in behavior and help protect people from vector-borne diseases, complementing existing vector control programs. For example, removing or punching holes in discarded automobile tires and filling tree holes with cement have been shown to reduce *Ae. triseriatus* populations by limiting breeding sites and therefore reducing the number of human infections with LACV.

Vector control measures include spraying or fogging insecticides (larvicides and adulticides) from the air or by ground equipment and reducing or altering habitat (source reduction). In many areas these measures are being supplemented by surveillance programs intended to provide early warning of virus activity. Collecting and testing blood samples from penned or caged sentinel birds (usually young chickens) or wild birds for antibody and testing mosquitoes for virus, can provide early warning of an impending increase of virus in the surroundings. Increasing prevalence of antibody in birds before and during months of expected virus activity is taken to indicate a build-up of infection and the need for increased vector control. Clearly, no single surveillance system may be adequate between ecological zones or for different viruses.

Education is the best defense. People should be aware of the arthropod-borne diseases in their home areas and in the areas they visit and learn to avoid contact with suspected vectors during the transmission season. Mosquitoes generally have preferred feeding periods: avoid their habitats at such times. Control mosquitoes in the immediate vicinity and use repellents. To avoid ticks, stay out of woods where infected ticks are common and stay on recommended paths; wear adequate clothing to minimize exposed skin, and trousers with close-fitting cuffs tucked into socks; treat clothes with insecticides or acaricides; and use repellents and insecticides as sprays, lotions or solid bars according to the manufacturer's directions. With the exception of a vaccine against YFV, vaccines for other arboviruses are not readily and generally available to the public.

Specific, or at least provisional, diagnosis of an arboviral infection is as important for the community as it is for the patient. Whole blood, serum or tissue samples taken for virus isolation attempts should be processed immediately or placed on dry ice ($-70\,^{\circ}C$ ($-94\,^{\circ}F$), or otherwise suitably frozen, until they can be tested.

Serological conversion from a negative or low titre to a positive or high titre is most often used for confirmatory diagnosis. Because a person can be infected and seroconvert to a virus without becoming ill, identifying a virus isolated from the patient is a more dependable basis for laboratory confirmation of a specific infection; however, viraemias in arbovirus infections are usually brief, being quenched by antibody at or before the time of onset of illness, and the probability of obtaining a virus isolate from patient blood is not high.

If an isolate is obtained, various methods are available for its identification, and special safety precautions are recommended for work with arboviruses. Methods used for virus identification include electron microscopy. Detection of viral antigen (protein) by a variety of methods and detection and identification of viral RNA by polymerase chain reaction (PCR) have replaced classical serological methods. See also **Electron Microscope**.

Infection of vertebrates with arboviruses leads to production of immunoglobulin M (IgM) and immunoglobulin G (IgG) class antibodies. These can be detected by enzyme-linked immunosorbent assays, hemagglutination-inhibition, complement-fixation, neutralization or any of a great variety of assays. As detected by IgM antibody-capture (MACELISA), IgM antibody to each of these viruses crossreacts with other viruses of the same group but is most reactive with other viruses of the same antigenic complex. IgM antibody in infections caused by most arboviruses is almost always present on the day of onset of illness, an interesting observation and a critical diagnostic issue. Thereafter, IgM antibody peaks 2–3 weeks after onset but persists at high levels for at least 2 months. IgM antibody to CTFV, on the other hand, is not detected until 1–2 weeks after the onset of illness. IgG antibody to CTFV also appears relatively soon after onset but, unlike IgM, persists for many months or years after the illness, or may persist for life.

The presence of IgM class antibody in a patient with an illness clinically compatible with that of one of the arboviruses is, in itself, not confirmatory of such an infection. As mentioned above, certain arboviruses may occur sympatrically in North America. Antibody to one of these viruses does not provide clear-cut evidence for infection with that virus, but may reflect infection with a related virus.

Antigens and antibodies, assistance in preparing such reagents and additional information can be obtained from any of the World Health Organization centers for arbovirus reference and research. The World Reference Center is located at the University of Texas Medical School at Galveston, TX.

ARTHROSCOPY. Arthroscopy is a surgical procedure orthopaedic surgeons use to visualize, diagnose and treat problems inside a joint.

The word arthroscopy comes from two Greek words, "arthro" (joint) and "skopein" (to look). The term literally means "to look within the joint." In an arthroscopic examination, an orthopaedic surgeon makes a small incision in the patient's skin and then inserts pencil-sized instruments that contain a small lens and lighting system to magnify and illuminate the structures inside the joint. Light is transmitted through fiber optics to the end of the arthroscope that is inserted into the joint. By attaching the arthroscope to a miniature television camera, the surgeon is able to see the interior of the joint through this very small incision rather than a large incision needed for surgery.

The television camera attached to the arthroscope displays the image of the joint on a television screen, allowing the surgeon to look, for example, throughout the knee-at cartilage and ligaments, and under the kneecap. The surgeon can determine the amount or type of injury, and then repair or correct the problem, if it is necessary.

Examinations

Diagnosing joint injuries and disease begins with a thorough medical history, physical examination, and usually X-rays. Additional tests such as an MRI, or CT also scan may be needed. Through the arthroscope, a final diagnosis is made which may be more accurate than through "open" surgery or from X-ray studies.

Disease and injuries can damage bones, cartilage, ligaments, muscles, and tendons. Some of the most frequent conditions found during arthroscopic examinations of joints are:

Inflammation

Synovitis — inflamed lining (synovium) in knee, shoulder, elbow, wrist, or ankle.

Injury — acute and chronic

Shoulder — rotator cuff tendon tears, impingement syndrome, and recurrent dislocations

Knee — meniscal (cartilage) tears, chondromalacia (wearing or injury of cartilage cushion), and anterior cruciate ligament tears with instability

Wrist — carpal tunnel syndrome

Loose bodies of bone and/or cartilage — knee, shoulder, elbow, ankle, or wrist.

Although the inside of nearly all joints can be viewed with an arthroscope, six joints are most frequently examined with this instrument. These include the knee, shoulder, elbow, ankle, hip, and wrist. As advances are made by engineers in electronic technology and new techniques are developed by orthopaedic surgeons, other joints may be treated more frequently in the future.

Surgery

Arthroscopic surgery, although much easier in terms of recovery than "open" surgery, still requires the use of anesthetics and the special equipment in a hospital operating room or outpatient surgical suite. You will be given a general, spinal or a local anesthetic, depending on the joint or suspected problem.

A small incision (about the size of a buttonhole) will be made to insert the arthroscope. Several other incisions may be made to see other parts of the joint or insert other instruments.

When indicated, corrective surgery is performed with specially-designed instruments that are inserted into the joint through accessory incisions. Initially, arthroscopy was simply a diagnostic tool for planning standard open surgery. With development of better instrumentation and surgical techniques, many conditions can be treated arthroscopically.

For instance, most meniscal tears in the knee can be treated successfully with arthroscopic surgery.

Some problems associated with arthritis also can be treated. Several disorders are treated with a combination of arthroscopic and standard surgery.

- Rotator cuff procedure
- Repair or resection of torn cartilage (meniscus) from knee or shoulder
- Reconstruction of anterior cruciate ligament in knee
- Removal of inflamed lining (synovium) in knee, shoulder, elbow, wrist, ankle
- Release of carpal tunnel
- Repair of torn ligaments
- Removal of loose bone or cartilage in knee, shoulder, elbow, ankle, wrist.

Although uncommon, complications do occur occasionally during or following arthroscopy. Infection, phlebitis (blood clots of a vein), excessive swelling or bleeding, damage to blood vessels or nerves, and instrument breakage are the most common complications, but occur in far less than 1 percent of all arthroscopic procedures.

Although arthroscopic surgery has received a lot of public attention because it is used to treat well-known athletes, it is an extremely valuable tool for all orthopaedic patients and is generally easier on the patient than "open" surgery. Most patients have their arthroscopic surgery as outpatients and are home several hours after the surgery.

The small puncture wounds take several days to heal. The operative dressing can usually be removed the morning after surgery and adhesive strips can be applied to cover the small healing incisions.

Although the puncture wounds are small and pain in the joint that underwent arthroscopy is minimal, it takes several weeks for the joint to maximally recover. A specific activity and rehabilitation program may be suggested to speed your recover and protect future joint function.

It is not unusual for patients to go back to work or school or resume daily activities within a few days. Athletes and others who are in good physical condition may in some cases return to athletic activities within a few weeks. *Remember, though, that people who have arthroscopy can have many different diagnoses and preexisting conditions, so each patient's arthroscopic surgery is unique to that person. Recovery time will reflect that individuality*.

ARTICULATION (Communications). In verbal communication, the main purpose of speech is to convey thoughts. In testing speakers (human) and communication systems, a number of tests have b een designed for measuring the percentage of words or individual speech sounds uttered by a speaker which are perceived correctly by listeners. For example, the Harvard PB-50 word list employs a set of phonetically balanced words and is widely used. During the testing procedure, the talkers read the word lists over the system under test to a number of listeners. As they hear them, the listeners record the words. Responses are examined and the percentage of words heard correctly is determined. This is termed *percent word articulation*.

During such tests, a number of communication system parameters are explored. Methods have been developed for computing speech intelligibility from system characteristics. The measure of intelligibility computed is termed the *articulation index* (AI). A number of observations concerning speech are taken into consideration by the articulation-index concept: (1) speech must be above threshold of audibility to be perceived; (2) noise that exceeds this threshold masks speech, effectively raising the threshold of audibility; (3) there is an upper limit to the sound pressure which the ear can utilize for perception of speech; (4) frequencies from 200 to 6100 Hz are needed for substantially perfect intelligibility; (5) speech has a 30-decibel dynamic range; and (6) different frequency regions contribute unequally to intelligibility, but the frequency range from 200 to 6100 Hz can be divided into bands of equal contribution to speech intelligibility.

Ultimately, of course, the articulation-index concept has its foundation on an analysis of the sound pressures (signal and noise) that are produced at the listener's ear. In practice, it is expeditious to reduce all statements of sound pressure at the listener's ear to spectrum level (the sound pressure level in decibels is 0.0002 dyne per square centimeter for a 1-Hz bandwidth).

While much too complex to describe in detail here, speech intelligibility and quality are of major concern in the design of certain communications systems.

ARTIFICIAL CLIMATE. See **Climate**.

ARTIFICIAL GRAVITY. The commercialization of outer space may depend upon an increased human presence in orbit, despite advances in automation and remote control. More people from a broader spectrum of the population will live in orbit for longer periods of time. This is the explicit goal of space tourism. One may suspect that it is the implicit goal of other commercial ventures as well, where space-based research and manufacturing are the means rather than the end.

If the costs of launch and reentry are significant compared to the per-day cost of lodging in space, and if the space habitat is comfortable, then it is reasonable to expect that clients or guests will want to maximize the duration of each visit, to get the most value for their money. Moreover, an experienced and efficient crew may need to serve tours of duty several times as long as the average guest visit.

Unfortunately, long-term exposure to weightlessness leads to a chain-reaction of undesirable physiological adaptations. Countermeasures such as diet and exercise have been only partially effective in preserving health, even for well-trained highly-motivated crews. Use of therapeutic equipment is expensive in time and volume and may be unworkable with a large diverse population.

There is both theoretical and experimental evidence that artificial gravity can substitute for natural gravity to maintain health in orbit. In the early days of space flight, experts assumed that space stations would incorporate artificial gravity. Romantic images of life in orbit have often envisioned space habitats as graceful rotating structures. The novelty of artificial gravity may be one of the features, along with easy access to weightlessness, which attracts people to space tourism.

Artificial gravity (AG) is not gravity at all. It is not a field force or a "force at a distance." Neither does its strength obey the inverse square law of attraction that determines the orbital motion of planets. However, in terms of its action on any mass, it is indistinguishable from "real gravity." Instead of gravitational pull, it exerts a centrifugal force, proportional to the mass that is being accelerated centripetally in a rotating device. Although the effect of AG on an extended body differs from that of true gravity, the effects on any given mass are equivalent. Thus AG is simply the imposition of acceleration on a body to recover the forces that are eliminated by the free fall of orbital flight. (Of course, real gravity is not eliminated in orbit. The pull toward Earth in Earth orbit and toward the Sun in interplanetary orbit is balanced by the "free fall" acceleration of the spacecraft and its contents toward Earth or the Sun. To an observer or instrument onboard the spacecraft, it *feels* as though the pull of gravity were removed.)

In principle, AG could be provided by various means. A continuously thrusting rocket that accelerated a spacecraft halfway to Mars would generate AG equal to the acceleration level. Intermittent impulsive AG would be imposed on an astronaut who jumps back and forth between two opposing trampolines or even between two stationary walls in a spacecraft. However, the term *artificial gravity* is generally reserved for a rotating spacecraft or a centrifuge within the spacecraft. Every stationary object within the centrifuge is forced away from the axis of rotation toward the outer "floor" by a force proportional to the mass of the object, its distance from the center of rotation, and the square of the angular velocity of the device.

Probably the most serious health threat to humans during interplanetary flight comes from radiation exposure en route and on some extraterrestrial surface. Beyond that, prolonged exposure to weightlessness itself can result in deconditioning many of the body's systems. For space voyages of several years, such as those envisioned for exploration of Mars, the human requires some sort of "countermeasure" to reduce or eliminate this deconditioning. Intensive and sustained exercise on a treadmill, bicycle, or rowing machine was used on the U.S. and Russian spacecraft to minimize the problems of weightlessness. The procedure is uncomfortable and excessively time-consuming for most astronauts. Furthermore, its effectiveness is not proven for all users. Other kinds of countermeasures, including diet, fluid loading before reentry, lower body negative pressure, or wearing a "penguin suit" to force joint extension against a resistive force are either marginally effective or present an inconvenience or hazard.

The *physiological effects* of weightlessness are generally adaptive to space flight and present a hazard only upon return to Earth or landing on another planet. However, they may present hazards in flight in the event of a bone fracture, a vigorous muscle contraction, or alterations in the heart's rhythm. See also **Weightlessness**.

Aside from the severe danger of space radiation, the principal physiological risk of long flight is deterioration of the skeleton. Bones are living tissue, constantly being strengthened by calcium extracted from the blood and destroyed by returning calcium to the blood. Bone maintenance requires a compressive load along the axis of the bone and some high-force impulsive loading. In the absence of these loads that are normally provided by gravity and walking, the major bones that support body weight begin to deteriorate, and a net loss of body calcium occurs, independent of the amount taken in with food or supplements. The long bones in the legs and the vertebrae in the spine lose crucial size and strength during prolonged bed rest. Similarly, they lose strength in spaceflight. Calcium is lost at a rate of about 1/2% per month, and the losses are reflected in the density and size of weight-bearing bones. For a spaceflight of two years, a 25% decrease in bone size might occur (unless the process reaches a plateau), thus increasing the risk of fracture and severely hampering the bone's ability to mend.

Muscles involved in weight bearing, as well as bones, begin to weaken with disuse in weightlessness. The major muscle groups in the legs and back that normally support weight lose mass and are also "reprogrammed," so that fibers previously devoted to slow steady tension are used for brief bursts instead. The shifting of fluid from the legs and lower trunk to the head and chest that produces the first symptoms of head-fullness discomfort on orbit initiates an early loss of body fluid, including blood plasma. The relative excess of red blood cells is countered by stopping their production

in the bone marrow and additionally by destroying young red blood cells. The cardiovascular regulating system that acts to maintain adequate blood pressure when we stand up, is no longer needed in space and shows signs of deterioration. Neither the fluid loss and resulting "space anemia," nor the loss of cardiovascular regulation and tone normally cause any difficulty in orbit. During reentry and back on Earth, however, the renewed exposure to gravity can cause weakness and fainting.

The balance system that keeps humans from falling depends on the detection of gravity by the otolith organs in the inner ear. Because the only stimulus to the organs in weightlessness is linear acceleration, considerable reinterpretation of vestibular signals takes place. A consequence of this process is the common occurrence of space sickness early in flight and postural disturbances and vertigo after return.

The immune system that fights infection may also be compromised by space flight, although it is unclear whether weightlessness alone is the major factor.

In addition, a variety of *human factor* problems arise in weightlessness, including the constant need for handholds or footholds for stabilization and the possibility of disorientation within a spacecraft. However, these problems are often balanced by the ease of moving heavy objects, the use of three-dimensional space, and the shear pleasure of floating in weightlessness.

History

The notion of creating a substitute for gravity through centrifugation was introduced early in the conception of human space travel. Tsiolkovsky, the influential Russian space visionary, discussed the idea in 1911, and his concepts were picked up 50 years later by Korolev, who designed a flexible tether system for the Voskhod manned missions. It was, however, never built. A detailed engineering proposal for an AG station was introduced by Noodhung in 1927, a full 50 years before the first satellite was launched. When Von Braun described his vision of space exploration in 1953, he included a large rotating torus to deal with weightlessness.

The physical theory behind artificial gravity is as old as Isaac Newton's *Principles*. Nevertheless, there was no significant research into the human factors of artificial gravity until Sputnik inaugurated the "space race". With the beginning of manned space flight in the 1960s, there was concerted effort to determine the comfort criteria for rotating habitats. In the USA, much of this research took place in centrifuges, rotating rooms and rotating space station simulators at the Naval Aviation Medical Acceleration Laboratory (Johnsville, Pennsylvania), the Naval Aerospace Medical Research Laboratory (Pensacola, Florida) and the NASA Langley Research Center (Hampton, Virginia).

The popularization of AG, however, is attributable to the science fiction community. The large rotating torus in Clarke and Kubrick's *2001*: *A Space Odyssey* presented an idealized version of life in space, free of health problems and the negative effects usually associated with transiting from the rotating to the stationary parts of the station. By 1965, preliminary tests on a short-radius centrifuge first showed that subjects who were deconditioned by bed rest could be protected against cardiovascular deconditioning by periodic centrifugation.

Experience with AG in space has been quite limited. Rats were centrifuged continuously at 1 g for several days and showed no deconditioning. Human experiments, however, have not been conducted to date. Early attempts to test AG by tethering a Gemini spacecraft to an Agena rocket were inconclusive and nearly led to disaster when the thruster nozzle stuck on Gemini 8, sending the pair of space vehicles into an uncontrollable spin. The 2.5-m-radius centrifuge on the International Space Station should afford the opportunity to examine the adequacy of various levels of AG in protecting rodents during spaceflight. See also **Space Stations**.

As experience with weightless space flight accumulated, artificial gravity assumed a lower priority. The NASA Langley simulator was dismantled in the early 1970s. Since the beginning of the Salyut and Skylab missions, access to a micro-gravity environment has been one of the main motivations for space flight. Ironically, while extended stays in weightlessness have revealed its dangers, they have also shown that it is survivable. Artificial gravity is now discussed primarily in the context of interplanetary missions, in which long periods of weightless coasting through empty space are an annoyance, not an objective.

Design Boundaries

The envelope of operation for AG is limited by several factors, as pointed out by Von Braun and adapted by others. The "comfort zone" for AG with a rotational radius of up to 1000 feet is bounded by several constraints. In one presentation, the nominal design point was for a 734-foot radius architecture, spinning at approximately 1.8 rpm. This large radius creates less than a 1% gravitational gradient from head to foot under a 4% ratio of Coriolis force to apparent weight for a crew moving at 3 ft/s. The rim velocity would exceed 200 ft/s. The basic design space is normally shown on a graph of rotational rate versus radius; the acceleration level appears as a derived parameter according to the equation $A = r\omega^2$. The design boundaries have generally been stated for continuous rotation but are also shown here for intermittent centrifugation (see Figs. 1**a,b**).

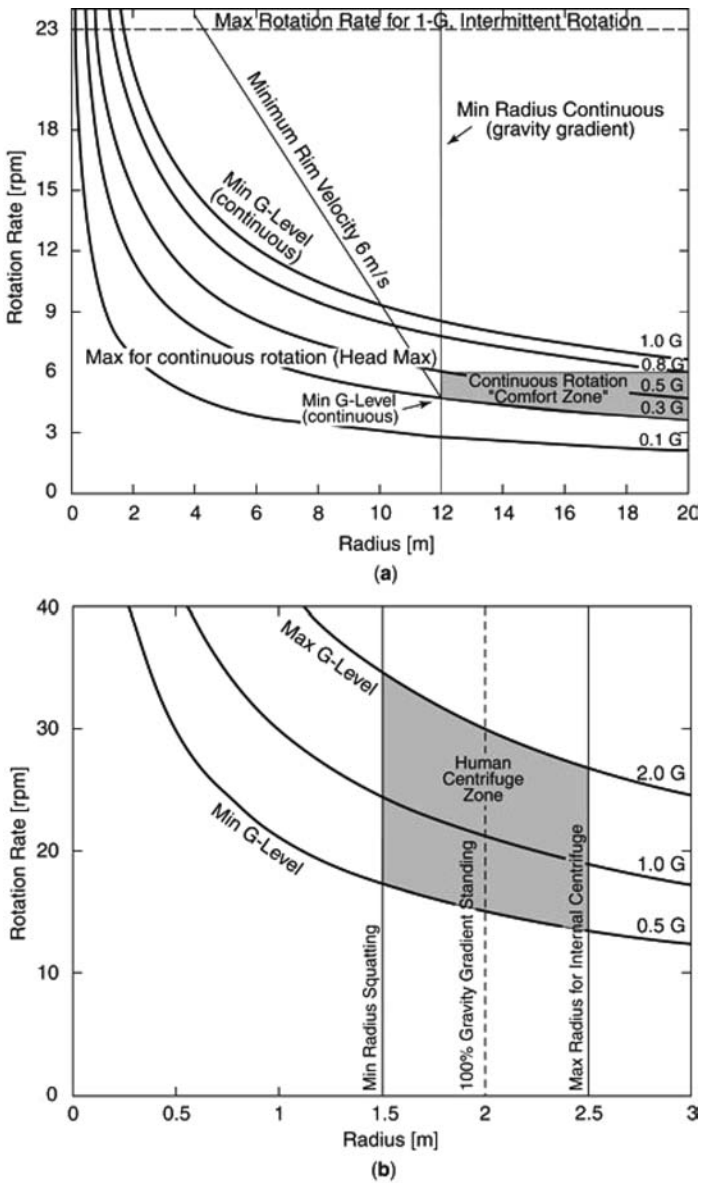

Fig. 1. (**a**) Comfort zone for continuous AG. (**b**) Centrifuge zone for intermittent AG. Adapted from R.Q.W., Stone, Jr. In A. Graybiel, ed., *5th Symposium on the Role of the Vestibular Organs in Space Exploration.*

The *minimum gravitational level*, normally measured at the rim of a centrifuge, is the key parameter in the design space. The limited animal tests in orbit confirm that continuous rotation to yield 1 g at the feet of a small rodent is sufficient to maintain normal growth. However, it remains to be determined whether a lesser g level will suffice. Based on centrifuge studies of long duration, Russian scientists suggest that the minimum level of effective AG is about 0.3 g and recommend a level of 0.5 g to increase a feeling of well-being and normal performance.

The *maximum gravitational acceleration level* is also a factor if short-radius intermittent AG is used. Levels up to 2 g are probably useful, especially if combined with exercise, but a level as high is 3 g's is likely to produce ill effects if maintained for more than 20 minutes.

The *maximum angular velocity* of the AG device is limited by the Coriolis forces encountered when walking or when moving objects, and by the motion sickness and disorientation experienced with certain kinds of head movements. Coriolis accelerations are real inertial accelerations that occur when moving within a rotating framework. Any movement in a straight line with respect to the rotating frame, except for one parallel to the axis of rotation, is in fact a curved motion in inertial space.

People trying to walk radially outward on a spinning carousel will feel a surprising force pushing them sideways, parallel to the circumference. As seen by an observer stationed outside the carousel, the walker's path is really curved in the direction of the carousel's spin. The sideward inertial acceleration requires a sideward force (*Coriolis force*), according to Newton's second law, and the subjects need to apply that unexpected force to avoid walking a path that is curved relative to the carousel. They also must apply an unexpected postural reaction to avoid falling over.

Additionally, anyone trying to walk along the rim of the AG spinning vehicle in the direction of the spin is subject to an unexpected radial inertial acceleration inward, which entails a downward Coriolis force, making the space walker feel heavier. If the astronaut were to turn around and walk along the rim in the direction opposite to the spin, the Coriolis force would be upward and the apparent weight of the astronaut would be reduced. The magnitude of the Coriolis force is given by the equation $|F_c| = |m\omega \times v|$. From considerations of human factors, the Coriolis accelerations should be kept to less than some fraction of the AG gravity level. Stone suggests that this be no higher than one-fourth. For radial movement at velocity v, this is given by

$$Coriolis acceleration/artificial gravity = \omega v_{\max}/r\omega^2 = v_{\max}/v_{\text{rim}},$$

where v_{rim} is ω times r and is the speed of the outer rim of the AG centrifuge. The *minimum rim velocity* is limited only by the need to maintain enough friction for locomotion when walking against the direction of spin. For walking, $v_{\max}$ is about 1 m/s, and it has been assumed that the estimated minimum rim velocity is 6 m/s.

The most disturbing aspect of AG rotation is probably the Coriolis cross-coupling accelerations detected by the semicircular canals in the vestibular systems of the inner ear. The organs function to detect angular velocity of the head relative to inertial space for most normal head movements. However, because of their mechanical structure, they fail to register long-lasting constant velocity motion and, instead, indicate that one is stationary in a turn that lasts more than 10–20 s. In AG, these vestibular signals are apparently inconsistent with what one sees in the spacecraft and also with the linear acceleration registered by the otolithic organs in the labyrinth. This conflict, before adaptation, produces both motion sickness and spatial disorientation.

When subjects in AG suddenly move their heads about an axis that is not parallel to the spin axis, two unexpected angular accelerations occur. First, during the head movement a "cross-coupled acceleration" occurs, equal to the product of the spin rate and the head angular velocity that produces transient acceleration about a third orthogonal axis. This is given by the equation $A = \omega_y \times \omega_s$. Second, when the head is turned, the spin angular velocity is moved from one head plane to another, producing a sensation of deceleration about the first axis and acceleration about the second one. A sensation of rotation with components around both axes usually occurs for up to 10 sec, as the semicircular canals return to their neutral position. The directions of both the Coriolis force and the cross-coupled accelerations depends on the direction the subject is facing in the rotating spacecraft, as well as the direction of head movement, thereby complicating the process of general adaptation to the unusual environment.

All of the unexpected Coriolis sensations are proportional to the AG spin rate. Although further adaptative schedules might increase the tolerable rate, the *maximum spin rate* for continuous rotation has been estimated at 6 rpm, with possible elevation to 10 rpm. Almost all subjects can adapt quickly to work in a 2-rpm rotating environment. It is believed that most could tolerate increased rotational rates to 6–10 rpm, providing that they are built up slowly in steps of 1–2 rpm with a period of 12–24 h at each increment.

The *gravitational gradient* refers to the change in AG level with radius and can affect both physiological function and the ease of handling materials in space. Since the "g level" is proportional to the radius, the gravitational gradient from head to foot is simply the ratio of height to radius: $Gradient = h/R$. For continuous rotation at smaller radii, comparable to the astronaut's height, the gravitational gradient may become more of a problem. For a 2-m astronaut, the radius would be at least 4 m for a 50% maximum gradient.

Experimental Results

Space Experiments. Despite the long-standing interest in artificial gravity, experimental evidence from space is very limited. Only two space missions early in the space program were devoted to animal studies, and all of the human in-flight results were anecdotal.

Flight Animal Experiments. The Soviet space research community expressed an early and intense interest in AG and, in 1961, began testing rats and mice in the 25-s weightless periods of parabolic flight. Animals showed normal appearing locomotion during these brief periods if they were housed in a centrifuge producing at least 0.3 g, thus setting this as a minimum g requirement. The first animals to be centrifuged in space were on the Cosmos 782 mission in 1975, when fish and turtles centrifuged at 1 g were found indistinguishable from their ground controls. Furthermore, turtles centrifuged at levels as low as 0.3 g showed none of the muscle wasting typical of weightlessness. A much more extensive investigation was carried out on rats centrifuged during the 20-day mission of Cosmos 936 in 1977. These animals, housed in a small-radius (32-cm), high-speed (53.5-rpm) 1-g centrifuge, showed deficits in equilibrium and postural control postflight, consistent with the observed reduction in vestibular sensitivity. Faring less well than their ground controls, they also failed to counter fully the usual effects of weightlessness on loss of muscle and bone, circumstances that may have been the result of the small cage size and the high-g gradient. The large animal centrifuge planned for the International Space Station is designed to provide a range of AG levels, above and below 1 g, to a large variety of fish, plants, and small animals.

Human Space Experience with AG. No formal human AG experiments were performed in space during the first 40 years of the space age. During the earliest years of human spaceflight, the major physiological disturbances involved "space adaptation syndrome" and were of concern only for the first few days in orbit. The debilitating effects of weightlessness on the bone, muscle, and cardiovascular system were demonstrated on the Skylab missions in the early 1970s and later on the long-duration Salyut and Mir flights. However, it was believed that in-flight exercise, augmented by resistance training and fluid loading, would solve the problem. As time passed, the opportunities for human centrifuges or rotating spacecraft in orbit disappeared. During a 1966 Gemini mission, an orbiting Agena rocket casing was tethered to the spacecraft, and the two were put into a slow spin. No data were taken. On Gemini 8, when Gemini was docked to the Agena, a planned slow rotation got out of control because of a stuck thruster, and the crew was saved only by the skillful use of an orbital maneuvering engine. No further spacecraft AG tests have been conducted. Since then, the only opportunities for investigation have come from uncontrolled, anecdotal reports.

During the Skylab missions, the crew took advantage of the large open compartment to run around the curved circumference. They produced a self-generated AG by running. The crew reported no difficulty with either locomotion or motion sickness.

Although no specific AG human experiments have been performed, some centrifugation for other purposes has produced a measure of centripetal acceleration. During the Spacelab International Microgravity Laboratory (IML-1) mission, subjects were spun on a rotator in which the head was 0.5 m off center, experiencing an acceleration of -0.22 g_z, and the feet were on the other side of the axis, experiencing an acceleration of $+0.36$ g_z. No unusual inversion phenomena were reported. Similarly, in the Neurolab Spacelab mission, four subjects received periodic rotation in a similar situation without reorientation. In that case, however, those subjects seemed to have achieved some measure of resistance to postflight orthostatic instability and did not show the usual decrease in vestibular sensitivity to tilt.

Ground Centrifuge Experiments. Despite the absence of flight-test opportunities, several laboratories worldwide have continued ground-based studies of the efficacy and acceptability of human horizontal centrifugation. Of course, all of these investigations are hampered by the presence of the steady gravitational pull. Gravity adds to the centrifugal force vectorially and produces a net specific gravitoinertial force $F = g\text{-}a$ directed between vertical and horizontal.

The earliest of the extensive tests of sustained rotation were conducted in Pensacola, beginning in 1958. The "slow rotating room" (SRR) exposed volunteers to prolonged rotation. This 3-m-radius room that has a horizontal floor permitted subjects to adapt to rotation during several days. Initially, most subjects developed motion sickness symptoms when they made head movements at room rotational rates in excess of 3 rpm and, through that experience, learned to restrict them. Incremental increase in the speed of the room was employed. After several days, most subjects were able to make head movements without symptoms at rotational rates up to 6 rpm. Only some of the subjects could go further to move comfortably at 10 rpm. When the rotation was stopped, subjects felt an aftereffect and an erroneous motion sensation during head movements. They were maladapted to rotation in the opposite direction.

Beginning in the 1960s a major ground research program on AG was conducted at the Institute for Biomedical Problems in Moscow (IBMP). Their earliest tests in the MVK-1 small rotating chamber at speeds up to 6.6 rpm allowed rotating one or two subjects for up to a week. It was followed by the roomier 10-m-radius "Orbita" centrifuge, capable of rotating two to three people for several weeks at speeds up to 12 rpm. The longest tests were for 25 days at 6 rpm. The initial exposures produced the expected disturbance of equilibrium and coordination. Within an hour, the usual pattern of motion sickness symptoms occurred, including vomiting in some cases. In 4–5 hours, subjects also complained of listlessness, sleepiness, and headache — similar to the Sopite syndrome identified by Graybiel. Three periods of vestibular adaptation were distinguished for these long-duration exposures. The first 1–2 days were characterized by severe motion sickness. This was followed by a week during which the nausea and related acute symptoms disappeared, but listlessness and headache remained. Finally, after the first 7–10 days, subjects showed immunity to motion sickness, even when additional vestibular stimulation was imposed. The generalizability of this adaptation has not been determined. The Soviet centrifuge tests indicated an absence of any motion sickness symptoms at 1 rpm, moderate symptoms at 1.8 rpm, and marked symptoms at 3.5 rpm. Head movements brought on discomfort in all cases.

More recent investigations have assessed the ability of subjects to avoid motion sickness during head movements while rotating at the high speeds associated with short-radius centrifugation. Antonutto and colleagues in Udine, Italy, found that subjects who were pedaling on a bicycle-powered short centrifuge were able to make head movements without acute motion sickness while rotating at 19–21 rpm. Young, Hecht, and colleagues used the 2-m-radius centrifuge at MIT to show that most subjects could adapt both their eye movements and their motion sickness symptoms to accommodate head movements while rotating at 23 rpm. Both the Udine and the MIT studies were conducted at speeds sufficient to produce 1 g of horizontal centripetal acceleration or a net gravitoinertial acceleration of 1.4 g's. In the Udine centrifuge, it was aligned with the subject's, head-to-foot axis, whereas in the more provocative MIT studies, the subject remained horizontal.

The Coriolis forces associated with limb movements, head movements, and walking in a rotating environment are initially both surprising and disturbing. However, in almost all cases, appropriate new motor control strategies are developed, so that subjects can adapt to the new environment and no longer are even aware of the unusual forces. Extensive experiments in the Brandeis University rotating room demonstrate the remarkable ability to adapt to unusual environments. A measure of dual adaptation apparently exists, so that subjects can switch from the rotating to the nonrotating environment with minimal relearning.

The adequacy of artificial gravity in stimulating the cardiovascular system has been investigated in ground studies. In most studies, the debilitating effects of weightlessness are simulated by sustained bed rest, often at 6° of head-down tilt and occasionally by partial submersion in water to approximate the fluid shift better that occurs in space. In a pioneering study in 1966, White and his colleagues at Douglas showed that intermittent exposure to 1 g or 4 g's on a 1.8-m-radius centrifuge was effective in alleviating the usual decrease in tolerance to standing (orthostatic intolerance). Exercise produced little additional benefit. The principal cardiovascular reactions of interest for centrifugation are the venous tone, especially in the legs, and the baroreflex regulation of blood pressure. For a short-radius centrifuge small enough to accommodate a subject only in a squatting position, the centrifugation does little to encourage venous return by stimulating the muscles. The IBMP ground centrifuge tests demonstrated that subjects who were deconditioned by 2 weeks of water immersion could increase their postimmersion tolerance to $+3\ g_z$ by intermittent acceleration on a 7-m-radius centrifuge. For some time, it was debated whether the intermittent centrifugation conditioned only the passive motor tone or whether the body's active baroreflex to counter the effects of gravity on blood pressure was also affected. Burton and Meeker, using a 1.5-m-radius centrifuge intermittently, showed that the baroreceptors are adequately stimulated during AG. Their slow compensation for the hydrostatic pressure drop during rotation permits the g tolerance to gradual onset acceleration to exceed that to rapid onset acceleration. Beyond even the benefit of intermittent acceleration on cardiovascular responses is the effect on blood volume. Normally, weightlessness or head-down bed rest produces a fluid shift toward the head that in turn leads to fluid loss, including plasma, and a resulting increase in hematocrit. However, Yajima and his colleagues from Nihon University School of Medicine in Tokyo) showed that 1 hour per day of $2\ g_z$ exposure of their subjects, using a 1.8-m-radius centrifuge, was sufficient to prevent hematocrit from increasing during a 4-day bed rest period. In other studies, they confirmed the effectiveness of intermittent centrifugation on maintaining baroreflex and parasympathetic activity. To prevent motion sickness, the Nihon investigators stabilized the head during these centrifuge runs.

The interaction between the cardiovascular fitness enhancement of regular exercise and the tolerance built up during centrifugation remains unclear. Certainly the two countermeasures are individually effective, but whether they contribute more in combination is still under study.

Artificial Gravity Design Options

The choice of AG design depends on a basic decision whether the crew is to be transported with *continuous* AG, requiring a large-radius device, or exposed to *intermittent* AG, in which case a small rotator can be employed. The classical large *spinning space station*, as epitomized by the von Braun torus, was the basis for early designs in the Apollo era. At one time, a large toroid 150 feet in diameter and constructed of six rigid modules joined by an inflatable material, was envisioned. The large mass and excess volume of a torus or hexagon forced consideration of other ways of generating centrifugal forces at large radii. The two that emerged are the rigid truss, or boom, and the tether concept. A *rigid truss* design typically would have the crew quarters and operations module at one end and a large counterweight at the other end. The counterweight might be an expended fuel tank or an active element such as a nuclear power source. In most cases a counterrotating hub is present at the center of rotation to provide both a nonspinning docking port and to allow for a zero-g workspace for experiments. A variation on the rigid truss is the extendable or telescoped boom concept, in which the radius of the AG systems could be varied more easily than with a fixed truss and slider. However, both of these designs imply considerably more mass and power requirements than a tether system. A variable length *tether* that could be unreeled in orbit and used to connect a spacecraft to a counterweight has emerged as the most acceptable design for a large AG system. As envisioned for a Mars mission, it would consist of a 80,000-kg habitat module 225 m from the center of mass, with a 44,000-kg counterweight 400 m beyond. The two are connected by a tether, weighing 2400 kg, reeled out by a deployer weighing 1700 kg. All told, the additional weight for accommodating a tethered AG system for a human Mars mission is about 21,000 kg, or about 5% of the 0-g weight, plus about 1400 kg of propellant.

One of the obvious concerns about a tethered AG system is its vulnerability to tether breakage. For the Mars mission design, a tether in the form of a band 0.5 cm × 46 cm × 750 m would provide a dynamic load safety factor of 7, offering a working strength of (630,000 N). That concern has otherwise been addressed by using webbing or braided cable to maintain tether integrity, even in the event of a meteoroid collision. (The probability of tether impact with a micrometeoroid of mass greater than 0.1 gm was calculated as .001 for a mission of 420 days.) A second concern about a tethered system lies in its dynamic stability, especially during unreeling and during spin up and spin down. The interaction with orbital maneuvers is complex, whether the spin axis is inertially fixed or tracking the Sun to facilitate the use of solar panels.

The alternative approach to AG is to use a *short-arm centrifuge* intermittently. In this case, the exposure would not be limited to less than 1 g, but might be as high as 2 or 3 g's to deliver adequate acceleration in exposures of perhaps 1 h daily or several times per week.

Of course, such a short device would have to spin much faster than the 6 rpm limit envisioned for a large continuous system — and would produce significant Coriolis forces and motion sickness stimuli if the head is moved, at least until adaptation occurs. The short-radius centrifuge becomes particularly attractive when its dimensions shrink to the point that intermittent centrifugation could be carried out within the confines of a spacecraft, rather than entailing rotation of the entire complex. A 2-m-radius AG device permits subjects to stand upright and even walk within its limited confines. Of course, the head is then close to the center of rotation, and a significant gravitational gradient appears as one goes from head to toe. Many of the ground studies of intermittent short-radius centrifugation have been conducted with rotators of radius from 1.8–2.0 m. As the radius shrinks even further to less than 1.5 m, the taller subjects can no longer stand erect but must assume a squatting or crouching posture. For many such designs, the subject would also provide the power to turn the device and perform valuable exercise by bicycling the centrifuge into rotation.

Although the power saving may be trivial, or not even used, the importance of active exercise while exposed to intermittent centrifugation might lie in its protection against syncope, or fainting, as the body is exposed to the unaccustomed footward forces that tend to pool blood in the lower extremities.

Conclusion

The design of an orbital habitat for artificial gravity depends on much more than physics. A few simple formulae relate the habitat's size and rotation to the apparent gravity. Unfortunately, the formulae are powerless to predict the satisfaction of the inhabitants. Many empirical studies have attempted to identify the comfort boundaries for artificial gravity, to constrain the values of the variables. Nevertheless, they have arrived at substantially different conclusions. The disagreement may be due in part to different assumptions regarding the mission, selection, motivation and adaptability of the target population. To support a large clientele, it may be safe to stay within the common ground of all of the empirical studies, choosing the most restrictive bounding value for each variable.

Ultimately, an inhabitant's ability to adapt to artificial gravity will depend on how well the habitat itself is adapted. As a matter of principle, it is probably not possible to design for artificial gravity without having lived in it. Nevertheless, in designing the first such habitats, one must make the effort.

ARTIFICIAL HEART. See **Cardiovascular Devices; and Heart and Circulatory System (Physiology)**.

ARTIFICIAL HORIZON. A planar reflecting surface that can be adjusted to coincide with the astronomical horizon, i.e., can be made perpendicular to the zenith. This instrument is used, usually in conjunction with others, in observing celestial bodies. See also **Horizon (Astronomical)**; **Horizon (Celestial)**; and **Sextant**.

ARTIFICIAL HORIZON (Aircraft). Several ways of presenting to the pilot the information as to direction of true vertical have been used. The artificial horizon indicator shown in Fig. 1 is one acceptable means. Gyros furnish an excellent means for determining dynamic vertical. If a gyro is arranged with gimbals as shown in Fig. 2, and there is some method of detecting instantaneous or dynamic vertical by which a torque may be applied to the gyro, with its downward component being directed to the rising side of the gyro wheel (Fig. 3), the spin axis will move toward the

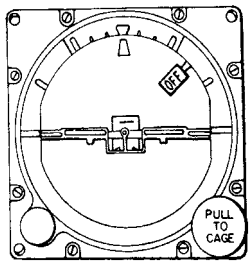

Fig. 1. Artificial horizon indicator.

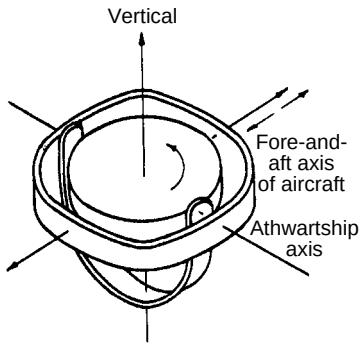

Fig. 2. Gyro in gimbals.

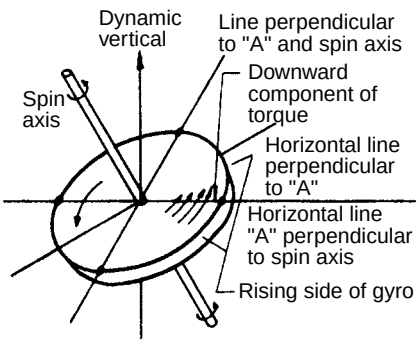

Fig. 3. Gyro vertical.

dynamical vertical. As the rate of this movement toward vertical (called the erection rate) is a relatively slow action, of the order of a few degrees in a minute, the spin axis indicates a long-time average of dynamic vertical, which usually is very close to true vertical.

Often, the detecting means may be pendulous switches, usually electrolytic or mercury, which energize torque motors causing the gyro to erect. This system has many advantages, in that the erection rate is externally adjustable if desired, and erection may be disconnected by means of switches actuated by rate gyros so that only when the dynamic vertical is near true vertical is it averaged by the gyro mechanism, and a more exact true vertical indication is obtained.

If the gyro spin axis is maintained horizontal instead of vertical, it will tend to keep its spin axis pointed in one direction. By putting a degree calibration on the gyro, it forms a stable heading reference. Methods of drive, erection, and signal takeoff are similar for both gyro verticals and horizontals.

ARTIFICIAL INSEMINATION. Introduction of semen into the vagina by means of surgical instruments and procedures. Although sparingly used in *Homo sapiens*, artificial insemination is widely practiced in the breeding of horses and livestock. See also **Embryo**; and **In-Vitro Fertilization**.

ARTIFICIAL INTELLIGENCE. Artificial intelligence (AI) is a branch of computer science that studies the computational requirements for tasks such as perception, reasoning, and learning, and develops systems to perform those tasks. AI is a diverse field whose researchers address a wide range of problems, use a variety of methods, and pursue a spectrum of scientific goals. For example, some researchers study the requirements for expert performance at specialized tasks, others model commonsense processes. Some researchers explain behaviors in terms of low-level processes, using models inspired by the computation of the brain, others explain them in terms of higher-level psychological constructs such as plans and goals. Some researchers aim to advance understanding of human cognition, some to understand the requirements for intelligence in general (whether in humans or machines), and some to develop artifacts such as intelligent devices, autonomous agents, and systems that cooperate with people to amplify human abilities.

AI is a young field, even its name, "artificial intelligence," was only coined in 1956. One of the challenges for AI has been to determine which tasks to study, What constitutes an "AI question." And how to evaluate progress. Much early AI research focused on tasks commonly thought to require high intelligence in people, such as playing high-quality chess. Skeptics viewed this as an impossible assignment, but AI made rapid progress. By the 1960s, programs were capable of tournament play. In 1997, in a landmark match, the chess system Deep Blue defeated Gary Kasparov, the world's human chess champion for the previous twelve years. At the same time, however, AI research was illuminating the enormous difficulty of commonsense tasks that people take for granted, such as understanding stories or conversations. Developing programs that can deal at a human level with rich everyday reasoning remains a fundamental research challenge.

The first half-century of AI has yielded a wide range of results. AI research has illuminated the nature of reasoning problems and the fundamental requirements for intelligent systems. AI research in the area of *cognitive science* has developed models that have helped to understand human cognition. Applied AI research has provided high-impact applications systems that are in daily use throughout the world. This article provides a brief introduction to the history of AI, sketches some major research areas, and closes by illustrating the practical impact of AI technology.

The History of AI

The name "artificial intelligence" dates only to the 1950s, but its roots stretch back thousands of years, into the earliest studies of the nature of knowledge and reasoning. Intelligent artifacts appear in Greek mythology. The idea of developing ways to perform reasoning automatically and efforts to build automata to perform tasks, such as game-playing, date back hundreds of years. Psychologists have long studied human cognition, helping to build up knowledge about the nature of human intelligence. Philosophers have analyzed the nature of knowledge, have studied the *mind-body problem* of how mental states relate to physical processes, and have explored formal frameworks for deriving conclusions.

The advent of electronic computers, however, provided a revolutionary advance in the ability to study intelligence by actually building *intelligent artifacts*, systems to perform complex reasoning tasks, and observing and experimenting with their behavior to identify fundamental principles. In 1950, a landmark paper by Alan Turing argued for the possibility of building intelligent computing systems. That paper proposed an operational test for comparing the intellectual ability of humans and AI systems, now generally called the "Turing Test." In the Turing Test, a judge uses a teletype to communicate with two players in other rooms: a person and a computer. The judge knows the players only by anonymous labels, such as "player A" and "player B," on the text that they send to him. By typing questions to the players and examining their answers, the judge attempts to decide which is which. Both the human and machine try to convince the questioner that they are the human; the goal for the machine is to answer so that the judge cannot reliably distinguish which is which. See also **Turing Machine**.

The game is intended to provide a rich test of intellectual abilities, separated from physical capabilities. The questions are unrestricted; Turing's samples range from "Please write me a sonnet on the subject of the Forth Bridge," to "Add 34957 to 70764." Turing's examples of possible responses make clear that the aim is to imitate human intelligence, rather than to demonstrate superhuman capabilities: His sample responses are "Count me out on this one. I never could write poetry," and, after a 30-second pause, 105,621, which is wrong.

The significance of the Turing Test has been controversial. Some, both inside and outside AI, have believed that building a system to pass the Turing Test should be the goal of AI. Others, however, reject the goal of developing systems to imitate human behavior. Ford and Hayes illustrate this point with an analogy between developing artificial intelligence and developing mechanical flight. Early efforts at mechanical flight were based on trying to imitate the flight of birds. At that time burds were the only available examples of flight. How birds flew was not understood, but their observed features (aspects such as beaks, feathers, and flapping wings) could be imitated, and become models for aircraft (even to the extent of airplanes with beaks were featured in a 1900's textbook on aircraft design). Success at mechanical flight, however, depended on replacing attempts at imitation with study of the functional requirements for flight, and the development of aircraft that used all available methods to achieve them. In addition, passing the Turing Test is not a precondition for developing useful practical systems. For example, an intelligent system to aid doctors

or to tutor students can have enormous practical impact with only the ability to function in a specific, limited domain.

The First Decades

Turing's paper surveys many common arguments against the possibility of AI and provides responses to each one. One of these arguments is that machines "can only do what they are programmed to do," from which some conclude that programs could never "take us by surprise." Shortly after the appearance of Turing's paper, a program provided concrete proof that programs can go beyond their creators: Arthur Samuel wrote the first checkers-playing program, which used learning techniques to develop tournament-level skills, surpassing its creator's own abilities.

Early AI research rapidly developed systems to perform a wide range of tasks often associated with intelligence in people, including theorem-proving in geometry, symbolic integration, solving equations, and even solving analogical reasoning problems of the types sometimes found on human intelligence tests. However, research also revealed that methods that worked well on small sample domains might not "scale up" to larger and richer tasks, and led to an awareness of the enormous difficulty of the problems that the field aimed to address. A classic example concerns early work in machine translation, which was recognized in the 1960s to be a far more difficult problem than expected. Funding for machine translation research was terminated.

Two impediments to wider application of early AI systems were their general methods and lack of knowledge. For small tasks, exhaustively considering possibilities may be practical, but for rich tasks, specialized knowledge is needed to focus reasoning. This observation led to research on knowledge-based systems, which demonstrated that there is an important class of problems requiring deep but narrow knowledge. Systems capturing this knowledge in the form of rules can achieve expert-level performance for these tasks. An early example, DENDRAL used rules about mass spectrometry and other data to hypothesize structures for chemical compounds. Using only simple inference methods, it achieved expert-level performance and was the source of results published in the chemical literature. Such systems provided the basis for numerous applied AI systems. See also **Artificial Intelligence: Expert Systems**. Continuing research revealed the need to develop additional methods for tasks such as acquiring the knowledge for systems to use, dealing with incomplete or uncertain information, and automatically adapting to new tasks and environments.

The accompanying timeline, prepared by Bruce Buchanan, provides a list of major milestones in the development of AI. Russell and Norvig provide an historical summary of the field in Chapter 1 of their AI textbook *Artificial Intelligence: A Modern Approach*. An article by Hearst and Hirsh presents a range of viewpoints on the greatest trends and controversies in AI, collected from leading figures in the development of artificial intelligence.

Brief History of Artificial Intelligence

The intellectual roots of AI and the concept of intelligent machines may be found in Greek mythology. Intelligent artifacts appear in literature since then, with real (and fraudulent) mechanical devices actually demonstrated to behave with some degree of intelligence. Some of these conceptual achievements are listed below under "Ancient History."

After World War II, modern computers became available. It has become possible to create programs that perform difficult intellectual tasks. From these programs, general tools are constructed that have applications in a wide variety of everyday problems. Some of these computational milestones are listed below under "Modern History."

Ancient History

Greek myths of Hephaestus and Pygmalion incorporate the idea of intelligent robots. Many other myths in antiquity involve humanlike artifacts. Many mechanical toys and models were actually constructed, e.g., by Hero, Daedalus, and other real persons.

5th century B.C. Aristotle invented syllogistic logic, the first formal deductive reasoning system.

13th century. Talking heads were said to have been created, Roger Bacon and Albert the Great reputedly among the owners.

Ramon Llull, Spanish theologian, invented machines for discovering nonmathematical truths through combinatories.

15th century. Invention of printing using moveable type. Gutenberg Bible printed (1456).

15th–16th century. Clocks, the first modern measuring machines, were first produced using lathes.

16th century. Clockmakers extended their craft to creating mechanical animals and other novelties.

Rabbi Loew of Prague is said to have invented the Golem, a clay man brought to life (1580).

17th century. Early in the century, Descartes proposed that bodies of animals are nothing more than complex machines. Many other 17th century thinkers offered variations and elaborations of Cartesian mechanism.

Hobbes published **The Leviathan**, containing a material and combinatorial theory of thinking.

Pascal created the first mechanical digital calculating machine (1642).

Leibniz improved Pascal's machine to do multiplication and division (1673) and envisioned a universal calculus of reasoning by which arguments could be decided mechanically.

18th century. The 18th century saw a profusion of mechanical toys, including the celebrated mechanical duck of Vaucanson and von Kempelen's phony mechanical chess player, The Turk (1769).

19th century. Luddites (led by Ned Ludd) destroyed machinery in England (1811–1816).

Mary Shelley published the story of Frankenstein's monster (1818).

George Boole developed a binary algebra representing (some) "laws of thought."

Charles Babbage and Ada Byron (Lady Lovelace) worked on programmable mechanical calculating machines.

20th century — First Half. Bertrand Russell and Alfred North Whitehead published "*Principia Mathematica*," which revolutionized formal logic. Russell, Ludwig Wittgenstein, and Rudolf Carnap lead philosophy into logical analysis of knowledge.

Karel Kapek's play "R.U.R." (*Rossum's Universal Robots*) opens in London (1923). First use of the word "robot" in English.

Warren McCulloch and Walter Pitts publish "*A Logical Calculus of the Ideas Immanent in Nervous Activity* " (1943), laying foundations for neural networks.

Arturo Rosenblueth, Norbert Wiener and Julian Bigelow coin the term "cybernetics" in a 1943 paper. Wiener's popular book by that name published in 1948.

Vannevar Bush published "As We May Think " (*Atlantic Monthly*, July 1945) a prescient vision of the future in which computers assist humans in many activities.

A.M. Turing published "*Computing Machinery and Intelligence*," (1950). Introduction of Turing's Test as a way of operationalizing a test of intelligent behavior.

Claude Shannon published detailed analysis of chess playing as search (1950).

Isaac Asimov published his three laws of robotics (1950).

Modern History

1956. John McCarthy coined the term "artificial intelligence" as the topic of the Dartmouth Conference, the first conference devoted to the subject.
Demonstration of the first running AI program, the Logic Theorist (LT) written by Allen Newell, J.C. Shaw, and Herbert Simon (Carnegie Institute of Technology, now Carnegie Mellon University).

1957. The General Problem Solver (&PS) demonstrated by Newell, Shaw and Simon.

1952–1962. Arthur Samuel (IBM) wrote the first game-playing program, for checkers, to achieve sufficient skill to challenge a world champion. Samuel's machine learning programs were responsible for the high performance of the checkers player.

1958. John McCarthy (MIT) invented the Lisp language.
Herb Gelernter and Nathan Rochester (IBM) described a theorem prover in geometry that exploits a semantic model of the domain in the form of diagrams of "typical" cases.

Late 1950s–Early 1960s. Margaret Masterman and colleagues at Cambridge designed semantic nets for machine translation.

1961. James Slagle (PhD dissertation, MIT) wrote (in Lisp) the first symbolic integration program, SAINT, which solved calculus problems at the college freshman level.

1962. First industrial robot company, Unimation, founded.

1963. Thomas Evans' program, ANALOGY, written as part of his PhD work at MIT, demonstrated that computers can solve the same analogy problems as are given on IQ tests.
Ivan Sutherland's MIT dissertation on Sketchpad introduced the idea of interactive graphics into computing.
Edward A. Feigenbaum and Julian Feldman published "*Computers and Thought*," the first collection of articles about artificial intelligence.

1964. Danny Bobrow's dissertation at MIT (tech.report #1 from MIT's AI group, Project MAC), showed that computers can understand natural language well enough to solve algebra word problems correctly.
Bert Raphael's MIT dissertation on the SIR program demonstrated the power of a logical representation of knowledge for question-answering systems.

1965. J. Allen Robinson invented a mechanical proof procedure, the Resolution Method, that allowed programs to work efficiently with formal logic as a representation language.
Joseph Weizenbaum (MIT) built ELIZA, an interactive program that carries on a dialogue in English on any topic. It was a popular toy at AI centers on the APPA-net when a version that "simulated" the dialogue of a psychotherapist was programmed.

Late 1960s. Doug Engelbart invented the mouse at SRI.

1966. Ross Quillian (PhD dissertation, Carnegie Inst. of Technology, now CMU) demonstrated semantic nets.
First Machine Intelligence workshop at Edinburgh — the first of an influential annual series organized by Donald Michie and others.
Negative report on machine translation killed much work in Natural Language Processing (NLP) for many years.

1967. Dendral program (Edward Feigenbaum, Joshua Lederberg, Bruce Buchanan, Georgia Sutherland at Stanford) demonstrated to interpret mass spectra on organic chemical compounds. First successful knowledge-based program for scientific reasoning.
Joel Moses (PhD work at MIT) demonstrated the power of symbolic reasoning for integration problems in the Macsyma program. First successful knowledge-based program in mathematics.
Richard Greenblatt at MIT built a knowledge-based chess-playing program, MacHack, that was good enough to achieve a class-C rating in tournament play.

1968. Marvin Minsky and Seymour Papert published Perceptrons, demonstrating limits of simple neural nets.

1969. SRI robot, Shakey, demonstrated combining locomotion, perception, and problem solving.
Roger Schank (Stanford) defined conceptual dependency model for natural language understanding. Later developed (in PhD dissertations at Yale) for use in story understanding by Robert Wilensky and Wendy Lehnert, and for use in understanding memory by Janet Kolodner.
First International Joint Conference on Artificial Intelligence (IJCAI) held at Stanford.

1970. Jamie Carbonell Sr., developed SCHOLAR, and interactive program for computer-aided instruction based on semantic nets as the representation of knowledge.
Bill Woods described Augmented Transition Networks (ATNs) as a representation for natural language understanding.
Patrick Winston's MIT PhD program, APCH, learned concepts from examples in the world of children's blocks.

Early 1970s. Jane Robinson and Don Walker established influential Natural Language Processing group at SRI.

1971. Terry Winograd's PhD thesis (MIT) demonstrated the ability of computers to understand English sentences in a restricted world of children's blocks, in a coupling of his language understanding program, SHRDLU, with a robot arm that carried out instructions typed in English.

1972. Prolog developed by Alain Colmerauer.

1974. Ted Shortliffe's PhD dissertation on MYCIN (Stanford) demonstrated the power of rule-based systems for knowledge representation and inference in the domain of medical diagnosis and therapy. Sometimes called the first expert system.
Earl Sacerdoti developed one of the first planning programs, ABSTRIPS, and developed techniques of hierarchical planning.

1975. Marvin Minsky published his widely-read and influential article on Frames as a representation of knowledge, in which many ideas about schemas and semantic links are brought together.
The Meta-Dendral learning program produced new results in chemistry (some rules of mass spectrometry) the first scientific discoveries by a computer to be published in a refereed journal.

Mid 1970s. Barbara Grosz (SRI) established limits to traditional AI approaches to discourse modeling. Subsequent work by Grosz, Bonnie Webber, and Candace Sidner developed the notion of "centering", used in establishing focus of discourse and anaphoric references in NLP.
Alan Kay and Adele Goldberg (Xerox PAPC) developed the Smalltalk language, establishing the power of object-oriented programming and of icon-oriented interfaces.
David Marr and MIT colleagues described the "primal sketch" and its role in visual perception.

1976. Doug Lenat's AM program (Stanford PhD dissertation) demonstrated the discovery model (loosely-guided search for interesting conjectures).
Randall Davis demonstrated the power of meta-level reasoning in his PhD dissertation at Stanford.

Late 1970s. Stanford's SUMEX-AIM resource, headed by Ed Feigenbaum and Joshua Lederberg, demonstrated the power of the APPAnet for scientific collaboration.

1978. Tom Mitchell, at Stanford, invented the concept of Version Spaces for describing the search space of a concept formation program.
Herb Simon won the Nobel Prize in Economics for his theory of bounded rationality, one of the cornerstones of AI known as "satisficing".
The MOLGEN program, written at Stanford by Mark Stefik and Peter Friedland, demonstrated that an object-oriented representation of knowledge can be used to plan gene-cloning experiments.

1979. Bill VanMelle's PhD dissertation at Stanford demonstrated the generality of MYCIN's representation of knowledge and style of reasoning in his EMYCIN program, the model for many commercial expert system "shells".
Jack Myers and Harry Pople at University of Pittsburgh developed INTERNIST, a knowledge-based medical diagnosis program based on Dr. Myers' clinical knowledge.
Cordell Green, David Barstow, Elaine Kant, and others at Stanford demonstrated the CHI system for automatic programming.
The Stanford Cart, built by Hans Moravec, became the first computer-controlled, autonomous vehicle when it successfully traversed a chair-filled room and circumnavigated the Stanford AI Lab.
Drew McDermott and Jon Doyle at MIT, and John McCarthy at Stanford began publishing work on non-monotonic logics and formal aspects of truth maintenance.

1980s. Lisp Machines developed and marketed.
First expert system shells and commercial applications.

1980. Lee Erman, Pick Hayes-Roth, Victor Lesser, and Raj Reddy published the first description of the blackboard model, as the framework for the HEARSAY-II speech understanding system.
First National Conference of the American Association of Artificial Intelligence (AAAI) held at Stanford.

1981. Danny Hillis designed the connection machine, a massively parallel architecture that brought new power to AI,

and to computation in general. (Later founds Thinking Machines, Inc.)

1983. John Laird and Paul Rosenbloom, working with Allen Newell, completed CMU dissertations on SOAR.

James Allen invented the Interval Calculus, the first widely used formalization of temporal events.

Mid 1980s. Neural Networks became widely used with the Backpropagation algorithm (first described by Werbos in 1974).

1985. The autonomous drawing program, Aaron, created by Harold Cohen, was demonstrated at the AAAI National Conference (based on more than a decade of work, and with subsequent work showing major developments).

1987. Marvin Minsky published "*The Society of Mind*," a theoretical description of the mind as a collection of cooperating agents.

1989. Dean Pomerleau at CMU created ALVINN (An Autonomous Land Vehicle in a Neural Network), which grew into the system that drove a car coast-to-coast under computer control for all but about 50 of the 2850 miles.

1990s. Major advances in all areas of AI, with significant demonstrations in machine learning, intelligent tutoring, case-based reasoning, multi-agent planning, scheduling, uncertain reasoning, data mining, natural language understanding and translation, vision, virtual reality, games, and other topics.

Rod Brooks' COG Project at MIT, with numerous collaborators, made significant progress in building a humanoid robot.

Early 1990s. TD-Gammon, a backgammon program written by Gerry Tescuro, demonstrated that reinforcement learning is powerful enough to create a championship-level game-playing program by competing favorably with world-class players.

1997. The Deep Blue chess program beat the current world chess champion, Garry Kasparov, in a widely followed match.

First official Robo-Cup soccer match, featuring table-top matches with 40 teams of interacting robots and over 5000 spectators.

Late 1990s. Web crawlers and other AI-based information extraction programs became essential in widespread use of the world-wide-web.

Demonstration of an Intelligent Room and Emotional Agents at MIT's AI Lab. Initiation of work on the Oxygen Architecture, which connects mobile and stationary computers in an adaptive network.

2000. Interactive robot pets (a.k.a. "smart toys") became commercially available, realizing the vision of the 18th century novelty toy makers.

Cynthia Breazeal at MIT published her dissertation on Sociable Machines, describing KISMET, a robot with a face that expresses emotions.

The Nomad robot explored remote regions of Antarctica, looking for meteorite samples.

BRUCE G. BUCHANAN, University of Pittsburgh

AI Perspectives

Just as AI researchers must select the goals they will pursue, they must select the frameworks within which to pursue them. These frameworks provide a perspective on AI problems, shaping researchers' choices of which questions to address, how to address them, and what constitutes an answer. One perspective, which can be described as *biomorphic*, takes inspiration from biological systems. Neural network models, for example, are inspired by neurons in the brain. See also **Artificial Intelligence: Neural Networks**. Another example is genetic algorithms, which take their inspiration from evolution, "evolving" promising solutions by a simulated process of natural selection. See also **Artificial Intelligence: Genetic Algorithms and Evolutionary Computing**. Such models may be used not only for the pragmatic goals of solving difficult problems, but also to study the biological processes that they model, in order to increase understanding of the factors affecting living organisms. See also **Artificial Intelligence: Artificial Life**.

Another perspective takes its inspiration from human cognition, focusing on functional constraints rather than on biologically inspired mechanisms. An illustration is research on case-based reasoning (CBR), which was inspired by the role of memory in human problem — solving. For example, doctors use case-based reasoning when they treat an illness by remembering a similar previous case — the treatment of a previous patient with similar symptoms — and adapting the prior treatment to fit changed circumstances (e.g., adjusting the dosage for a child). See also **Artificial Intelligence: Case-Based Reasoning**. This view of problem-solving suggests studying issues such as how a memory of cases must be organized to model the retrievals of human reasoners, which can provide hypotheses about human reasoning as well as useful mechanisms for AI systems. How case-based reasoning provides a stance towards cognitive science, is described in the 1998 Leake reference listed and a overview of major trends in CBR research and applications can be found in his 1996 reference.

Yet another perspective is more technological: it studies the requirements and mechanisms for intelligence, without restricting the mechanisms considered. Practitioners seeking to develop useful systems, and researchers interested in understanding the general nature of intelligence, need not be constrained by biology or psychology. The processes that evolved in human reasoners are not necessarily the best ones for achieving high-quality performance in intelligent machines. For example, studies of the psychology of chess suggest that chess masters consider perhaps two moves per second, with their ability to recognize known board patterns playing a key role in their choice of moves. Deep Blue, however, defeated Gary Kasparov by exploiting a special architecture that enabled it to consider 200 million positions per second. See also **Artificial Intelligence: and Games**.

A Sampling of AI Research Areas

Search. In 1976, Newell and Simon proposed that intelligent behavior arises from the manipulation of *symbols* entities that represent other entities, and that the process by which intelligence arises is *heuristic search*. Search is a process of formulating and examining alternatives. It starts with an initial state, a set of candidate actions, and criteria for identifying the goal state. It is often guided by heuristics, or "rules of thumb," which are generally useful, but not guaranteed to make the best choices. Starting from the initial state, the search process selects actions to transform that state into new states, which themselves are transformed into more new states, until a goal state is generated. For example, consider a search program to solve the "8-puzzle" for children, which is shown in Fig. 1. A child solves the puzzle by sliding the numbered tiles (without lifting them) to reach a configuration in which the tiles are all in numerical order, as shown in the second board in the figure. When the 8-puzzle is seen as a search problem, the initial state is a starting board position, each action is a possible move of one tile up, down, left, or right (when the position it will move to is blank), and the goal state is the second state in Fig. 1. Here a heuristic function might suggest candidate moves by comparing their results to the goal, in order to favor those moves that appear to be making progress towards the solution. For this search problem, what is of interest is the solution path (how the solution was generated). However, for some problems, only the final state is important. A designer may only be interested in generating a successful design, rather than how it was generated.

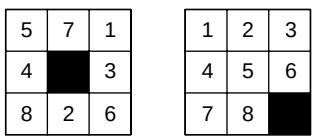

Fig. 1. Sample initial and goal states for the 8-puzzle.

A central problem in search is the *combinatorial explosion* of alternatives to consider. For example, if there are 10 possible actions from each state, after 5 moves there are a million possibilities to consider for the next move. Numerous techniques have been developed to improve search performance, and the combination of intelligent strategies and special-purpose computing hardware has enabled AI systems to rapidly search enormous spaces of alternatives. For examples of the role of search in two specific AI areas. See also **Artificial Intelligence: Automated Reasoning**; and **Artificial Intelligence: Game Playing Systems**.

Knowledge Capture, Representation and Reasoning. In order to guide search — or even to describe problems, actions, and solutions — the relevant domain knowledge must be encoded in a form that can be effectively manipulated by a program. More generally, the usefulness of any reasoning process depends not only on the reasoning process itself, but also on having the right knowledge and representing it in a form the program can use.

In the logicist approach to knowledge representation and reasoning, information is encoded as assertions in a logic, and the system draws conclusions by deduction from those assertions. See also **Artificial Intelligence: Automated Reasoning**. Other research studies nondeductive forms of reasoning, such as reasoning by analogy and abductive inference — the process of inferring the best explanation for a set of facts. Abductive inference does not guarantee sound conclusions, but is enormously useful for tasks such as medical diagnosis, in which a reasoner must hypothesize causes for a set of symptoms.

Capturing the knowledge needed by AI systems has proven to be a challenging task. The knowledge in rule-based expert systems, for example, is represented in the form of rules listing conditions to check for, and conclusions to be drawn if those conditions are satisfied. For example, a rule might state that *IF* certain conditions hold (e.g., the patient has certain symptoms), *THEN* certain conclusions should be drawn (e.g., that the patient has a particular condition or disease). A natural way to generate these rules is to interview experts. Unfortunately, the experts may not be able to explain their decisions adequately in a rule-based way, resulting in a "knowledge-acquisition bottleneck" impeding system development.

One approach to alleviating the knowledge acquisition problem is to develop sharable knowledge sources that represent knowledge in a form that can be re-used across multiple tasks. The CYC project, for example, is a massive ongoing effort to encode the "consensus knowledge" that underlies much commonsense reasoning. Much current knowledge representation research develops sharable *ontologies* that represent particular domains. Ontologies provide a formal specification of the concepts in the domain and their relationships, to use as a foundation for developing knowledge bases and facilitating knowledge sharing.

Reasoning Under Uncertainty. AI systems, like people, must often act despite partial and uncertain information. First, the information received may be unreliable (e.g., a patient may misremember when a disease started, or may not have noticed a symptom that is important to a diagnosis). In addition, rules connecting real-world events can never include all the factors that might determine whether their conclusions really apply (e.g., the correctness of basing a diagnosis on a lab test depends whether there were conditions that might have caused a false positive, on the test being done correctly, on the results being associated with the right patient, etc.) Thus in order to draw useful conclusions, AI systems must be able to reason about the probability of events, given their current knowledge. Research on Bayesian reasoning provides methods for calculating these probabilities. (see Charniak in reference). *Bayesian networks*, graphical models of the relationships between variables of interest, have been applied to a wide range of tasks, including natural language understanding, user modeling, and medical diagnosis. For example, Intellipath, a commercial system for pathology diagnosis, was approved by the AMA and has been fielded in hundreds of hospitals worldwide. Diagnostic reasoning may also be combined with reasoning about the value of alternative actions, in order to select the course of action with the greatest expected utility. For example, a medical decision-making system might make decisions by considering the probability of a patient having a particular condition, the probability of bad side-effects of a treatment and their severity, and the probability and severity of bad effects if the treatment is not performed.

In addition to dealing with uncertain information, everyday reasoners must be able to deal with vague descriptions, such as those provided in natural language. For example, a doctor who is told that a patient has a "high fever," must be able to reason about the fuzzy concept of "high fevers." Whether a particular fever is "high" is not simply a true or false decision decided by a cutoff point, but rather, a matter of degree. Fuzzy reasoning provides methods for reasoning about vague knowledge. See also **Artificial Intelligence: Fuzzy Reasoning**.

Planning, Vision, and Robotics. The conclusions of the reasoning process can determine goals to be achieved. Planning addresses the question of how to determine a sequence of actions to achieve those goals. The resulting action sequences may be designed to be applied in many ways, such as by robots in the world, by intelligent agents on the Internet, or even by humans. Planning systems may use a number of techniques to make the planning process practical, such as *hierarchical planning*, reasoning first at higher levels of abstraction and then elaborating details within the high-level framework (e.g., as a person might do when first outlining general plans for a trip and then considering fine-grained details such as how to get to the airport), and *partial-order* planning, enabling actions to be inserted in the plan in any order, rather than chronologically, and subplans to be merged. Dean and Kambhampati provide an extensive survey of this area.

In real-world situations, it is seldom possible to generate a complete plan in advance and then execute it without changes. The state of the world may be imperfectly known, the effects of actions may be uncertain, the world may change while the plan is being generated or executed, and the plan may require the coordination of multiple cooperating agents, or counterplanning to neutralize the interference of agents with opposing goals. Determining the state of the world and guiding action requires the ability to gather information about the world, through sensors such as sonar or cameras, and to interpret that information to draw conclusions. See also **Artificial Intelligence: Machine Vision**. In addition, carrying out actions in a messy and changing world may require rapid responses to important events (e.g., for a robot-guided vehicle to correct a skid), or an ongoing process of rapidly selecting actions based on the current context (for example, when a basketball player must avoid an opponent). Such problems have led to research on reactive planning, as well as on how to integrate reactive methods with the deliberative methods providing long-term guidance. See also **Artificial Intelligence: Robotics**. The RoboCup Federation sponsors an annual series of competitions between robot soccer teams as a testbed for demonstrating new methods and extending the state of the art in robotics (*www.robocup.org*).

Natural language processing. Achieving natural interactions between humans and machines requires machines to understand and generate language. Likewise, understanding human communication requires the understanding of how language is processed by people. The nature of human language raises many challenging issues for language processing systems: natural language is elliptic, leaving much unstated, and its meaning is context-dependent ("Mary took aspirin" will have a different meaning when explaining how she recovered from her headache, or her arrest for shoplifting). Some natural language processing approaches investigate algorithms for syntactic parsing, to determine the grammatical structure of textual passages; others take a cognitively inspired view, studying the knowledge structures underlying human understanding and modeling the process by which they are applied, or even attempting to directly apply expectations from memory to the parsing process. Other systems apply statistical methods to tasks such as information extraction from newspaper articles. Machine translation systems, although still far from replacing human translators for literature, can now generate useful translations. See also **Artificial Intelligence: Natural Language Processing**.

Machine Learning. In a complex world, it is difficult to encode all the knowledge that a system may need, and may also be difficult to keep system knowledge up-to-date. Machine learning research focuses on how AI systems can augment or refine their own knowledge to improve their performance. Just as people use different learning techniques, machine learning systems use a wide range of approaches. Some of these are *supervised*, in that they presume that the learner will have access to the correct answers; others are *unsupervised*, requiring the learner to proceed without benefit of feedback.

Inductive learning systems learn by analyzing examples to identify correlations between inputs and outputs. For example, neural network models process inputs according to networks of idealized neurons, and learn by algorithms that adjust the weights of neural connections based on correlations between inputs and outputs in training examples. A neural network system to recognize faces might be trained on a digitized set of photographs of faces (inputs) and the associated identities (outputs), to learn which facial features are correlated with different individuals. See also **Artificial Intelligence: Neural Networks**. Theory-driven learning approaches use background knowledge to guide generalizations, in order to focus on important types of features. Instance-based learning systems and case-based reasoners perform "lazy learning:" rather than attempting to generalize experiences as they are encountered, case-based reasoning systems store learned cases as-is, adapting or generalizing their lessons

only if needed to solve new problems. See also **Artificial Intelligence: Machine Learning**.

Practical Impact of AI

AI technology has had broad impact. AI components are embedded in numerous devices, such as copy machines that combine case-based reasoning and fuzzy reasoning to adjust the copier automatically to maintain copy quality. AI systems are also in everyday use for tasks such as identifying credit card fraud, configuring products, aiding complex planning tasks, and advising physicians. AI is also playing an increasing role in corporate knowledge management, facilitating the capture, and reuse of expert knowledge. Intelligent tutoring systems make it possible to provide students with more personalized attention, and even for the computer to listen to what children say and respond to it (http://www.cs.cmu.edu/~listen/). Cognitive models developed by AI can also suggest principles for effective support for human learning, guiding the design of educational systems.

AI technology is being used in autonomous agents that independently monitor their surroundings, make decisions and act to achieve their goals without human intervention. For example, in space exploration, the lag times for communications between Earth and probes make it essential for robotic space probes to be able to perform their own decision-making. Depending on the relative locations of the Earth and Mars, one-way communication can take over 20 minutes. In a 1999 experiment, an AI system was given primary control of a spacecraft, NASA's Deep Space 1,60,000,000 miles from earth, as a step towards autonomous robotic exploration of space (see *rax.arc.nasa.gov*). Methods from autonomous systems also promise to provide important technologies to aid humans. For example, in a 1996 experiment called "No Hands Across America," the RALPH system, a vision-based adaptive system to learn road features, was used to drive a vehicle for 98% of a trip from Washington, DC, to San Diego, maintaining an average speed of 63 mph in daytime, dusk, and night driving conditions. Such systems could be used not only for autonomous vehicles, but also for safety systems to warn drivers if their vehicles deviate from a safe path.

In electronic commerce, AI is providing methods for determining which products buyers want and configuring them to suit buyers' needs. The explosive growth of the internet has also led to growing interest in internet agents to monitor users' tasks, seek needed information, and learn which information is most useful. For example, the Watson system monitors users as they perform tasks using standard software tools such as word processors, and uses the task context to focus search for useful information to provide to them as they work.

Continuing investigation of fundamental aspects of intelligence promises broad impact as well. For example, researchers are studying the nature of creativity and how to achieve creative computer systems, providing strong arguments that creativity can be realized by artificial systems. Numerous programs have been developed for tasks that would be considered creative in humans, such as discovering interesting mathematical concepts, in the program AM, making paintings, in Aaron, and performing creative explanation, in SWALE. The task of AM, for example, was not to prove mathematical theorems, but to discover interesting concepts. The program was provided only with basic background knowledge from number theory (e.g., the definition of sets), and with heuristics for revising existing concepts and selecting promising concepts to explore. Starting from this knowledge, it discovered fundamental concepts such as addition, multiplication, and prime numbers. It even rediscovered a famous mathematical conjecture that was not known to its programmer: Goldbach's conjecture, the conjecture that every even integer greater than 2 can be written as the sum of two primes. Buchanan surveys some significant projects in machine creativity and argues for its potential impact on the future of artificial intelligence.

In addition, throughout its history of AI research has provided a wellspring of contributions to computer science in general. For example, the computer language Lisp, developed by John McCarthy in 1958, provided a tool for developing early AI systems using symbolic computation, but has remained in use to the present day, both within and outside AI, and has had significant impact on the area of programming languages. Later AI research also gave rise to the computer language, Prolog, used for logic programming. A key idea of logic programming is that the programmer should specify only the problem to be solved and constraints on its solution, leaving the system itself to determine the details of how the solution should be obtained.

Conclusion and Resources

In its short existence, AI has increased understanding of the nature of intelligence and provided an impressive array of applications in a wide range of areas. It has sharpened understanding of human reasoning and of the nature of intelligence in general. At the same time, it has revealed the complexity of modeling human reasoning, providing new areas and rich challenges for the future.

AAAI, the American Association for Artificial Intelligence, maintains an extensive on-line library of articles on AI, ranging from general introductions to focused articles on specific areas, *at http://www.aaai.org/Pathfinder/.AI Magazine*, the official magazine of AAAI, publishes accessible articles on current research and applications, as well as tutorials on important AI areas. After a delay, full-text electronic versions of articles from back issues are freely available from the magazine home page *http://www.aimagazine.org*. The magazines *IEEE Intelligent Systems* and *Intelligence* are additional sources for accessible articles on new developments in AI and its applications.

ARTIFICIAL INTELLIGENCE: ARTIFICIAL LIFE. Artificial life (Alife), as a field of scientific investigation, officially came into being in the late 1980s. The name was coined by Chris Langton, who organized the first conference in 1987. Alife concerns itself with a wide range of topics. However, the primary focus of most Alife studies is to understand life as it is and "life as it could be". Alife seeks to study all aspects of living and lifelike entities (e.g., economies, ecosystems) through *synthetic* methods: simulation, robotics, and even biochemical experiments. Langton has pointed out that synthesis contributes greatly to the understanding of phenomena, as was the case in chemistry. Before the advent of easy methods of chemical synthesis, chemists could only study the motley and limited mix of chemicals that nature readily provided. Once synthetic techniques were available, chemical properties could be rigorously explored through the creation and study of new compounds.

Current areas of great interest in Alife include evolution and ecology, animal behavior, robotics, emergent and coordinative behaviors, the relationship between evolution and learning, adaptation in general, complexity, diversity, self-replication, reproduction and sexuality, development, stability and self-maintenance (how a molecule, cell or organism maintains its current structure despite changes in the environment). Each of these areas has many avenues to explore. Those who study evolution are interested in a huge range of issues, including the evolution of communication, the evolution of morphology (an animal's physical form), the importance of mutation and recombination in genetics, and the evolution of learning itself. Developmental studies might focus on how a coloration pattern in some animal forms over time, or perhaps how a neural network might grow in order to be "wired" properly for processing visual patterns. Still other Alife studies try to explain the dynamics of population extinctions or how diversity is maintained among all of the species that populate the earth. The field of Alife continues to grow, with more areas being added to it as researchers from diverse domains discover the usefulness of Alife methodologies and perspectives.

Methodology

Alife methods of investigation involve the use of mathematical models, computer simulations, robotics and biochemicals. Each of these has its strengths, and each complements the others. For instance, a biochemical experiment can reveal important biological properties of RNA, while a computer simulation can show how chemicals similar to RNA might arise on planets with different chemical makeups.

Some researchers study biological properties with mathematical models. Long before the field of Alife officially existed, Lotka and Volterra derived a set of simple equations to model the dynamics of predator–prey populations. These equations were useful because they simply and concisely described a system with complex behavior (the interactions of predators and prey). More recent game–theoretical models tackle properties such as competition, cooperation, and evolution (John Maynard Smith). More commonly, practitioners of Alife avail themselves of new technologies. Many use computer simulations since computers are powerful and relatively inexpensive. A model or theoretical construct can be simulated on a computer and the results can give hints as to the model's validity. Several important Alife simulations include Reynolds' Boids and Conway's Game of Life (both described below). Standard simulation tools include genetic algorithms, neural networks, and artificial worlds.

Although simulations can explore biological properties in ways that are impossible or impractical for field biologists, they are often too idealized and simple to answer some questions due to both the discrete nature of computer representations and the limitations on the level of detail possible in a simulation. To test an idea with a noisier and more complex world, some researchers build robots and place them in a physical environment to study the kinds of behavioral mechanisms, sensors, and effectors that are necessary to achieve various behaviors. An example of this is Angle, Maes, and Brooks' Genghis, a six-legged robot that *learns* how to walk with an insect-like gait. See Fig. 1. To get even closer to real life, some researchers manipulate biochemicals. Modern biochemical techniques, such as the synthesis and replication of strings of RNA, allow researchers to explore both how RNA works and how it could have worked in the early stages of the evolution of life on earth. Researchers can even evolve specialized RNA molecules that serve specific biological functions, often for the purpose of developing a new drug. It is important to realize that results from one method can often guide another method, as when a simulation of an RNA-based drug is then tested with real RNA in a biochemistry laboratory. The results of the RNA test can then inform the simulation, and so the cycle continues. Alife is a truly interdisciplinary field.

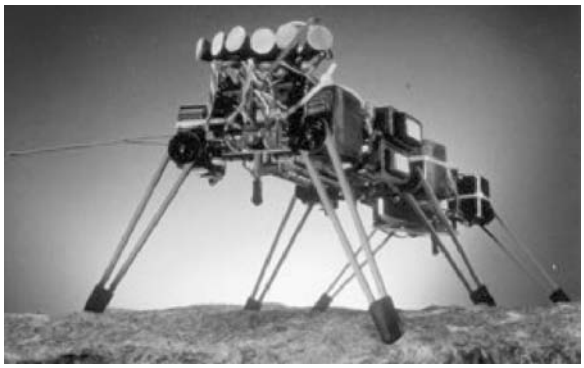

Fig. 1. Genghis robot.

Two Examples

Boids. A good illustration of Alife work is provided by an early Alife investigation into the nature of flocking behavior in birds. Craig Reynolds sought to produce computer animations of flocking and herding behavior using simple, computationally tractable rules. When birds fly together in a flock, it seems as if they are computing trajectories, making complex judgments based on optimal distances between themselves and other birds, and also maintaining a distinctive "shape" of the flock (a "V" for some species). It is unlikely that birds are using trigonometry, differential equations, and flock-shape aesthetics to govern their flocking behavior, however. Instead of these complex mathematical mechanisms, Reynolds found that he could get flocking behavior with three simple rules and the assumption that birds knew their velocity relative to those around them and the location of the flock's center of mass. See Fig. 2. Each boid (simulated bird) would modify its velocity vector based on the following three rules:

1. Keep a certain average distance away from all nearby boids.
2. Keep heading in the average heading of nearby boids.
3. Move to be close to nearest boids.

Each of these rules might conflict with the others, so the higher-numbered rule takes precedence in such a case. Recent modifications to these rules have produced a variety of flocking formations, including a "V" formation. The Boids simulation illustrates some of the characteristics of the Alife approach. Each boid independently follows a simple set of rules. The boids are causally connected to their environment, and their individual behaviors produce the higher-level, or *emergent* behavior, of flocking.

Cellular Automata. Perhaps the area that best epitomizes Alife is that of Cellular Automata (CAs). CAs were invented by John von Neumann in the 1940s, and their properties have been investigated by many researchers since then. A finite-state automaton ("automaton" for short) is a simple machine that exists in one of a finite number of states and produces outputs based on its inputs. A common automaton is a television, where the inputs are the channel selector and on/off switch, the outputs are whatever show is playing on the current channel (or a blank screen if the TV is off), and the states consist of the channels that the TV can be tuned to. A cellular

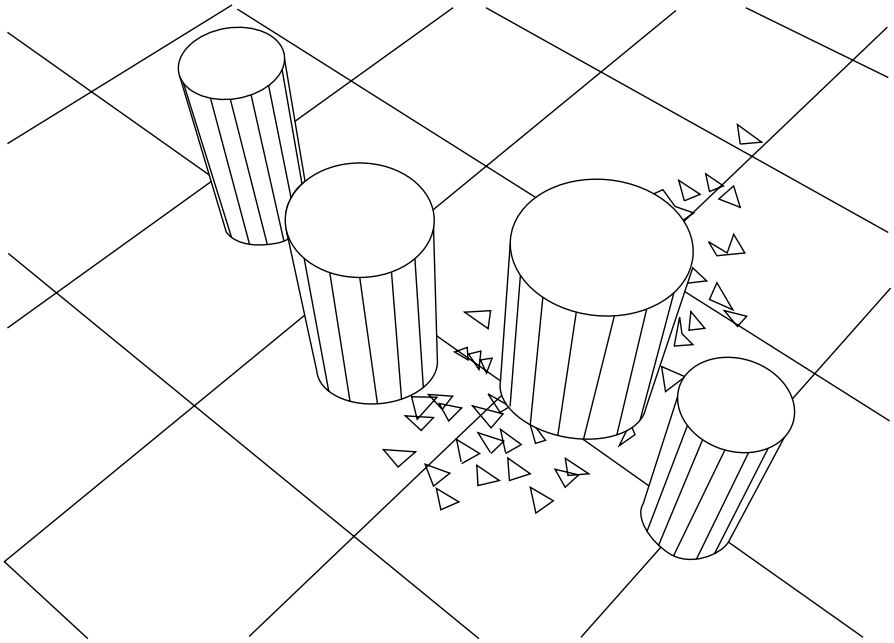

Fig. 2. Boids in a flock.

automaton is similar to an automaton except that it is located on a matrix (a grid) with other cellular automata, and all of its input comes from the other automata surrounding it. CAs vary widely, but interesting effects can emerge from a matrix of CAs with just two states: on or off. Each cellular automaton updates itself (changes its state) based on the states of the CAs directly adjacent to it (for instance, a cell might go from on to off if it were surrounded by too many other cells, kind of like overcrowding in plants). Of interest is the particular pattern of CAs that are on or off at any one time step. John Conway explored the kinds of patterns that could arise from a matrix of CAs where each CA had only two states. He found a pattern called a glider that would change over five time steps into the same pattern, but displaced by a bit. Thus, this pattern could move and still maintain its original shape (a kind of long-term stability). Other researchers have shown that CAs with two or more states can self-replicate. Many have investigated self-replicating loops, which are square ("loop") arrangements of CAs that will, over many time steps, copy themselves. After the copying is made, two loops will now exist, and both can continue the process of self-replication. See Fig. 3.

Principles of Alife

Although there is great diversity in the approaches taken in Alife, there are some common principles that pervade the field, especially with respect to computer simulation and robotic approaches. Alife systems (and the theories that accompany them) often contain *multiple, simple, interacting agents* (things that exhibit behavior) which are *autonomous* (*mean*ing that each agent is in control of what it does). Systems often are described at *multiple levels*, in much the same way as humans can be described at the levels of atoms, molecules, cells, tissues, organs and populations. Agents are *embodied*, meaning that they have bodies with specific abilities and limitations, and they are *embedded*, meaning that they interact with a (simulated or real) environment and receive inputs from that environment (rather than receiving inputs that the researcher has specifically designed, which will likely be biased and unrealistic). Many Alife agents are *adaptive*, in that they are generally either evolved for a specific purpose or they learn how to do their task.

Applications

Alife is mainly a scientific endeavor, but it also has several important applications. Since Alife concerns itself with animal behavior, many of the techniques used (genetic algorithms, neural networks, other forms of machine learning, various robotic architectures) can be applied to constructing robots for hazardous tasks. In fact, one robot, the Mars Polar Lander, was sent on an interplanetary exploration mission; it was designed to autonomously explore the planet, negotiate rough terrain, analyze samples and send the results back to Earth. This robot, along with Genghis, is a good example of one of the goals of Alife, to make artificial entities which can behave independently of humans. Nuclear reactors, chemical-processing plants and other dangerous environments are prime candidates for custom-designed adaptive robots. Robotic toys are also popular, as Sony's AIBO and other kinds of "adaptive pets" have demonstrated. Computer anti-virus programs may be most effective if designed along the lines of biological immune systems (Stephanie Forrest). Finally, new drugs are being created with proteins designed by both evolutionary techniques in the biochemistry laboratory and genetic algorithms.

Future of Alife

Alife is a new field. Much like a living entity itself, it is still growing, adding new parts and deleting others. The potential gains are enormous: more complete biological theories; an understanding of what factors encourage, maintain and destroy life; applications in entertainment, human industry and medicine. Alife tells us more about ourselves and our world, and it can help predict the impact of our actions on this world. Through the work of Alife researchers, great advances have been made in understanding the growth, change, and extinction of biological populations, the dynamics of economies, the interdependencies of ecosystems, and the origins and diversity, of life. The study of cellular automata, self-replicating systems, robotic and multi-agent systems has shown that simple rules and local interactions can account for much of the complexity of behavior in the natural world. The next century will be an exciting period for the development of this field.

Societies, Journals and Conferences

The main society for Alife is called, simply, Artificial Life, which produces a journal and organizes an annual conference under that same name. The International Society for Adaptive Behavior (ISAB) holds a biennial conference known as From Animals to Animats: The International Conference on Simulation of Adaptive Behavior and also produces a journal, *Adaptive Behavior*. Many other journals related to Alife exist, including *Complexity*, *Biosystems* and the *Journal of Theoretical Biology*. Another important conference in the field is the European Conference on Artificial Life. See also **Artificial Intelligence**; **Genetic Algorithms and Evolutionary Computing**; and **Artificial Intelligence: Robotics**.

ARTIFICIAL INTELLIGENCE: AUTOMATED REASONING. The ability to draw *logical inferences* is one of the central components of intelligent behavior, as a consequence, automated reasoning systems components of some form are at the heart of many artificial intelligence systems. The applications of automated reasoning are no longer restricted to the mechanization of proving mathematical theorems — the original motivation of the field. Automated reasoning techniques have led to the development of *logic programming languages* like PROLOG, they are used in *natural language understanding* as well as *expert system, software engineering*, or large-scale *planning* and *scheduling systems*; they even fly into space on the NASA Jupiter missions.

The field of automated reasoning is one of the oldest branches of Artificial Intelligence; it has contributed general logic-based methods, which now form one of the fundamental paradigms of artificial intelligence research. In the remainder of this article, we will explain the fundamental ideas, discuss some paradigms for building automated reasoning systems,

and and briefly present some applications. Further information can be found in Bibel and Schmitt, Robinson and Voronkov and the specialized given in the additional Reading or at *http://www.mathweb.org/mr*.

Logical Calculi

The common trait of all automated reasoning systems is the reliance on some form of logic as a *representation formalism*, on logical *calculi* to infer new representations from initial ones, and on search procedures to navigate the search spaces induced by these calculi.

Let us consider a simple example; theorem proving in first-order logic. Suppose we know that all men are mortal, that Socrates is a man and a philosopher, and we want to deduce that Socrates will eventually die.

The first step in building a an automated reasoning system for this task is to decide on a suitable logic, i.e., a formal language that can be used to represent the knowledge at a level of detail that is sufficient to draw the desired inference; we will take classical first-order logic.

We represent our goal (the theorem we want to prove) as the formula $\mathcal{T} :=$ mortal(Socrates), and the world knowledge as the following set of formulae

$$\forall x.\,\mathrm{man}(x) \Rightarrow \mathrm{mortal}(x)\mathrm{man}(\mathrm{Socrates}) \wedge \mathrm{philosopher}(\mathrm{Socrates})$$

which we will take as hypotheses and denote by $\mathcal{H}$. You may read the $\forall x$ as "for all x holds", man(x) as "x is a man", and finally $\wedge$, $\Rightarrow$ as "and, implies". This formulation has the advantage that the meaning is now clearly defined (by a mathematical function, called the semantics) and void of ambiguities. The key intuition behind logic (due to the ancient Greeks) is that the truth of mortal(Socrates) in a world, where $\mathcal{H}$ are true, will only depend on their *syntactic form*, and not on the complex state of the world, such as aging of humans, or the danger of accepting drinks from people who do not like you. In fact, the set of formulas would still be true, if we read mortal(x) as "x loves a woman". As a consequence, the truth of $\mathcal{T}$ given $\mathcal{H}$ can be determined by purely syntactic means of formula manipulation by a *calculus*. We will take the so-called calculus of *natural deduction* introduced by Gerhard Gentzen in 1931. A calculus consists of a set of inference rules (that allow to transform (sets of) formulae) given by schemata, in our example:

$$\frac{A \wedge B}{A} ND(\wedge) \quad \frac{A \Rightarrow B \; A}{B} ND(\Rightarrow) \quad \frac{\forall X.\, A(X)}{A(B)} ND(\forall)$$

They can be read as "if I have the top formulae", then I can deduce the bottom ones. Thus a proof of a formula $\mathcal{T}$ from a set $\mathcal{H}$ of hypotheses is a sequence or tree generated by inference rules that has the hypotheses from $\mathcal{H}$ at the leaves and $\mathcal{T}$ at the root, in our case

1. $\forall x.\,\mathrm{man}(x) \Rightarrow \mathrm{mortal}(x)$	given
2. man(Socrates) $\wedge$ philosopher(Socrates)	given
3. man(Socrates)	$ND(\wedge; 2)$
4. man(Socrates) $\Rightarrow$ mortal(Socrates)	$ND(\forall; 2)$
5. mortal(Socrates)	$ND(\Rightarrow; 4, 3)$

Note that obtaining this proof even from our very restricted set of hypotheses and inference rules is not straightforward (at least for a machine that does not have any insights into guiding principles). Given other individuals like a god, we could have deduced the true formula man(zeus) $\Rightarrow$ mortal(zeus) (first-order logic interprets implications as true, iff the antecedent is false or the succedent is true), which would not help us in our proof (a god is not a man, therefore we do not care whether he is mortal). As a consequence, an automated reasoning system has to search in the space of all well-formed derivations for a proof of the desired theorem.

Automated Theorem Proving as Heuristic Search

Automated reasoning programs usually use calculi optimized towards mechanization on a machine. In contrast to Gentzen's calculus of natural deduction discussed above, which is modeled after patterns of human argumentation and derives theorems from generally accepted truths (axioms), machine-oriented calculi are usually *refutation calculi*, which show validity of a given formula by assuming its negation, and showing that it leads to a contradiction. This simple trick usually makes the calculi much more *goal-oriented* preventing unnecessary search. Moreover, machine-oriented calculi often use (meta)-variables to delay the decision about the instantiation of universal quantifiers (in step 4 of our example above). These variables are maintained in the proof and instantiations are only computed when a potential contradiction has been found by a process called *unification*, which finds most general solutions for term equations.

There are hundreds of calculi built on these ideas, which can be categorized into two classes. *Analytical calculi* such as *tableaux* (D'agastino et al.) develop the formula they try to refute in a case-analysis tree, showing that every case leads to a branch of the tree where both A and $-$A (read this as "not A") are present which is a contradiction. The *resolution* calculus (Robinson) is paradigmatic for the other class (*generative calculi*). It first converts formulate into a specialized form, called *clause normal form* (a conjunction of disjunctions, the clauses), and generates new clauses by the resolution rule, a generalization of the middle rule in the natural deduction calculus above. A refutation has been found in this calculus, if the empty clause is derived. As an empty disjunction it can never be true, it serves as an elementary contradiction for resolution.

Even with these refined calculi, the search spaces are so large, that they cannot be systematically be searched: They typically grow exponentially in the size of the proof, for instance the size of the full search space for proofs of length 100 exceeds the number of atoms in the universe ($4.10^7 9$); this phenomenon is known as the *combinatorial explosion* problem. The only exception to this rule of thumb are calculi that are not complete, i.e., they cannot prove all valid formulae for principal reasons. Moreover, theorem proving for all but the simplest logics is an undecidable problem, i.e., there cannot be an algorithm that terminates in all cases, and correctly answers, whether a given formula is entailed by a given set of hypotheses. There are, however so-called *semi-decision procedures* that are guaranteed to terminate on all valid formulae, but may run forever looking for a proof of invalid ones (i.e., those that have counterexamples).

Generally, automated theorem provers are computer programs that implement such semi-decision procedures by heuristically searching for a proof of a given conjecture in the space all possible proofs. Available systems have reached a great maturity in the last 45 years, both from the point of logical sophistication (they are available for a wide variety of logics and employ calculi specialized towards mechanized search), as well as from an engineering point of view (systems like OTTER (*http://www-unix.mcs.anl.gov/AR/otter*), SPASS (*http://spass.mpi-sb.mpg.de*), or WALDMEISTER (*http://agent.informatik.unikl.de/waldmeister*) can productively search through spaces of literally billions of formulae even on traditional hardware at the rate of tens of thousands of logical inferences per second, see Sutcliffe.

It is safe to characterize the state of the art by the following dichotomy: In applications where humans have little or no intuitions that guide the search for solutions, automated theorem proving techniques can be vastly more efficient than humans; General-purpose automated theorem provers have been known to prove problems in mathematics, some that were open for decades, e.g. the Robbins conjecture (McCune).

In applications where humans have obtained intuitions by training, they usually outclass the general-purpose systems dramatically. Sometimes, the human intuitions can be formalized and used to build special-purpose theorem proving systems. In these cases, the systems can compete again, for instance in the case of elementary plane geometry, where systems can prove all known theorems in a matter of seconds each (Wu).

Tactical Theorem Proving and Proof Planning

In applications like program verification (see below), where formalization is necessary, but systems are too weak for fully automated proof search, the research attention has turned towards semi-automatic systems. These rely on the human user to provide intuitions and guidance in proof search. In the extreme, the user can prescribe every single calculus-level proof step, but normally relies on so-called *tactics* to provide some automation. Tactics are specialized programs that construct parts of the desired proof and can drastically enhance the user's productivity. In this so-called *tactical theorem proving*, automation is usually achieved by exploring a specific mathematical theory, gradually building up a repertoire of useful lemmata and tactics that lead up to the main theorem or verification task and allow the reuse of results and past proof experience. As a consequence, tactic theorem provers like IMPS (*http://imps.mcmaster.ca*), ISABELLE (*http://isabelle.in.tum.de*) PVS (*http://pvs.csl.sri.com*), or NUPRL (*http://www.cs.cornell.edu/Info/Projects/NuPrl/nuprl.html*) come with large theory and tactic libraries. In effect, tactics act as derived inference rules (they abbreviate proofs at a lower level) and allow the user to specify the proof at a higher level of abstraction.

To regain a higher level of mechanization, a class of automated theorem provers called proof planners, tries to automate the proof search at the tactic level. The proof-change potentials of tactics are specified (the resulting combinations of tactic and specifications are called methods), and planning techniques from artificial intelligence are used to search for a high-level proof, which can later be refined down to the calculus level by executing the tactics. Proof planners like the OMEGA (*http://www/ags.uni-sb.de/omega*), LAMBDACLAM (*http://dream.dai.ed.ac.uk/software/systems/lambda-clam*), and INKA (*http://www.dfki.de/vse/systems/inka*) system explicitly take human proof search behavior as a model, and try to formalize the complex method and control knowledge available to human specialists. This approach capitalizes on the fact that the method level is closer to the level humans think in and therefore supports human-oriented techniques in proof search.

Applications of Automated Reasoning Techniques

Logic programming languages such as PROLOG are one of the most prominent applications of automated reasoning techniques. The intuition behind this approach to programming languages is that programs are specifications of data together with a set of rules of how to act on this (and other) data. Note that automated reasoning can fulfill the same requirement in a very principled way: we can read formulae like the first one in our example $(\forall x.\,\mathrm{man}(x) \Rightarrow \mathrm{mortal}(x))$ as a prescription to derive mortal(a), whenever we have man(a), thus automated reasoning can serve as nondeterministic programming language. Thus we only have to prescribe a proof strategy to arrive at a regular programming language: PROLOG does just this for the resolution calculus by restricting the set of admissible clauses and prescribing proof search to proceed in a depth-first search with clauses in the input order, acting on the disjuncts in the clauses from left to right. The advantage of this approach is that the meaning of a program is given by the semantics of first-order logic, for which we have a very clear mathematical understanding. Another advantage is that logic programming (and in particular the unification procedure employed in it) can be extended by calculi specialized to certain applications. If we for instance generalize unification to equation solving over finite sets, then we obtain *constraint-logic programming* (see Marriott and Stuckey for an introduction), which is the state-of-the-art method e.g. for solving large-scale scheduling applications, like managing the container port in Singapore harbor.

Another important application of automated reasoning techniques is *software engineering* (see *http://archive.comlab.ox.ac.uk/formal-methods.html*). Here, the goal is to create programs or computer hardware with certain guaranteed properties. We might be interested to guarantee that certain program computes the square root up to 10 significant digits, or that an e-commerce protocol cannot be exploited without knowing the private keys, or that a railway scheduling program will never allow two trains at the same time at the same location (crash). These properties are usually written down in a suitable logic (the ensuing representation is called a *specification*), then either the specification is proven to hold of existing program (program verification), or a suitable piece of software or hardware is generated from them (program synthesis).

Program verification systems usually consist of a tactical theorem prover that can deal with logics that are optimized towards dealing with program constructs (higher-order logics for functional programs (Thompson), dynamic logics (Harel et al.) for imperative programs or temporal logics (Lamport) for parallel and distributed programs) and a system to deal with large specifications.

Program synthesis works even more directly with proofs. Take for instance the problem of generating a program for sorting lists. In a (constructive) proof of the fact that for each list l, there exists a permutation l that is sorted, we had to construct a witness w for that claim about l. As w may depend on l, the proof actually has to construct a function $w(l)$. Program synthesis systems consist of a calculus where proofs of theorems like the above can be transformed into actual computer programs (they guarantee the specification by construction), and of a theorem prover that is optimized towards producing proofs that result in efficient programs.

A third application of automated reasoning that is somewhat paradigmatic for the applications in artificial intelligence, lies in *natural language understanding*. There the goal is to build systems that transform natural language input (either spoken or written) into a form that can be used by a problem-specific application (e.g. for translation or data base querying); this is usually a logic-based representation. The need for automated reasoning techniques in natural language understanding is that the meaning of a sentence depends on the knowledge of the world. Let us consider a simple but illustrative example: The two sentences "Every man loves a woman" and "Every car has a radio", have exactly the same structure, so an analysis that does not take world knowledge into account should give them similar meanings. However, the first sentence has two readings: the wide scope reading, where there is one woman, every man loves (e.g. Marilyn Monroe), and the narrow scope reading, where every man loves e.g. his wife. For the second sentence, we only get the narrow scope reading, since the wide scope is inconsistent with out knowledge that radios are physical parts of cars and if a is part of both b and c, then $b = c$. Other examples involve e.g. anaphoric references to or definite descriptions of entities that are not explicitly given in the discourse, but have to be inferred from the context. For instance in "Mary could not start her car. The battery was empty", we have to consult our knowledge about car parts again, to infer a suitable battery for the second sentence to refer to. Automated reasoning provides a rich selection of techniques to study such phenomena. Automated theorem proving for proving newness and consistency constraints, abduction (a variant of reasoning that tries to find plausible explanations that deductively entail observations) to compute the new information given by an utterance, and model-generation (a variant of theorem proving that instead of trying to refute a formula tries to construct an explicit model for it) for constructing an explicit discourse model that is closed under immediate logical consequences.

The interesting point for automated reasoning is that the rich structure of natural language (syntax, word order, stress, or discourse structure) provides rich extra-logical information that can be used to guide the search for proofs or models. For instance in resolving the definite description "the battery" we should not try to find just any battery, but one that is *salient*, i.e. that has been referred to recently. This restricts the search for possible batteries enormously, compared to say a mathematical investigation of batteries that would have to consider all batteries in the world to be complete.

Conclusion

Automated Reasoning is one of the oldest subdisciplines of artificial intelligence and has helped shape the field by introducing logic-based representation formalisms and the reliance on inference as a primary computational device. It is an active research field pursued with a number of applications in mind.

After the foundations are relatively well-studied, the great challenges of the field are defined by the applications. For mathematics it is the development of specialized reasoners for particular subdomains such as group theory or real intervals, their integration into general-purpose theorem provers, and the representation of human-oriented method- and control knowledge in proof planning.

For software engineering it is the development of logics and inference methods that are optimized towards reasoning about the various programming paradigms and the creation and manipulation of large-scale specifications and proofs.

For computational linguistics it is in the study of the interaction of linguistic knowledge with the proof search, and in augmenting of automated reasoning techniques with mechanisms to take advantage of this knowledge for guiding the proof search.

While the applications of automated reasoning techniques in (logical) programming languages are so common now that these are no longer considered part of the field, the use of formal methods in software engineering applications have reached the industrial mainstream only in the last five years. The applications in mathematics and natural language understanding are still largely academic.

ARTIFICIAL INTELLIGENCE: CASE-BASED REASONING. Case-based reasoning (commonly abbreviated as CBR) is a technique in artificial intelligence that derives solutions to problems by retrieving similar prior experiences and adapting their solutions to fit the new problems. It originates from the observation that human beings engaged in everyday reasoning and problem solving are often reminded of experiences from the past, and draw analogies between recalled experiences and their current task.

A case-based reasoning system contains a "memory" of *cases*: descriptions of specific situations that have occurred in the past, *and their outcomes*. The reasoner solves new problems by adapting the solutions in memory for similar past problems.

Case-based reasoning joins together artificial intelligence research from a number of areas, including Schank's cognitive model of memory organization, Rissland's work in legal reasoning, and Porter's work on medical reasoning. (See Schank; Rissland; Porter, Bareiss and Holte). Roger Schank and others examined the importance of remindings in human reasoning, and Schank's cognitive model of memory organization, *Dynamic Memory*. MEDIATOR used case-based reasoning to suggest resolutions of conflicts (See Kolodner, Simpson and Sycra-Cyranski); JUDGE used case-based reasoning to suggest sentences for juvenile offenders (see Bain); CHEF use case-based reasoning to construct new recipes (See Hammond). Edwina Rissland pioneered work on CBR for legal reasoning through a number of projects, including HYPO, and CABARET (See Ashley; Rissland and Skalak). Porter and Bareiss created the PROTOS system, which diagnoses hearing disorders.

Over the next decade, case-based reasoning matured, and was applied to a broad range of tasks, both in research and in commercial applications. (Janet Kolodner has produced an excellent work on both theory and applications and Ian Watson has created a nice book on commercial applications. Their references are listed at the end of this article. It is now well-established both as a technique for continuing research in artificial intelligence and as a practical artificial intelligence technique for industry applications.

Some CBR systems are "interpretive"; using old cases to aid in the interpretation and classification of new situations. Diagnosis is one common application of interpretive CBR systems. Medical diagnosis systems have demonstrated a high level of performance: e.g., the PROTOS system mentioned earlier is a notable success. CBR systems have also been successfully deployed to assist "help desk" customer service representatives; e.g., Compaq's SMART system, a case-based help-desk program to assist engineers in resolving customer problems over the telephone (See Acorn and Walden).

Many reasoning tasks require a more complex solution than a simple classification. As an example, route planning is a task requiring the reasoning system to create a set of directions for navigating between two locations. "Problem-solving" CBR systems must, in addition to retrieving similar cases, adapt a solution from an old case to apply to the similar, but not identical, current problem. For example, FORMTOOL is a case-based system for color-matching plastics created by General Electric (See Cheetham and Graf); ROBBIE is a case-based route planner (See Fox and Leake).

A case-based system is only as good as its memory of prior cases. Learning of new cases to augment the case memory has always been a central theme. David Leake notes: "Complementary with the principle of *reasoning is remembering* is the principle that *reasoning is remembered*—that reasoning and learning are intimately connected". (See reference listed). Many CBR systems "learn" new cases by storing the new results they generate, both successes and failures. Failure cases may serve as warnings of solutions to avoid in the future.

The general case-based reasoning process is illustrated in accompanying Fig. 1 (Leake). This process (1) describes a given problem in terms of features, called "indexing features," by which its case memory is organized, (2) compares these indexing features to the features of cases in the case memory, (3) extracts the stored solution or solutions with the most similar features, (4) maps, in the space of solutions, from the stored solution to a solution suitable for the original problem, (5) evaluates the resulting new solution, and (6) stores the new solution and its evaluation in the case memory for future use. Each portion of the process is described in greater detail below.

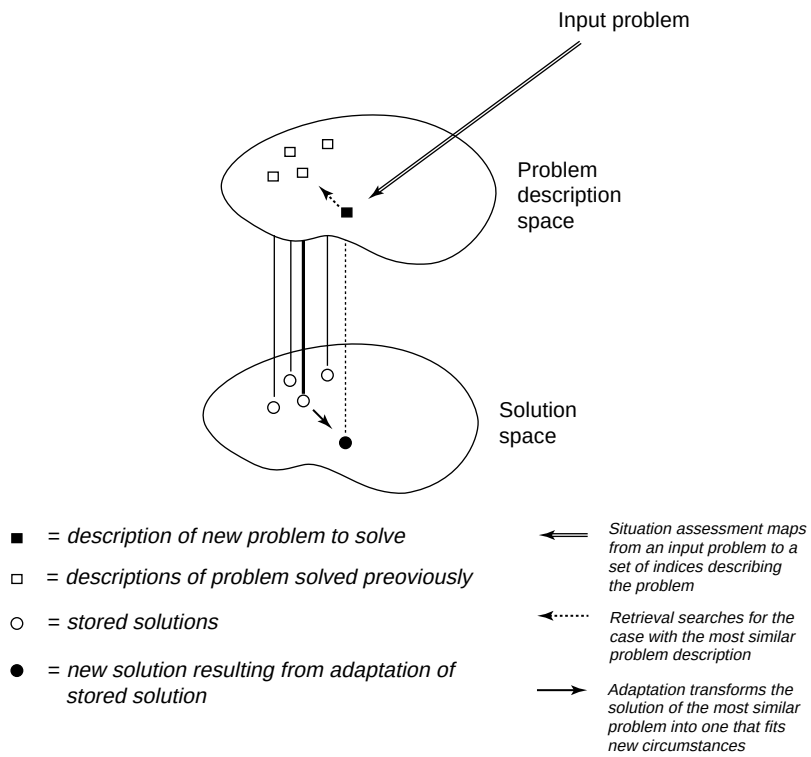

Fig. 1. How basic case-based problem-solving generates a new solution. (*AAAI Press* by permission.)

When given a new problem, a case-based reasoning system first interprets that problem in terms of the features used to describe cases in its memory. The process of interpretation may involve extracting feature from the problem description, deriving new features from those given, or seeking out additional information from other sources. The result of this "situation assessment" is the creation of an "index" of features describing the new problem. This index matches the form and content of the indices of cases in memory, permitting a comparison to be made between stored cases and the new problem.

Once an index is created, a CBR system searches its memory and compares the new index to the indices of stored cases. Various methods for assessing similarity have been developed for different applications. The most common method is "nearest-neighbor:" it calculates a measure of "distance" between the problem index and each case index in memory, and selects for retrieval the case or cases with the smallest distance value. Distance is computed by a weighted sum of a difference measure between each pair of features in the two indices. The difference measure quantifies the difference between the two feature values.

The goal of case retrieval is to find the best match for the new problem. For a classification task like diagnosis, the best matches are the cases that are most likely to have the same classification. Case-based reasoners that perform adaptation of retrieved cases should retrieve the case whose solution is most easily adapted to new problem. Adaptation methods require specific knowledge about the domain from which the problem comes, and frequently involve additional reasoning techniques besides CBR.

An "on-line" CBR system produces new solutions and gets immediate feedback about their quality, either from a human user or from applying the new solution immediately. A case-based route planner for a mobile robot would immediately execute a generated route and see whether it was successful. A case-based system assisting an expert might get immediate feedback about the appropriateness of the suggested solution. For many CBR systems, however, evaluating the quality of new solutions occurs "off-line" and after the fact (e.g., a system that suggests restaurants to users may have to wait until the user has actually tried the restaurant).

In either case, the results of evaluating the quality and correctness of new solutions are frequently used to permit the case-based system to "learn" from its experiences by adding new cases to the case memory.

Case-based reasoning is a powerful technique for problem domains where (1) similar problems have similar solutions, and (2) where similar problems are likely to recur. From an applications perspective, CBR systems may require less work to create than a rule-based expert system, and can produce reasonably good solutions without the cost of reasoning from scratch. From a cognitive perspective, it demonstrates the power of exemplar-based reasoning, and models a kind of human reasoning common in everyday reasoning tasks. See also **Artificial Intelligence**.

ARTIFICIAL INTELLIGENCE: EXPERT SYSTEMS. Expert systems are computer programs that reflect human expertise in well-defined, deep but narrow domains. They came about from the realization in the early 1970s by researchers in artificial intelligence that the general problem solvers and heuristic searches, which formed the basis of artificial intelligence tools at that time, were not knowledgeable enough to address the hard problems they were now being asked to solve. Instead, methods were needed that would take advantage of the deep and high-quality knowledge that experts often brought to bear when solving such difficult problems.

Since their inception, expert systems have been used to solve a variety of problems. They are best at addressing problems of explanation (diagnosis, classification), synthesis (design, computer system configuration), and decision support (tactical action to undertake, loan approval, investment advice). But whenever human expertise can be used to solve a problem, it is likely that an expert system can be built to reproduce the problem-solving process effectively.

Three fundamental concepts in expert systems separate them from conventional software:

1. The use of highly specific domain knowledge.
2. The heuristic (rather than algorithmic) nature of the knowledge employed.
3. The separation between the knowledge and how it is used.

Expert systems are specifically designed to integrate and manipulate the highly specific (and often voluminous!) domain knowledge efficiently and effectively. Expert systems excel at representing *heuristic* knowledge. This type of knowledge is characterized as being rules of thumb or shortcuts that experts often develop over the years of experience in a domain. In some cases, the heuristic simply exists as a shortcut for an algorithmic process. In others, it may represent a mapping of observations (symptoms) to solutions that have been noted over the several years of experience (e.g., when it is cloudy, expect rain). In the latter cases, exact algorithmic processes may not be available, possibly because of lack of understanding of the natural phenomena, or because of the intractable nature of an existing algorithm. Therefore, heuristics are the only means to effectively solve these problems.

The separation of the knowledge from how it is used is what permits expert systems to represent the often-voluminous knowledge efficiently. This came from the realization by the developers of the expert system MYCIN (described later) that the reasoning process used to diagnose blood disorders was similar in nature to that used to diagnose other problems in other domains. These domains were not limited to those related to the human body. Only the knowledge itself made the results different. The generality of this problem-solving process permitted them to strip away the knowledge of one domain (blood disorders) and add that of another: lung disease, geology, and structural analysis among others. This gave rise to the concept of *expert system shells*: tools that contain the knowledge manipulation mechanism (called the *inference engine*), but no knowledge. The developer of the expert system (called the *knowledge engineer*) then incorporates the knowledge to create a specific expert system application.

The first modern expert system that contains the three fundamental concepts mentioned above is MYCIN (Buchanan). Developed at Stanford

University in the late 1970s to diagnose blood disorders, this system is generally considered to have pioneered the concepts now found in modern expert systems. But it was not the first one to act expertlike. DENDRAL (Lindsay) in the mid-1960s and early 1970s was the first to exploit the concept of highly specific knowledge. DENDRAL infers the molecular structure of unknown chemical compounds from mass spectrographic data. However, none of these systems is still in operation, as they served their purpose of investigating some significant concepts.

Other systems built in the 1970s and 1980s are important because of the commercial success of their applications. The most notable of these are PROSPECTOR (Duda), XCON (McDermott) and GenAID (Gonzalez). These systems were in highly successful service for several years, and at least one (GenAID) is still in commercial service as of this writing.

One of the critical issues in the design and application of an expert system is how to represent the knowledge. Knowledge representation has taken on several aspects during the years following MYCIN. The most common one, however, was the same one MYCIN used: *productions* (also called *rules*). Rules are simple *if-then* statements, where the procedure or assertion expressed by the *then* portion is executed only if the *if* portion is satisfied. Rules are very intuitive, as humans often use this representation when asked about their expertise. Therefore, they found immediate acceptance among the expert systems developers.

The other critical issue in expert systems is: how will the knowledge be manipulated? This is how they can be distinguished from conventional programming languages. For rule-based expert systems, there are two basic ways:

1. To reason from a goal to the inputs to determine whether the goals are supported by the inputs: *backward reasoning*.
2. To reason from the inputs to the outputs to determine what conclusions can the inputs support: *forward reasoning*.

Both of these place the rules in lists and execute them in a manner that was not predetermined by the programmer. This is what makes expert systems *declarative*, rather than *procedural*, as are most conventional languages. The developer only specifies the knowledge, not how it is to be manipulated. The inference engine does the latter. While seemingly similar, backward and forward reasoning in fact are not so. To explain how they work and how to determine which one to use for what type of problem is beyond the scope of this discussion. Suffice it to say, that they represent different approaches that can have significant effects on the execution, efficiency, and results of the expert system.

Although rules are excellent at representing conditional knowledge, they are deficient in expressing structured knowledge. For example, knowledge about an automobile encompasses details about the composition of the automobile — the engine, the chassis, the transmission, the brakes, the driver controls, etc. These are awkward to express as rules (if it is an automobile, then it has an engine, a transmission, ...). It was found that *Frames*, conceived by Minsky in 1975 (Minsky), were far more natural and efficient in representing structured knowledge. Frames are clusters of related information represented as attribute/value pairs. They provide the structure or framework for representing templates of known things or concepts, with their relationships built into the attribute/value pairs. They can be organized hierarchically, where the higher levels are more general, and the lower ones are more specific. To ensure efficient use of the knowledge, inheritance between the lower and higher level frames was conceived. Thus, if a lower level frame is designated as a kind of a particular higher level frame, it will inherently possess all its attributes and values of the higher level frame. As an example, assume that the *automobile* frame is "a kind of" *motorized-vehicle*, and the latter has an attribute called *engine* with a value of *V*-8. Then *automobile* will also have the same attribute with the same value, unless it is overwritten at the lower level frame with something more specific (such as, for example, *V*-6).

The inference mechanism for a frame-based system can vary. There are no specific mechanisms to describe, as is the case in rule-based systems.

As defined here, it is necessary for a system to meet the three fundamental concepts laid out above in order to be considered an expert system. Whether it is rule-based or frame-based, or based on some other knowledge representation technique, it is considered an expert system if it meets the above criteria. However, as the technology has evolved and matured in the intervening 20 to 25 years since its inception, expert systems have become synonymous with rule-based expert systems. This is unfortunate. However, it is probably true that expert systems are now mostly considered a mature technology. Research in expert systems, therefore, has largely turned from the core issues of knowledge representation and manipulation, to peripheral ones. Some of these peripheral ones are knowledge acquisition, validation and verification, and on-line learning.

For more information on expert systems, refer to the references of Giarratano and Riley, Gonzalez and Dankel, or Jackson, as noted below.

ARTIFICIAL INTELLIGENCE: FUZZY REASONING. The birth and development of Artificial Intelligence has pushed the study of reasoning formalisms that are complementary or alternative to those of classical logic. This is mainly due to the need to emulate as closely as possible the way humans reason. Probability theory is possibly the best formalism to deal with uncertain reasoning but cannot easily cope with the inherent vagueness of natural language, which is at the origin of fuzzy reasoning. Fuzzy set theory is a good formalism to model such vagueness and, through the methods and tools of fuzzy reasoning, allows making inferences in the presence of vague knowledge.

Zadeh, a prominent expert in system analysis from UC Berkeley, observed that increased precision in a system led to more complex and less understandable models, and stated (1973): 'In retreating from precision in the face of overpowering complexity, it is natural to explore the use of what might be called linguistic variables, that is variables whose values are not numbers but words or sentences in a natural or artificial language...' An example of linguistic variable is *temperature* whose linguistic values could be {*very low*, *low*, *medium*, *high*, *very high*}. Some years earlier (1965), Zadeh had introduced the notion of fuzzy set with the aim of filling the gap between classical numerical precision and the fuzziness of reality. It was, therefore, a very natural idea to model the meaning of the linguistic values of a linguistic variable by means of fuzzy sets. Reality is fuzzy in the sense that most things in the real world do not fall into the neat categories defined by classical set theory. In other words, membership in a class should be a matter of degree (the set of tall persons, the set of warm days, etc.) giving rise to the notion of fuzzy set.

The Notion of Fuzzy Set

Let us consider a proposition of the form "X is A" such as "The temperature of the reactor is high". In such proposition, X is a variable, taking its values on a universe U (for example the temperatures from 0 °C to 1200 °C), and A is a vague predicate (such as "high"). This predicate denotes a fuzzy subset of U represented by the membership function

$$A(x) : U \longrightarrow [0, 1]$$

Which is an extension of the concept of characteristic function for classical sets. Figure 1 shows an example of membership function for the fuzzy set of "high temperatures" in the context of a reactor. The notion of fuzzy set consists therefore in attributing, in a given context, degrees of membership, between 0 (no membership) and 1 (full membership), to the elements of U. For example, a temperature of 600 °C has a degree of membership of 0.8 to the fuzzy set of high (reactor) temperatures.

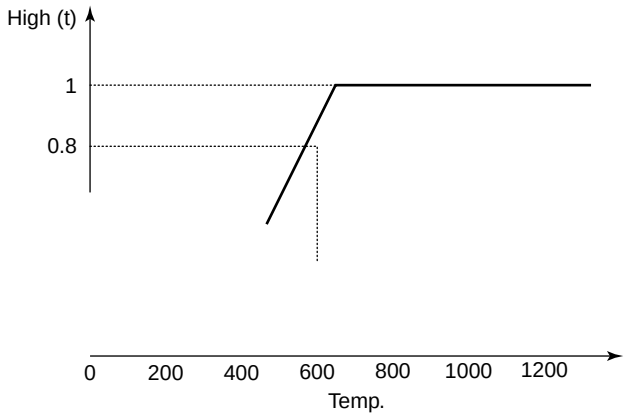

Fig. 1. Example of membership function for the fuzzy set of high temperature.

The usual classical set operations of complementation, intersection, and union can be easily extended to the case of fuzzy sets. In the literature there are many alternatives for such extensions, the ones initially proposed by Zadeh and very common are:

$$A(x) \cap B(x) = \min[A(x), B(x)], \quad \text{for all } x \in U$$

$$A(x) \cup B(x) = \max[A(x), B(x)], \quad \text{for all } x \in U$$

$$\neg A(x) = 1 - A(x), \quad \text{for all } x \in U$$

Where $A(x)$ and $B(x)$ are the membership functions of fuzzy sets A and B respectively.

This set of operators, called the max-min model, preserves the properties of a Boolean algebra except for the law s of excluded middle and non-contradiction.

From Fuzzy Sets to Fuzzy Logic: The Logic of Fuzzy Reasoning

Further developments of the above seminal ideas, led to a number of inference schemes for fuzzy reasoning known as Fuzzy logic. Fuzzy logic uses, indeed, concepts and methods of fuzzy set theory to model reasoning with vague propositions involving linguistic variables. This is possible because of the natural connection between degrees of membership and degrees of truth. For example, the degree of membership 0.8 of a temperature of 600 °C in the fuzzy set of "high (reactor) temperatures" may be interpreted as the degree of truth of the vague proposition '600 °C is a high reactor temperature' and vice versa.

As in classical syllogisms, the statements involved in fuzzy reasoning can be classified into two classes, minor and major premises. Minor premises are assertions about facts, but in fuzzy reasoning such assertions can be vague (such as 'the temperature is high'). Major premises are statements linking the truth of one proposition, called antecedent, with the truth of another proposition called consequent. However, in fuzzy reasoning the antecedent and the consequent can be vague. Furthermore, the link itself, called fuzzy conditional or fuzzy rule, can be qualified by a linguistic truth-value expressing partial truth. For example: 'If the price is cheap, then the duration is short is quite true'.

Fuzzy conditionals are modeled by means of fuzzy implication operators that generalize classical implication operators such as the so called material implication, that is, $p \rightarrow q \equiv \neg p \vee q$. Fuzzy implications allow us to generalize classical inference rules such as *modus ponens*. The generalized modus ponens (GMP) is the fundamental fuzzy inference rule of fuzzy reasoning but in the specialized literature one can also find a generalized modus tollens. These generalizations are based on the *compositional rule of inference* (Zadeh 1973). Let us explain this rule. Consider variables X and Y taking values in U and V respectively, and assume that for all $x \in X$ and for all $y \in Y$ these variables are related by a function, that is, $y = f(x)$. Clearly, given a value x of X, we can infer the corresponding value y of Y. Similarly, knowing that the value of X belongs to some subset A of U, we can infer that the value of Y belongs to the following subset of V:

$$B = \{y \in Y / y = f(x), \ x \in A\}$$

Assume now that the variables are related by a relation on $U \times V$ instead of a function. From the knowledge that the value of X is in a subset A of U, we can infer that the value of Y is in the following subset of V:

$$B = \{y \in Y / (x, y) \in R, x \in A\}$$

As shown in Fig. 2.

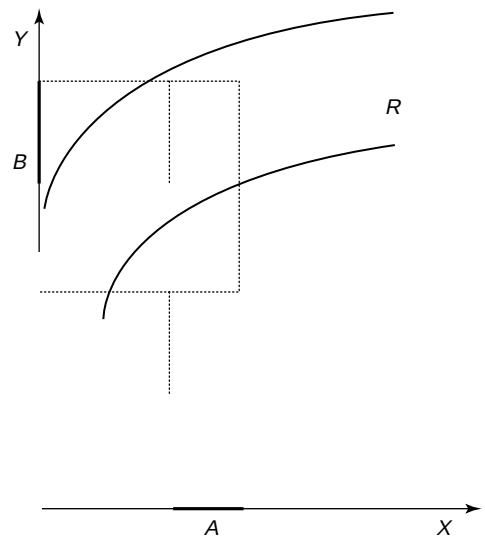

Fig. 2. Compositional rule of inference.

Notice that this can be also expressed in terms of the characteristic functions of the sets A and B and the relation R as follows:

$$\chi_B(y) = \sup_{x \in X} \{\min[\chi_A(x), \chi_R(x, y)]\}$$

If R is a fuzzy relation and A^* a fuzzy set, we can infer the fuzzy set B^* from A^* and R by generalizing the above expression substituting the characteristic functions by the membership function of A^*, B^* and R, that is

$$B^*(y) = \sup_{x \in X} \{\min[A^*(x), R(x, y)]\}$$

This last expression is the *compositional rule of inference*.

In the context of fuzzy reasoning, the fuzzy relation R is a fuzzy implication $I(A(x), B(x))$ that models fuzzy conditionals of the form:

$$\text{If } X \text{ is } A, \text{ then } Y \text{ is } B$$

And it that particular case the compositional rule of inference becomes the Generalized Modus Ponens (GMP). That is, given:

The fuzzy conditional:	If X is A, then Y is B
And the fuzzy proposition:	X is A^*
The GMP concludes	$Y$is B^*

Where the membership function $B^*(y)$ of the fuzzy set B^* is given by:

$$B^*(y) = \sup_{x \in X} \{\min[A^*(x), I(A(x), B(y))]\}$$

That is, by composing the membership function of the given fuzzy set A^* with the fuzzy implication $I(A(x), B(y))$. This implication is computed from the given membership functions $A(x)$ and $B(y)$ of the fuzzy sets A and B. There are many ways to compute the implication in the specialized literature. One of the most common implications is

$$I(A(x), B(y)) = \begin{cases} 1, & \text{if } A(x) \leq B(y) \\ B(y), & \text{otherwise} \end{cases}$$

A desirable property of the GMP is to recover the classical modus ponens, that is, to infer $B^* = B$ when $A = A^*$. Fulfilling this property depends on the choice of the fuzzy implication and this choice depends on the conjunction operator used in the composition of A^* and the implication $I(A(x), B(y))$. The above implication preserves this property with the 'min' conjunction operator.

The key aspect of the GMP in fuzzy reasoning is that it provides a conclusion even if the observed fact, represented by the fuzzy proposition X is A^*, only partially matches the antecedent, X is A, of the fuzzy conditional. That is, even if A^* is somewhat different from A. The closer is A^* to A, the closer should be B^* to B. If $A*$ is very different from A, the conclusion will not be useful. In the extreme case where $A^* = \neg A$, the conclusion is that any value is equally possible for B^*, which is equivalent to not concluding anything useful. How much B^* departs from B when A* departs from A depends on the particular conjunction and implication operators used in the GMP. Additional desirable properties guiding the choice of these operators are: If $A^* \subset A$, then $B^* = B$. And If $A^* \supseteq A$, then $B^* \supseteq B$. This last property should be obvious. The first of these two last properties means that even if the observed fact is more precise than the antecedent of the fuzzy conditional, we cannot conclude something more precise than what the consequent states. This is, in general, a reasonable result, because to conclude something more precise than the consequent it is necessary to assume a monotonous dependency between Y and X. If this is the case, a fuzzy conditional of the form 'The more X is A, the more Y is B' should be used instead. The specialized literature also has addressed how to make inferences based on this type of fuzzy conditionals.

An example of a fuzzy conditional that would be part of a set of rules to control the avoiding obstacle behavior of autonomous robots could be:

If left obstacle is NEAR, then turn right is SHARP

Where the membership functions of the fuzzy sets modeling the meaning of the linguistic values NEAR and SHARP would be given. Then, if the sensors of the robot provide readings that are interpreted as "left obstacle is QUITE NEAR", the GMP would conclude "turn right is RATHER SHARP" assuming that the value "RATHER SHARPLY" is the one that best approximates the shape of the membership function SHARPLY* inferred by the GMP. That is inferred as follows:

From	If left obstacle is NEAR, then turn right is SHARP
And	obstacle is NEAR* (that is QUITE NEAR)
Conclude	turn right is SHARP*

Where

$$\text{SHARP}^*(y) = \sup_{x \in X}\{\min[\text{QUITE NEAR}(x), I(\text{NEAR}(x), \text{SHARP}(y))]\}$$

Complex fuzzy conditionals involving several antecedents linked by AND, OR and negation operators can be also easily modeled within the GMP formulation by means of the corresponding fuzzy set operators for conjunction, disjunction, and complementation.

In the specialized literature there are thousands of successful applications of fuzzy reasoning ranging from medicine to industrial applications. To name a few: antiskid brakes, automatic focusing for cameras, automatic transmissions, autonomous robots, control of elevators, control of unmanned trains and helicopters, water purification processes, medical diagnosis, etc. See also **Artificial Intelligence**.

ARTIFICIAL INTELLIGENCE: GAME PLAYING SYSTEMS. Games are ideal domains for exploring the capabilities of computational intelligence. The rules are fixed, the scope of the problem is constrained, and the interactions of the players are well defined. Contrast this to the real world, the game of life, where the rules often change, the scope of the problem is almost limitless, and the participants interact in an infinite number of ways. Games can be a microcosm of the real world (e.g., the role of game theory in economics, social settings, and animal behavior), and successfully achieving high computer performance in a nontrivial game can be a stepping stone towards solving more challenging real-world problems.

Game playing programs typically include two major artificial intelligence components. The first is application-dependent knowledge that is used to differentiate good game states from bad game states. At one extreme, this knowledge could be entirely supplied by human experts; at the other is could be entirely discovered by the computer. For most game-playing programs, a combination is used. There are a variety of techniques for gathering, representing, and using this information.

The second component is search, techniques for sifting through the myriad of possibilities that can arise in a game. In chess, for example, a typical position has 35 legal moves. Analyzing five moves into the future means considering 35^5 possibilities — over 50 million. One of the popular search algorithms, alpha–beta, can dramatically reduce this number to something more manageable.

Of interest is that the techniques used in game-playing programs bear little resemblance to the techniques used by humans. For example, chess programs typically use lots of search and little knowledge, compared to the extensive knowledge and little search used by humans. The *Deep Blue* chess machine took this to an extreme, searching 200 million chess positions per second, as compared to a typical human grandmaster's speed of one or two positions per second.

In the late 1940s and early 1950s, ground-breaking research was done by Claude Shannon and Alan Turing (chess) and Arthur Samuel (checkers). In 1967, Richard Greenblatt's *Mac Hack* chess program competed in a human tournament, achieving a creditable result. Since then, computers have regularly competed in human events (a controversial issue, even to this day). Since 1970, there have been a regular series of computer chess tournaments making this the longest on-going experiment in computing science history.

The 1990s saw the culmination of four decades of research into computers playing games, resulting in several computer successes against the best of humanity. In 1994, the checkers program *Chinook* (Jonathan Schaeffer) won the World Man-Machine Checkers Championship and has retained it since then. In 1997, the chess machine *Deep Blue* (Feng-hsiung Hsu, Murray Campbell, Joseph Hoane) defeated World Chess Champion Garry Kasparov in a six-game exhibition match. *Logistello* (Michael Buro) defeated the human world Othello™ (Reversi) champion in an exhibition match in 1997. Since 1998, Brian Shepphard's Scrabble™ program, *Maven*, had several successes that indicated it was superior to the best human players; the program's dominance remains unchallenged.

There are a number of interesting games where computer progress has lagged behind. In bridge, Matt Ginsberg has developed a master-class program, *GIB*, that has had some notable successes against world-class players. The poker program *Poki* (Darse Billings, Aaron Davidson) is strong enough to win consistently at casino-level games, but its play remains considerably below that of world-class players. For the oriental game of *Go*, the best programs are still considered to be weak players. Of all the popular board and card games that are receiving intense research and development effort, success at *Go* remains the most elusive. The conventional techniques that were successful for other games are of limited value for *Go*, meaning it may be many decades before world-class performance is achieved.

Some games have few enough possibilities that the game can be perfectly solved by a computer. The list of solved games includes Connect-4, Qubic, Go-moku (all first player wins), and Nine Men's Morris (draw).

Computers have also made significant progress in solving one-player games (puzzles). Computers can optimally solve sliding tile puzzles (up to size 5-by-5) and Rubik's Cube. *Proverb* (Greg Keim, Michael Littman) does amazingly well solving crossword puzzles, without understanding the meaning of the clues!

The commercial games industry has moved on to other types of games. There are numerous products on the market covering the gamut of action games (e.g., shoot'em-up games), role-playing games (e.g., player goes

on a quest, evolving their character), adventure games (e.g., navigating through a scripted story), strategy games (e.g., controlling armies in a war), "god" games (e.g., evolving a simulated population), and team sports (e.g., controlling a player or coaching a sports team). The computer games industry has surpassed the movie industry in terms of revenue generated. The next set of challenges for artificial intelligence research includes creating characters in these games that exhibit humanlike behavior.

The research in computer games has been tremendously beneficial to the artificial intelligence community. First, games have been a convenient way to communicate artificial intelligence advances to the public. Second, the man-versus-machine quests echo turn-of-the-century man-versus-technology challenges that capture the imagination of the public. The *Deep Blue* versus Kasparov matches have permeated the public consciousness and, indeed, *Deep Blue* has become part of our every day language. Finally, the research that has been done to achieve world-class game-playing programs gave rise to many techniques that have been successfully applied to domains outside of games. See also **Artificial Intelligence**.

ARTIFICIAL INTELLIGENCE: GENETIC ALGORITHMS AND EVOLUTIONARY COMPUTING. *Genetic Algorithms* are a family of computational models inspired by evolution. Other genetic and evolutionary algorithms include *Evolution Strategies*, *Genetic Programming* and *Evolutionary Programming*.

Genetic algorithms have been used for parameter optimization problems, scheduling applications and design optimization. In terms of fielded applications, genetic algorithms have been used to optimize a paper production process, to schedule the assembly lines of major automobile, truck and tractor manufacturing companies, and genetic algorithms have been used to design turbine engines currently used on commercial passenger aircraft.

Genetic and evolutionary algorithms encode a potential solution to a specific problem on a chromosomelike data structure and apply recombination operators to these structures so as to preserve critical information. Mutation operators are also used to alter potential solutions.

An implementation of a genetic algorithm begins with a population of (typically random) artificial chromosomes. One then evaluates these structures and allocates reproductive opportunities in such a way that those chromosomes that represent a better solution to the target problem are given more chances to "reproduce" than those chromosomes representing poorer solutions. The "goodness" of a solution may be computed by comparing its evaluation against the population average, or it may be a function of the rank of that individual in the population relative to other solutions.

The term genetic algorithm can have two meanings. In a strict interpretation, *the* genetic *algorithm* refers to a model introduced and investigated by John Holland and by his Ph.D. students. Most of the existing theory for genetic algorithms applies either solely or primarily to the model introduced by Holland. In a broader sense, a genetic algorithm is any population-based model that uses selection and recombination operators and mutation operators to generate new sample points in a search space.

Evolutionary algorithms do not use gradient information. Thus, solutions may be evaluated using a mathematical function, or by using a computer simulation. For example, when genetic algorithms were used to design aircraft engines, a simulation used to determine the fuel savings associated with different designs. This makes is possible to use genetic and evolutionary algorithms for applications where other mathematical optimization techniques are not appropriate. These algorithms are particularly useful for ill-structured search problems that are characterized by having a large number of local optima.

Encodings, Operators and Evaluation

The problem encoding and the evaluation function both interact to determine the best recombination and mutation operators to use.

For example, we may wish to minimize (or maximize) some function

$$F(X_1, X_2, \ldots, X_M)$$

where X_i is an input parameter. For this kind of parameter problem, the encoding may be composed of bit strings or real values.

On the other hand, we might want to schedule a manufacturing line. For this kind of combinatorial optimization problem, a permutation based representation might be used, where the permutation represents the order in which tasks are scheduled. Also, consider a routing problem, where we must decide the order in which a truck make deliveries to some large number of customers.

Once an encoding is chosen, appropriate recombination and mutation operators must be developed.

For parameter optimization a simple binary string can be used:

1101001100101101

If the string could broken apart and decoded into parameters such as values for temperature or pressures or material-ratios in the paper production process for example. New solutions are generated by recombining two parent strings. Consider the string 1101001100101101 and another binary string, yxyyxyxxyyyyxyxxy, where the values 0 and 1 are denoted by x and y. Using two randomly chosen crossover points, recombination might occur as follows.

11010 \/ 01100 \/ 101101

yxyyx /\ yxxyy /\ yxyxxy

Swapping the fragments between the two parents produces the following offspring.

11010yxxyylollo and yxyyx01100yxyxxy

After recombination, mutation can be applied. Typically the mutation rate is low so that only one bit changes in the offspring.

Integer and real values can be represented as bit strings in various ways. A discretization of real-values can be mapped to integers, and integers can be mapped to bits using standard Binary Coded Decimal representations. However, standard binary encodings have certain disadvantages. For example, the integers 15 and 16 are encoded as 01111 and 10000. Note that these values are neighbors in integer space, but are not neighbors in terms of the bit-space or *Hamming* neighborhood associated with the standard Binary representation. In fact, these strings form a Hamming cliff: adjacent integers are represented by complementary bit strings, and thus, share no bits in common.

It may be desirable to use a different bit encoding where adjacent integers are represented by bit strings that are neighbors in Hamming space, and thus, differ by a single bit. A *Gray code*, by definition, is any bit representation where adjacent integers are represented by bit strings that differ by a single bit. There are in fact many Gray codes. The actual number of Gray codes is unknown. Standard Binary Reflected Gray code is most commonly used. Although the use of Binary Code Decimal representations can induce new local optima in Hamming space that do not exists in the original function, Gray codes are always guaranteed to produce a representation in Hamming space where the number of local optima is less than or equal to the number of optima in the original real-valued or integer function representation.

Some researchers argue that if the "natural" representation of a problem is integer, or real valued, then that representation should be used. Recombination and mutation operators can certainly be applied to real valued strings. Some forms of evolutionary algorithms, such as Evolution Strategies, are designed specifically to work with real valued representations of parameter optimization problems.

Scheduling problems may use complex representations, but often can be represented using permutations indicating the sequence in which tasks or events occur. Simple cut and swap recombination operations work

well for parameter optimization problems, but more complex operators are needed for permutation representations. Furthermore, both scheduling problems and routing problems may use permutation representations, but the recombination and mutation operators may be very different. For routing problems, the *adjacency* of events is often important; in scheduling the *relative order of* events is important. *Adjacency* implies the evaluation function is sensitive to the fact that event A occurs immediately before (or after) event B in a permutation such as *KQABCD*. *Relative order* implies the evaluation function is sensitive to the fact that event A occurs at some time before (or after) event B, but it need not be immediately before (or after), as in the permutation such as *QAKCBD*. Many operators have been developed to try to maintain either adjacency or relative order, and operators that work well on one type of permutation-based problem (e.g., scheduling) often perform poorly on a different type of permutation-based problem (e.g., routing or the Traveling Salesman Problem).

Beyond Simple Genetic Algorithms

While genetic algorithms were being developed in the United States between 1970 and 1990, German researchers Ingo Rechenberg and Hans-Paul Schwefel were developing *Evolution Strategies*.

Evolution Strategies are also a population-based form of search that have largely been developed for parameter optimization problems. Evolution Strategies generally use real-valued parameter encodings and emphasize the use of mutation rather than recombination. Evolution Strategies use "strategy parameters" that control the mutation step size for each parameter on the chromosome. These strategy parameters are also encoded onto the chromosome and evolve along side the regular parameters. The strategy parameters are not really fixed step sizes, but rather standard deviations. Mutation is usually defined in terms of a sampling distribution around the current members of the population. A Gaussian or log-normal distribution might be used for each parameter and the strategy parameters would be the standard deviations associated with the distributions. Thus, the actual step is chosen stochastically by selecting the step-size based on the corresponding probability distribution. The mutation step-size is different in each dimension of the search space. In addition, a correlation or rotation parameter can also be used for each pair of parameters. This rotation allows the search to not only adapt the step size used by mutation, but also allows it to adapt the direction of mutation. This idea is illustrated in Fig. 1.

Encoding the strategy parameters onto the chromosome also makes Evolution Strategies self adaptive. Addition strategy parameters are also sometimes added onto the chromosome that control the direction of new mutations. Recombination operators, such as swapping parameter values or averaging parameter values, are also sometimes used but recombination does not have the same primary role that it does in genetic algorithms.

Evolution Strategies (ES) have a rich notation for describing different types of evolutionary algorithms. For example, parents may "die" upon reproducing and are replaced by their offspring. This happens in Holland's standard genetic algorithms. This is also known as a (μ, λ)—*ES*. The population with μ number of parents is replaced by λ offspring. On the other hand, some forms of the algorithm allow the best members of both the parent population and the offsprings to survive into the next generation. This is known as a $(\mu + \lambda)$—*ES*. This strategy is also used in what has come to be known as "steady-state" genetic algorithms.

Evolutionary Programming as practiced today is a reincarnation of earlier evolutionary computing methods developed by Lawrence Fogel, A.J. Owens and M.J. Walsh in the 1960s. During the 1960s evolutionary programming used mutation to change finite state machines. The main idea behind evolutionary programming is to search in "phenotype" (or behavior) space rather than searching in "genotype" space (the space of genes that indirectly control for behavior after decoding and development). Hence, operators act directly on the finite state machines as opposed to some special genotype or encoded representation. In the 1990s David Fogel, reintroduced evolutionary programming as a general parameter optimization method, but for all practical purposes, the modernized evolutionary programming algorithms are virtually identical to evolution strategies, except that recombination is never used. Real valued encoding and mutation controlled by strategy parameters are used instead.

The most recent addition to the family of Genetic and Evolutionary Algorithms is *Genetic Programming*. Genetic Programming is used to evolve computer programs. Thus, the chromosomes are programs. Traditionally these programs are in the language "Lisp." Lisp programs take the form of "s-expressions." An s-expression can be defined recursively as

s-expression = (operator s-expression s-expression . . .

s-expression) s-expression = primitive

Because each recursively defined s-expression is itself an executable form, one can recombine subparts of an s-expression and still produce a syntactically legal and executable form.

For example

s-expressionl = (add 1 (add 7 8) 5)

s-expression2 = (multiply 2 (multiply 2 X))

might be recombined to produce

s-expression3 = (add (add 7 8) (multiply 2 X))

One can evolve polynomial forms, for example, that can be used for general function approximation. The evaluation function, in this case, might take the form of a least-mean-square error function that matches the output of the evolving polynomials against known sample training data.

Finally, genetic and evolutionary algorithms lend themselves to highly parallel implementation. Members of the population can be selected, recombined, mutated, and evaluated in parallel. Sometimes subpopulations are evolved in parallel producing an *Island Model Evolutionary Algorithm*. Surprisingly, evolving distinct subpopulations that only occasionally

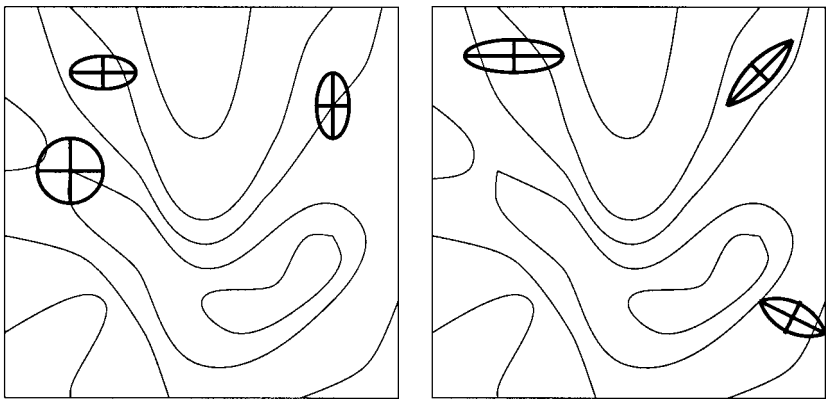

Fig. 1. A two dimensional search space $F(X_1, X_2)$ is shown, along with elipses representing chromosomes in the population. Contours represent changes in evaluation. In (**a**) simple mutation used with only a step-size in each direction. In (**b**) adaptive rotation parameters are also used.

exchange chromosomes can often result in faster and more robust optimization than using a single large population. The ability to execute these algorithms using a high degree of parallelism can make them well suited for optimization problems where good results are needed quickly. ARTIFICIAL INTELLIGENCE: MACHINE LEARNING. Machine learning (ML) is a subfield of artificial intelligence that studies methods by which intelligent systems can automatically improve their performance on some task. ML has long been a significant subfield of AI, with its own conference (the International Conference on Machine Learning), journals (*Machine Learning* and the *Journal of Machine Learning Research*), and Internet mailing lists (*ml@ics.uci.edu*, *inductive@listserv.unb.ca)*, as well as numerous workshops, symposia, and paper sessions in wider AI conferences. ML has been an active area of research since the early days of artificial intelligence in the 1950s and 1960s. In the past few decades, there has been substantially increased interest in ML, along with the related fields of data mining and knowledge discovery in databases. Statistical methods recently have become very popular, leading to a rich and productive interchange between the fields of ML and statistics.

The field of ML encompasses several distinct styles of learning. In the most widely studied case, **supervised** learning, the system is provided with a set of **training instances** that are labeled with a **class value** by a human operator, a database, or the environment. The task is one of **classification**: given a **test instance** (that is, a previously unseen instance), predict its class value. For example, in a cancer tumor diagnosis domain, the instances might be patient records, with fields such as gender, age, symptoms, and characteristics of the tumor's size and shape. The class value in this case would be the type of tumor (e.g., benign or cancerous). A test instance would be a patient record that does not yet have a value for the tumor type.

In **unsupervised learning**, the training instances do not have a distinguished class value; the goal is to find **clusters** of instances that behave similarly. The task may be to identify the appropriate cluster for an unseen instance, to predict an arbitrary feature value for a previously unseen instance, or simply to describe the clusters observed in the data. For example, in a marketing analysis domain, instances might be individual consumers, with features such as gender, age, and characteristics of the consumer's shopping habits. Clusters would consist of collections of "similar" individuals, i.e., demographic groups with similar characteristics that could be used to target new products or marketing campaigns.

Other important areas of investigation within ML include goal-directed learning, learning by demonstration, language learning. See also **Artificial Intelligence: Natural Language Processing**. Learning planning or control knowledge, knowledge acquisition. See also **Artificial Intelligence: Expert Systems**. **Knowledge-Based Systems**, pattern recognition, explanation-based or analytical learning, and reinforcement learning.

ML techniques have been applied to a wide variety of domains, including credit rating analysis, autonomous automobile driving, soccer playing, adaptive user interfaces, collaborative filtering, celestial object classification, consumer purchasing patterns, backgammon playing, and speech recognition.

ML Approaches

A typical ML architecture for a classification problem is shown in Fig. 1. The performance task, which may range from simple instance classification to complex robot control, is handled by the performance engine, drawing on the knowledge in a knowledge base, and sending actions to the environment via a set of effectors. (These may be physical effectors situated on a robot, or virtual effectors that send outputs to a database or user display.)

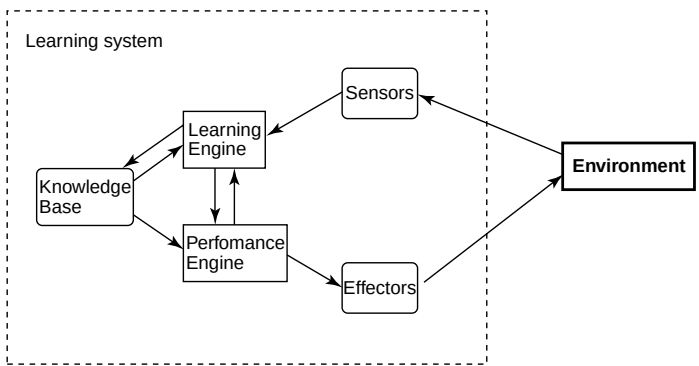

Fig. 1. A typical ML architecture for a classification problem.

The learning engine may receive background knowledge and training instances from the performance engine itself, from the knowledge base, or from the environment via sensors. (We use "environment" and "sensors" in a very general way here: for example, in many cases, the "environment" is a human operator, and the "sensors" are scripts for reading files of training instances provided by the user.) The learning engine may output its learned models to the knowledge base, or directly to the performance engine.

Classification of ML Approaches

1. **Characteristics of the training and test instances**. The most common instance representation is feature vectors, but other representations such as structured relational models have also been studied. Instances can vary in the number and types of features they include (real-valued, discrete, ordinal), whether there are missing feature or class values, the order in which the instances are received, the number of instances available, the cost of acquiring additional instances, the process used to gather training and test instances, the cost of measuring individual feature values, and whether there are errors in the feature or class values. (Note that most algorithms handle only a few of these variations, and virtually no algorithm handles all of them.)

2. **Representation of the learned model**. Representations that have been most commonly explored include decision trees, propositional or first-order rules, neural networks. See also **Artificial Intelligence: Neural Networks**. Bayesian networks, and probabilistic rules. A currently popular approach is **ensemble learning**, in which a collection of models are learned; performance is accomplished by weighting the predictions of the individual models.

3. **Learning method**. The process of learning is most often viewed as search through a space of possible models. This search may be performed using version spaces (exploration of a lattice representing a generalization/specialization relationship among models), greedy or hill-climbing search methods, or genetic algorithms. In unsupervised learning,

there are a variety of methods for searching through the space of possible clusters; two of the more common methods are regression trees and k-means clustering.

Recently there has been a great deal of interest in methods to improve the quality of learned models by resampling the training data. In **bagging**, several models are learned (e.g., ensemble learning) by repeatedly generating samples (with replacement) from the original training instances. In **boosting**, a series of models are learned, each time re-weighting the training instances to give greater importance to instances that were misclassified by the previous model.

An alternative learning style is sometimes termed **lazy learning**. In this approach, which includes nearest neighbor and case-based reasoning approaches, rather than learning a model, the instances themselves are stored. See also **Artificial Intelligence: Case-Based Reasoning**. At task performance time, an instance is classified or analyzed by finding the stored instances that are most similar to the new instance.

Learning algorithms also vary in how they process the training data. In **incremental** or **online** learning, learning occurs continuously throughout the life cycle of the performance engine, with training instances processed and incorporated into the learned model as they arrive. Conversely, in **batch** learning, the learning system receives all of its training data simultaneously, processes it at one time, and then provides a final output.

4. **Learning bias.** The term **bias** is used to mean any preference that a learning algorithm shows for one hypothesis over another. Bias can be represented explicitly or implicit in the learning algorithm.

Any parameters that are provided to a learning algorithm will bias it in a particular way. Some common biases are to prefer models that most closely match the data, and to prefer simple models over more complex ones. Some algorithms can incorporate various forms of background knowledge (e.g., preferences, prior probabilities, partial models), all of which provide additional sources of bias. A class of techniques called **wrapper** methods search through the space of possible biases by repeatedly running the base algorithm with different biases, then selecting the bias with the best performance on a separate test set.

5. **Evaluation.** For classification tasks, learning methods are typically evaluated using a predictive accuracy metric: what proportion of a set of test instances are assigned the correct class by the model (or models, in the case of ensemble learning). In cases where different types of classification errors have different costs, a weighted predictive accuracy may be more appropriate. Clustering methods may be evaluated by measuring how closely the clusters found by the algorithm match a set of clusters provided by a domain expert, or by measuring predictive accuracy for one or more features based on group membership.

Metrics other than predictive accuracy may be equally important for both supervised and unsupervised learning: e.g., the computational effort required to learn a model, the time required to apply the model, the comprehensibility of the learned model, or the degree to which the learned model matches an expert's understanding of the domain.

Computational learning theory provides formal analytical models of learning performance. In particular, Probably Approximately Correct (PAC) analyses provide guarantees on the average performance of classification algorithms.

6. **Model understanding.** In some cases, learned models are used directly by a performance engine, and the user does not need to view the model directly. However, in many cases, a user is actively involved in the learning process. This is particularly important in safety-critical domains, where brittleness in the model may lead to catastrophic failures in unforeseen situations. Graphical displays may allow the user to interactively explore the model (e.g., browsable decision tree representations or graphical, manipulable views of Bayesian networks). More sophisticated visualization techniques can be used to explore high-dimensional model spaces using a variety of dimension reduction techniques. See also **Artificial Intelligence**.

ARTIFICIAL INTELLIGENCE: MACHINE VISION. The aim of machine vision is to provide computers with the ability to "see". The concept of seeing involves a number of different tasks such as: "recognition of objects", "tracking of objects", "interpretation of scenes and objects", "detection of new activities". Machine vision is also used for automatic recovery of 3-dimensional models of the environment. Example applications of machine vision include quality control of objects in manufacturing, medical diagnostics (interpretation of X-rays and mammography), generation of CAD models from images, intelligent interfaces (interpretation of gestures and motion), traffic monitoring and surveillance, and control of robots to mention a few.

The inspiration for machine vision and the methods used are largely inspired by biological systems ranging from simple creatures to what we know about the human visual systems. The applications do, however, go well beyond "seeing" systems to include everyday applications such as bar-code readers and automatic sorting of mail based on zip-code (optical character) recognition.

The input to the machine vision system is images generated by cameras. The most common camera model by far is the type developed for broadcasting applications. Recently new digital cameras developed for the Web and other multi-media applications have also entered the field. The process of producing an image involves projection of the world onto a CCD (Charge-Coupled Device) chip through an optical lens. Once a picture is generated on the chip, the impinging optical pattern is digitized to generate a *digital image*. This process is normally termed image generation. Other similar processes are used for generation of X-rays, MR images, etc. A typical image has a size of 768 times 480 cells. Each cell in an image is termed a pixel (picture element). Normally images used a rectangular sampling pattern. There are two dominant types of images: gray-scale and color. Gray scale images are typically digitized in 8 bit, while the color images are digitized according to a three color component model (red, green, and blue termed RGB), where each channel is digitized at 8-bit, resulting in a 24 bit image. The human visual system does not use a rectangular sampling pattern. In human eyes have a high spatial resolution in the center of the image, termed the fovia, with an exponential degradation in resolution towards the periphery. The full visual area of the eye is termed the retina. Such images models, termed log-polar, have recently been replicated in CMOS cameras to allow a wide field of view while still maintaining a high resolution of the center. An example of such an image is shown Fig. 1. A significant problem in many machine vision applications is the massive amount of information. A typically gray-scale camera will generate about 8 MB of information/second, and the color camera will generate about 24 MB/s. As cameras typically generate 25 (in Europe) or 30 (in USA and Japan) images per second.

Once images have been acquired it is necessary to perform a computer analysis of the images to enable extraction of characteristics that can be utilized for the task at hand. The full process from images to recognition can involve a rich set of processes; two typical processes are illustrated in Fig. 2.

The process of enhancing images so that unique characteristics can be identified is termed *image processing*. The result of image processing is new images that highlight particular information of interest. The characteristics of interest are typically referred to as *features*. Typical features include edges, texture, color, motion, and corners. The process involved in computation of features is termed *image filtering/processing* to enhance the image. Subsequently the information in the enhanced image(s) is subject to a classification, i.e. based on the digitized information. The simplest way of classifying information is according to intensity level using a threshold, e.g., all pixels larger than some value. This is termed *global thresholding*. Other approaches to feature classification involves recognition of simple local patterns such as corners. The generation of

(**a**) (**b**) (**c**)

Fig. 1. (**a**) Regular image and corresponding image sampling in a manner similar to the human eye. (**b**) Humanlike sampling; (**c**) Resampled log-polar image.

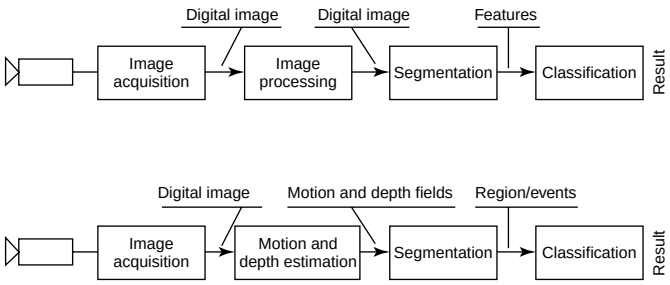

Fig. 2. Example processes involved in machine vision.

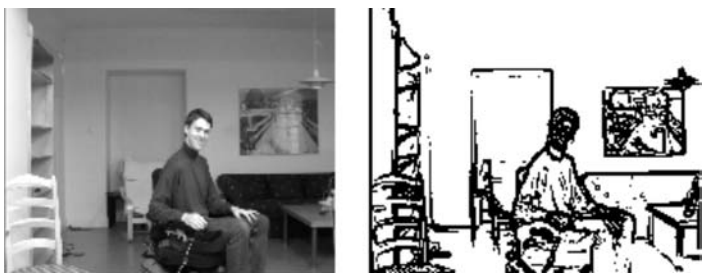
enhanced images for extraction of features is some times referred to as *intrinsic images*, as the derived images attempt to estimate intrinsic scene characteristics; the classification of information in intrinsic images is termed *feature extraction*. From biological vision it is widely recognized that a variety of features are combined to enable robust detection of objects and phenomena, e.g., color or edges along might not be enough to recognize objects such as cars. To accommodate generation of a wide variety of features a number of efforts have attempted to build *a visual front-end* that provide an array of features for subsequent processing.

Visual features can either be used directly or assembled into more complex features through a feature analysis. As an example edge elements (termed *edgels*) might be combined into line or curve hypotheses. The combination of edge elements into lines is typically carried out through a least-square fit of a mathematical line, i.e.:

$$l_{\min} = \arg\min_{l \in \Re^3} \sum_{p \in E} lgp$$

Where l is a representation of the line parameters $1 = (a, -1, b)^T$ and the point $\vec{p} = (x, y, 1)^T$ belong to the set of edge elements. An example image and the corresponding edges are shown in Fig. 3.



(**a**) (**b**)

Fig. 3. (**a**) An image and (**b**) the corresponding set of edges. The edges are found by differentiation of the image and subsequent thresholding.

Direct or derived features can both be used for recognition of objects, but they can also be used in geometric computations to compute 3-dimensional characteristics such as depth maps and geometric models. For computation of the depth, several cameras are normally used. Through analysis of the projected images from two cameras that are slightly displaced it is possible to estimate depth. The basic model for projection of the world onto the camera is given by traditional optics, e.g.,

$$x = -f\frac{X}{Z}$$

$$y = -f\frac{Y}{Z}$$

Where (x, y) are image coordinates and (X, Y, Z) are the coordinates for the object in the world. The parameter f is termed the focal length. Through a slight translation of one of the cameras it is possible the X or the Y coordinates will change and this give rise to a difference in the image. An example is shown in Fig. 4, with two pictures of a scene and the corresponding changes between the two images.

Using methods similar to computation of depth, it is also possible to estimate the motion of objects. In that case the difference between images taken at slight different times are analyzed to enable detection of moving objects.

Through analysis of motion and depth it is possible to detect independently moving objects, which for example may be used for tracking of objects such as cars or people to allow design of surveillance systems or intelligent user interfaces. Figure 5 illustrates an example where a sequence of images from the scene shown in Fig. 3 have been analyzed. Here motion and depth are first computed independently. It is apparent from the images that the estimation of both motion and distance is noisy due to variation in illumination, etc. Through combination of the two images it is, however possible to generate more robust results.

Once the image has been segmented and information of interest has been extracted, e.g., a region, a line, edges or similar the new representation can be used for recognition of objects. Recognition can be achieved using many different techniques from pattern recognition. One of the most common techniques used is statistics. Using a set of test images it is possible to build a database of examples. In such an approach two different parameters are estimated, the prior probability $P(x)$, i.e. how often is a particular pattern seen, and $P(y|x)$, e.g., how often do you see the pattern y when there is a object of type x in the image. As an example, consider monitoring of people. It can be assumed that there is 50% chance that the person is a man and 50% that it is a woman, this $P(\text{man}) = 0.5$ and $P(\text{woman}) = 0.5$. Analyzing a set of images (test examples) it is then possible to estimate features such as skin color, eye-makeup, lipstick, etc. Each of these features allow estimation of $P(\text{lipstick}|\text{woman})$ and $P(\text{lipstick}|\text{man})$. Using a large number of images it is possible to generate good estimates of the conditional probabilities $P(y|x)$. Using Bayes rule

$$P(x|y) = \frac{P(y|x)P(x)}{P(y)}$$

it is then possible to estimate the probability ($P(\text{gender}|\text{features})$) that the person in the image is a woman given that a certain set of features (y) have been observed. One can consider both $P(\text{man}|\text{features})$ and $P(\text{woman}|\text{features})$ and choose the class that has the highest probability. As an example consider the example in Fig. 6. Here a person is sitting in front of a computer and the computer has been trained on recognition of skin colors. Using this method it is possible to detect the faces and

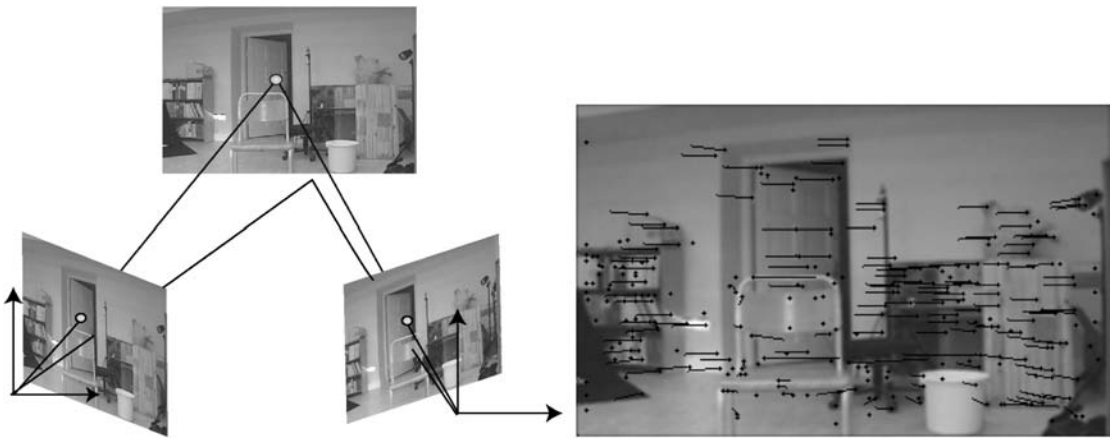


Fig. 4. Two cameras provide slightly different images of a room. Through analysis of the difference as shown to the right it is possible to estimate the distance to the different objects in the room. The lines in the image correspond to the difference between the images from the left and right camera, respectively. Short distances between points correspond to small distances, while larger distances correspond to larger distances. Thus, the back wall is further away than the chair in the middle of the image.

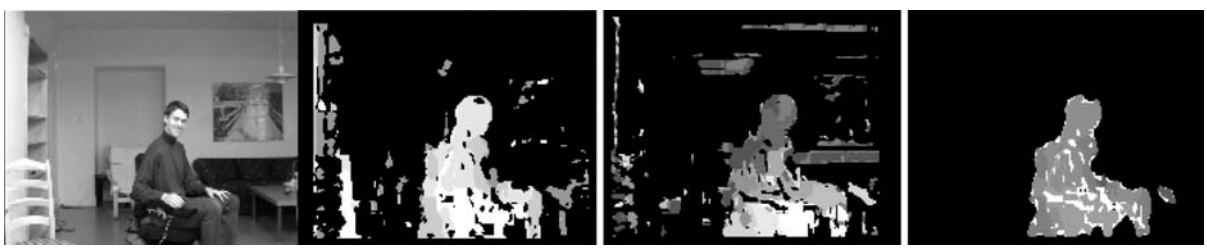

Fig. 5. Original image, motion estimate for the person driving the wheelchair, estimate of depth, and finally an example of information from a combination of depth and motion to generate a mask for the independently moving person. Large values are encoded as white and small values as gray. For the regions where no information can be computed a value of 0 (black) has been entered.

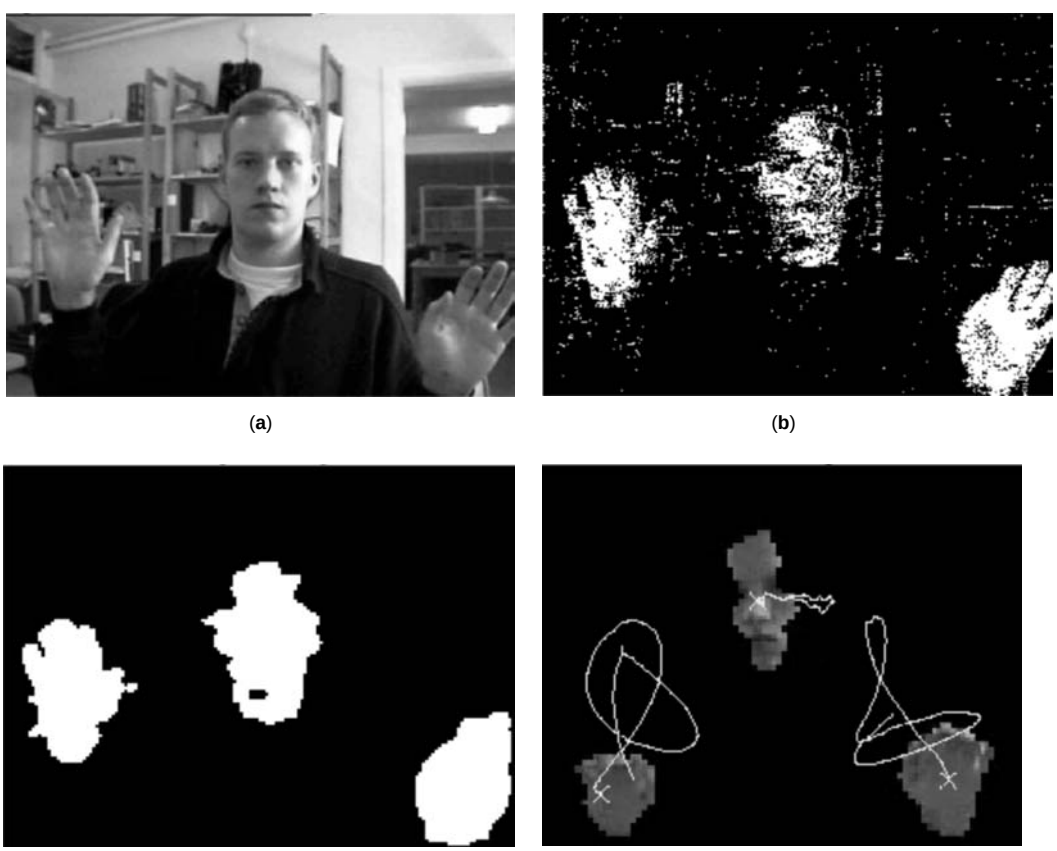

(**a**) (**b**)

(**c**) (**d**)

Fig. 6. Example of monitoring of people. (**a**) An original image is shown. (**b**) Using classification based on skin color a set of "noisy" regions are detected. (**c**) By finding, the three largest connected regions the face and hands can be located. (**d**) Finally these regions can be tracked over a sequence of images and used for interpretation of the activities of the person sitting in front of the computer.

the hands of the person. Once hand and face have been identified the regions can be tracked and used for recognition of particular gestures. The trajectory of the hand is shown in the final image of the sequence. Here particular trajectories are recognized. Through analysis of how the hands move it is possible to understand what the person is doing. Such methods are for example of significant value for new computer interfaces.

Using these techniques it is possible to provide efficient interfaces and advanced surveillance systems. Similar techniques for example also used for monitoring of traffic. Once the trajectory of a car has been extracted it can be registered with a map of the environment and used for detection of traffic violations both in terms of speed, incorrect turning, erratic driving etc. See also **Artificial Intelligence**; **Machine Vision (Recognition and Applications)**; and **Optical Character Recognition (OCR)**.

ARTIFICIAL INTELLIGENCE: NATURAL LANGUAGE PROCESSING. Comprehension of language is one of the abilities that separates humans from other animals. To date, this ability also separates humans from computers. A typical 10-year-old child is far more adept at communicating in a natural (human) language than any computer program. However, researchers in the field of *natural language processing* (NLP) are trying to change this. NLP researchers study human languages, attempt to codify the knowledge required to use language, and then program this knowledge into computer systems so that they can interact with their users in natural language, at least in limited ways.

Computer systems are usually referred to as NLP systems if they process language in textual, rather than spoken, form. Textual input is easier to process, because typed characters are easy for programs to decipher. Computer systems which process spoken input are usually referred to as *speech recognition* systems. These systems face the additional task of translating sound waves into individual words. The difficulties associated with this task are beyond the scope of this article.

Humans appear to use a great deal of knowledge about language and about the world in general in order to comprehend natural language. First, they must use *syntactic* knowledge, or knowledge about how sentences are constructed in a particular language. Examples of syntactic knowledge about English include the following:

- Declarative sentences are generally composed of a subject, then a verb, and then possibly an object.
- The subject of a sentence and its verb must agree in both number (singular or plural) and person (1st, 2nd, or 3rd).
- Noun phrases often start with an article (for example, "the"), followed possibly by one or more adjectives, followed by a noun.

In NLP systems, syntactic knowledge is usually encoded in the form of a set of rules, called a *grammar*. The grammar is used to *parse* sentences; that is, to derive their structure. Fig. 1 illustrates an example of how an NLP system might parse the sentence *The jockey rides the horse*.

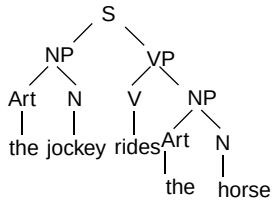

Fig. 1. Parsing the sentence, "The jockey rides the horse".

Parsing a sentence enables an NLP program to (a) eliminate some possible meanings of words in the sentence; and (b) decode information about what roles are played by the words. In the above example, the parse indicates that *rides* is a verb rather than a noun (e.g., *The pony rides were for the children*), that *horse* is a noun rather than a verb (*The jockeys often horse around*) and that it is the jockey that is riding the horse, and not the other way around.

In addition to syntactic knowledge, humans also use knowledge about word meanings, often called *semantic* knowledge; and their general knowledge about the world, often called *encyclopedic* knowledge. An example of semantic knowledge is the fact that the word *bank* can refer to either a river bank or to a savings institution. Encyclopedic knowledge includes various facts about these two types of banks and about related concepts: people deposit money in savings institutions, river banks are next to rivers, rivers contain water, and so on. People use this knowledge to understand how a word is used in a particular sentence, and to construct an overall understanding of a sentence. For example, in *The water ran over the bank*, it is likely that *bank* refers to a river bank, and the sentence should be understood to describe a flood.

Semantic or encyclopedic knowledge is much more difficult to encode in a computer program. Recently, attempts have been made to build large computer databases, or so-called *knowledge bases*, which contain semantic or encyclopedic knowledge in a form that could be used by an NLP system. One such knowledge base, WordNet, can be thought of as an electronic thesaurus, in which different senses of words have been grouped together in sets of synonyms, or *synsets*. In addition, simple relationships are encoded between synsets, such as part-whole relationships (e.g., a bank is part of a river), and general-specific relationships (e.g., a bank is a type of institution). An NLP system can sometimes use these synsets to determine which is the most likely meaning of a word in a given context. A much more ambitious attempt to build a knowledge base of encyclopedic knowledge is the CYC system, in which a large body of common-sense knowledge about the world has been encoded in a form which could be used by an NLP system.

Since construction of the large amounts of knowledge required by NLP systems is difficult, many researchers have investigated statistical techniques for automated construction of knowledge bases. Programs scan large corpora of text to try to discover regularities in word usage. Sometimes the corpus is manually analyzed by linguists, so that this manual analysis can be used by a program to automatically infer rules about the language. For an overview of statistical approaches to NLP, see Charniak in the references.

Attempts to build NLP systems have met with limited success thus far, with most successful applications limited to very specific language understanding tasks. Some of the earliest NLP systems were built to translate text from one language to another. The first *machine translation* systems were developed in the late 1940s and 1950s. At first, researchers thought that it would be possible to build general-purpose, fully automated machine translation systems. However, it soon became clear that the pervasiveness of ambiguity in natural languages (e.g., the multiple meanings of *bank*) would make the goal of fully automated machine translation difficult to achieve. Fully automated machine translation systems have been successfully built for limited-domain applications, such as translating weather forecasts. General-purpose machine translation systems have also been built and successfully used, but their outputs must be edited by a human in order to produce professional-quality translations. For example, the SYSTRAN system (*http://www.systransoft.com*) is used by the AltaVista search engine to translate Web pages, but the translation is often quite rough.

Another application of NLP is in the task of *information extraction*. An information extraction system "reads" documents such as newspaper articles in a particular area of interest and extracts summary information from these articles. For example, a system which reads articles about mergers

and acquisitions might extract the name of the purchasing corporation, the name of the corporation being bought out, the amount of the transaction, and the type of transaction (cash, stock, or some mixture). Information extraction systems must be customized for the particular area of interest, by coding encyclopedic information about the domain. Such systems are able to successfully extract 50–70% of the summary information from articles in a typical domain. See also **Artificial Intelligence**.

ARTIFICIAL INTELLIGENCE: NEURAL NETWORKS. Artificial neural networks consist of simple processing units that interact via weighted connections. They are sometimes implemented in hardware, but most research involves software simulations. They were originally inspired by ideas about how the brain computes, but some types of neural network that are biologically unrealistic are nevertheless technologically useful. Neural networks learn from examples and so they can solve problems, such as recognizing handwriting, for which it is very hard to write a conventional computer program.

The most widely used learning algorithms are supervised: they assume that there is a set of training cases, each consisting of an input vector and a desired output vector. Learning involves sweeping through the training set many times, gradually adjusting the weights on the connections so that the actual output produced by the network gets closer to the desired output. The simplest neural network architecture consists of some input units with directed, weighted connections to an output unit. Such networks were extensively studied in the 1960s because there are very simple learning algorithms that are guaranteed to find the optimal weights when the output unit uses a linear or binary threshold activation function, but such simple networks can only compute a very limited class of functions. They cannot, for example, decide if two binary inputs have the same value.

The limitations of simple networks can be overcome by adding one or more intermediate, "hidden" layers of nonlinear units between the input and the output. The architecture remains feedforward, with each unit only receiving inputs from units in lower layers. With enough hidden units there will always be a set of weights for the connections that allow the network to produce the correct outputs for nonpathological problems. Finding these optimal weights, is generally intractable, but methods that gradually adjust the connection weights to improve the performance work remarkably well for many practical tasks.

Performance can be significantly improved if natural symmetries of the task are imposed on the network by forcing different weights to have the same values. For example, a net that converts preprocessed sound waves into a sequence of phonemes (the elementary constituents of spoken words) works much better if its weights are constrained so that the conversion from sounds to phonemes is the same no matter when the sounds occur. For tasks in which the data is expected to come from a number of different but unknown regimes, it is advantageous to use a "mixture of experts" architecture containing a different network for each regime and a "gating" network that decides on the probability of being in each regime.

When the amount of training data is limited, a complicated network with a large number of weights is liable to overfit: it performs very well on the training data, but much less well on test data drawn from the same distribution. On the other hand, a simple network with few weights may perform poorly on both training and test data because it is unable to approximate the true function. Many different methods have been developed for optimizing the complexity of the network. If part of the training data is held out as a validation set, it is possible to try different numbers of hidden units and to pick the number that gives best performance on the validation set. The "early stopping" method, which is appropriate when computational resources are limited, stops the training of a complicated network as soon as its performance on the validation set starts to deteriorate. A more principled way to deal with overfitting is to learn a whole ensemble of different neural networks with different complexities and to make predictions by averaging together the predictions of each network in the ensemble. The coefficients used in the averaging depend on how well each network fits the training data and on how likely the weights in the network are according to some prior model of what kinds of weights ought to occur. This approach has proved very effective in practice when the amount of training data is limited.

Unfortunately, supervised learning has a serious deficiency. For technological applications it is often difficult to get the very large number of labeled training examples that are needed to fit a network with a lot of adjustable weights. The problem is that each example must be labeled with the correct answer. This is also a problem for learning in the brain since there is usually no teacher to supply the correct categorization of all the objects in a scene or all the sounds in a sentence. Many neural network researchers now believe that a complete learning system should consist of two parts. The "action system" learns to associate appropriate actions with an internal representation of the system's current environment. Its aim is to agree with a teacher or to maximize the amount of reinforcement it receives. The "perceptual system" learns to convert the stream of sensory input into a concise representation of the current environment and it does this without requiring any additional signal from a teacher.

In the absence of a teaching signal, it is not at all obvious what the perceptual system is trying to achieve. How should the connection weights be adjusted? An influential answer to this question comes from thinking about "generative models". A generative model stands in the same relationship to perception as computer graphics does to computer vision. It allows the sensory data to be generated from a high-level description of the scene. Perception can then be seen as the process of inverting the generative model — inferring the high-level description from the sensory data under the assumption that it was produced by the generative model. Learning is the process of updating the parameters of the generative model, to maximize the likelihood that it would generate the observed sensory data.

The best algorithms for clustering data into classes can be understood in terms of generative models. We assume that the observed data was generated by picking the center of one of the clusters at random and then perturbing it by adding Gaussian noise. If we know in advance where the cluster centers are, the inference problem is simply to figure out which cluster was used to produce the data. Obviously, if the data is much closer to one cluster center than to all the others, it was probably generated by perturbing that cluster center. But if the data is equally close to two cluster centers and they have the same spread, the best that inference can do is to say there is a probability of one half that it came from each cluster. This inference process can be implemented in a neural network in which a datapoint is represented by the activities of a layer of "visible" neurons, and the clusters are represented by a layer of "hidden" neurons. The weights connecting each hidden neuron to the visible neurons represent the location of a cluster center, and inference involves a competition between the hidden neurons so that the one whose weights are most similar to the current datapoint gets the highest activation.

If we do not know in advance where the cluster centers are, we need to learn their locations which means learning the weights between the visible units and the hidden units. We start by just guessing the locations. Then we look at all the data and, using the guessed locations, we infer the probability that each datapoint came from each cluster. Then we move each cluster center to the center of gravity of the datapoints weighted by the probability that the datapoints came from that cluster. If we keep alternating between an "expectation" step, in which we infer the probability that each cluster

produced each data point, and a "maximization" step, in which we update all the cluster centers in parallel, we will eventually reach a locally optimal set of cluster centers that cannot be improved by small adjustments. This is a simple example of the widely applied Expectation-Maximization or EM algorithm for fitting generative models.

The inference step is easy if we assume that each datapoint was produced by exactly one of the clusters. But this is a very limited kind of generative model. Complicated data, like images of real scenes, clearly has many different things going on at once in each image and this requires a generative process that involves multiple objects, distortions, viewpoints, illumination and a host of other underlying factors that generally have nonlinear relationships to the things that are actually observed such as the intensities of the pixels in an image.

If the generative model is nonlinear and allows multiple simultaneous causes, it can be very difficult to compute the likely causes of a pattern of sensory inputs, because there are exponentially many possible combinations of causes. When exact inference is infeasible, it is possible to use approximations that wholly or partially ignore some of the possible ways in which the generative model might have produced the currently observed sensory data. Surprisingly, it is still possible to adjust the connection weights in the generative model to optimize a sensible overall measure of the quality of the model. The overall measure takes into account both the likelihood that the model would generate the observed data and the degree to which the approximate inference procedure ignores some of the possible ways in which the model could have produced the data. ARTIFICIAL INTELLIGENCE: ROBOTICS. According to Russell and Norvig, authors of a widely used textbook on artificial intelligence, an agent is "anything that can be viewed as perceiving its environment through sensors and acting upon its environment through effectors." Furthermore, they define a robot as "an active, artificial agent whose environment is the physical world." So a robot should do something, be different from a biological animal, and most importantly must operate in the real world.

What makes a robot distinct from any other artificial intelligence project is that it is physically embodied with intrinsic limitations in its sensing and acting capabilities. It is possible for a robot to gather information about its current situation using its sensors, but it only has a limited field of view and every physical device is subject to noise. Therefore, "the real world is only partially knowable, and this in turn implies that it is predictable only to a limited extent".

Traditionally, artificial intelligence has focused on developing explicit, predictive models of problem domains. Given such a model, it is possible to consider all possible actions and then choose the action with the best predicted outcome. This technique has been used successfully in constrained domains such as game playing, where the result of every action is known. However, applying this technique to choosing a robot's actions becomes problematic due to the difficulty of maintaining an accurate model of the real world. Rodney Brooks has pointed out that in working with robots, explicit models just get in the way, and "it turns out to be better to use the world as its own model".

To be truly useful, robots must be autonomous, meaning that they can function independently without external control, but also that they can base their action choices on their own experience rather than solely on built-in knowledge. Ultimately, robots should have a collection of basic abilities that can be brought to bear in tackling a variety of tasks in a wide range of environments. These fundamental abilities might include navigation to a goal location, obstacle avoidance, object recognition, and object manipulation.

To date, this desired level of autonomy and adaptability has not been fully realized. Yet, the most exciting potential applications involve much more complex and dynamic environments than have typically been attempted so far (for example outdoor, subsea, and other planet environments). We should expect that the burden on the human designer of robot control software will only increase as we try to move towards these more difficult applications.

One of the most promising avenues for overcoming the bottleneck of the human engineer in the robot design process is the use of evolutionary computation techniques. In fact, it has been proposed that an evolutionary approach to the design of robots will eventually supercede design by hand. The fundamental idea of this approach is to maintain a population of possible robot control architectures. The initial population is typically a collection of randomly configured architectures. Each architecture is evaluated according to an objective fitness measure and the better the robot performs using that architecture the more offspring it is allowed to produce in the next generation of the population. Over a number of generations, the fitness of the population increases and successful architectures are created. A human engineer must develop the evolutionary framework, but the actual design of the robotic systems is then automatically generated.

Evolutionary computation methods attempt to mimic the process of natural evolution by employing three operators: selection, recombination, and mutation. Selection is usually implemented as a probabilistic process using the relative fitness of an individual to determine its selection probability. In this way, fitter individuals are more likely to participate in producing the next generation. Recombination is the means of mixing the genetic material of two parents to produce an offspring. Mutation creates random alterations in the genetic material of an offspring.

A central question when adopting the evolutionary computation approach is: What type of robot control architecture should be evolved? There are a number of options: high-level code in languages such as C or Lisp, machine code, parameter settings for a hand-designed system, situation-action rules, or entire rule-based strategies. Perhaps the most innovative direction, however, is the combination of evolutionary computation with artificial neural networks. Neural networks allow the evolutionary process to operate at a very low level, placing minimal constraints on the possible solutions. When a higher-level architecture is used, designer bias is more prevalent. In addition, neural networks are robust, noise-tolerant and can be used for local learning starting from the points discovered by the global evolutionary process. See also **Artificial Intelligence: Neural Networks.**

Hans Moravec likens today's robots to simple invertebrates in the global evolutionary sense. He predicts that in the next decade robots should improve to the level of reptiles and within 50 years to the level of mammals. One of the crucial impediments to producing adaptive behavior in robots has been the size and speed of computers. Employing evolutionary techniques for developing neural network-based controllers is computationally expensive. Significant progress has been made recently partly due to continuing exponential increase in the computational resources. As Moravec points out, the amount of computational power that a dollar can purchase has increased a thousandfold every two decades since the beginning of the century. There has been a trillionfold decline in the cost of computation. If this trend continues, as seems to be the case at present, Moravec predicts that the computational power required for a humanlike

robot would be available in a $10 million super computer before 2010 and in a $1000 personal computer by the year 2030.

Work on a humanlike robot has already begun at MIT with the Cog project. MIT's approach is to build a humanoid robot that develops and acts in the real world in the same way that humans develop and act. This human-inspired development plan has so far led to the incorporation of several behaviors: the arms have grasping, withdrawal, and reflexes like those of a child; the arms also have adaptive spring-like behavior; the arms follow smooth motion trajectories; the eyes have foveation behavior that can be used to coordinate hand-eye movements in reaching for objects; and the eyes and the head exhibit saccading motion and gaze control. Even though Cog's performance today is below those of conventionally designed robots, it is expected that the developmental approach will eventually pay off. Most of the models incorporated in Cog are based on biological models.

Given the incredible computational power at hand, it is becoming increasingly attractive to experiment with evolutionary methods in robots. Onboard computers in mobile systems are now powerful enough to run experiments in real-time. It is also becoming feasible to incorporate robotics into school and college curricula. As robots become less expensive and more prevalent, rapid innovations should be expected in the future. ARTIFICIAL LINE. An artificial line is an electrical network consisting of resistance, inductance and capacitance so connected that it has the same characteristics (electrical) as the actual transmission line. Sometimes where the artificial line is not required to duplicate exactly the actual line the inductance or capacitance may be omitted. Such a line is very valuable for making laboratory tests as it makes possible connection at points corresponding to an actual line over a long distance. Artificial lines are also used in telephone and telegraph practice to balance actual lines to give desired operating characteristics in bridge type circuits.

ARTIODACTYLA *(Mammalia)*. Hoofed animals that retain an even number of toes, the axis of the foot passing between the third and fourth digits. In older terminology, the term even-toed ungulates was used. Organization of the *Artiodactyla* is shown in the Table 1, along with references to specific entries in this volume that describe the various families, subfamilies, and species found in the order of *Artiodactyla*.

ASAFETIDA. The gum-resin exudate from the roots of a commonly-occurring plant in the steppes region of Asia. Upon steam distillation, it yields a pale-yellow to orange-yellow liquid having a garliclike odor and slightly bitter, pungent taste. The resin from this plant (*Ferula assafoetida* L.) of the family *Umbelliferae* contains methylpropenyldisulfides, along with small amounts of vanillin. Asafoetida has been used as a flavoring in a number of food products, including nonalcoholic beverages, ice creams, candies, baked goods, and condiments, among others. Most countries consider the available fluid extracts and tinctures as GRAS (generally regarded as safe).

ASBESTOS. [CAS: 132207-33-1], The term asbestos, is a generic designation referring usually to six types of naturally occurring mineral fibers which are or have been commercially exploited. These fibers are extracted from certain varieties of hydrated alkaline silicate minerals comprising two families: serpentines and amphiboles. The serpentine group contains a single fibrous variety: chrysotile; five fibrous forms of amphiboles are known: anthophyllite, amosite, crocidolite, tremolite, and actinolite.

These fibrous minerals share several properties which qualify them as asbestiform fibers: (*1*) they are found in large clusters which can be easily separated from the host matrix or cleaved into thinner fibers; (*2*) the fibers exhibit high tensile strengths; (*3*) they show high length:diameter ratios, from a minimum of 20 up to >1000; (*4*) they are sufficiently flexible to be spun; and (*5*) macroscopically, they resemble organic fibers such as cellulose.

Since asbestos fibers are all silicates, they exhibit several other common properties, such as incombustibility, thermal stability, resistance to biodegradation, chemical inertia toward most chemicals, and low electrical conductivity.

The usual definition of asbestos fiber excludes numerous other fibrous minerals which could be qualified as asbestiform following the criteria listed above. However, it appears the term asbestos has traditionally been attributed only to those varieties which are commercially exploited.

The fractional breakdown of the recent world production of the various fiber types shows that the industrial applications of asbestos fibers have now shifted almost exclusively to chrysotile. Two types of amphiboles, commonly designated as amosite and crocidolite are still being used, but their combined production is currently less than 2% of the total world production. The other three amphibole varieties, anthophyllite, actinolite, and tremolite, have no significant industrial applications presently. This statement excludes asbestiform amphiboles which may occur in other industrial minerals.

Early uses of asbestos exploited the reinforcement and thermal properties of asbestos fibers. The first recorded application can be traced to Finland ($\sim$2500 BC), where anthophyllite from a local deposit was used to reinforce clay utensils and pottery. Numerous early references also can be found describing the use of asbestos fibers for the fabrication of lamp wicks and crematory clothing. Other applications of asbestos fibers in heat- or flame-resistant materials have been sporadically reported. At the end of the seventeenth century, Peter the Great of Russia initiated the fabrication of asbestos paper, using chrysotile fibers extracted from deposits in the Ural mountains. The use of asbestos fibers on a true industrial scale began in Italy early in the nineteenth century with the development of asbestos textiles. By the end of the nineteenth century, significant asbestos deposits had been identified throughout the world and their exploitation had begun in Canada (1878), South Africa (1893, 1908–1916), and the USSR (1885).

From the beginning of the twentieth century, the demand for asbestos fibers grew in a spectacular fashion for numerous applications, in particular for thermal insulation. The development of the Hatschek machine in 1900 for the continuous fabrication of sheets from an asbestos–cement composite also opened an important field of industrial application for asbestos fibers as did the development of the automobile industry for asbestos brakes, clutches, and gaskets.

World War II supported the growth of asbestos fiber production for military applications, typically in thermal insulation and fire protection. Such applications were later extended into residential or industrial constructions for several decades following the war.

TABLE 1. ARTIODACTYLA
(Even-toed Hoofed Mammals)

ANTELOPINES	**See Antelope**.
Horse-Antelopes (*Hippotraginae*)	
Sabre-horned Antelopes (*Hippotragus*)

During the late 1960s and 1970s, the finding of health problems associated with long-term heavy exposure to airborne asbestos fibers led to a large reduction in the use of asbestos fibers. In most of the current applications, asbestos fibers are contained within a matrix, typically cement or organic resins.

The world production of asbestos fibers reached a maximum in 1977 of 4.8×10^6 tons, decreasing to 1.9×10^6 tons in 2000.

Geology and Fiber Morphology

The genesis of asbestos fibers as mineral deposits required certain conditions with regard to chemical composition, nucleation, and fiber growth; such conditions must have prevailed over a period sufficiently long and perturbation-free to allow a continuous growth of the silicate chains into fibrous structures.

Crystal Structure of Asbestos Fibers

The microscopic and macroscopic properties of asbestos fibers stem from their intrinsic, and sometimes unique, crystalline features. As with all silicate minerals, the basic building blocks of asbestos fibers are the silicate tetrahedra which may occur as double chains $(SiO)^{6-}114$, as in the amphiboles, or in sheets $(SiO)^{4-}104$, as in chrysotile.

In the case of chrysotile, an octahedral brucite layer having the formula $(MgO_4(OH)_8)^{4-}6$ is intercalated between each silicate tetrahedra sheet.

The crystalline structure common to amphibole minerals consists of two ribbons of silicate tetrahedra placed back to back.

Properties

Asbestos fibers used in most industrial applications consist of aggregates of smaller units (fibrils). This is most evident with chrysotile which exhibits

an inherent, well-defined unit fiber. Typical diameters of fibers in bulk industrial samples may reach several tens of micrometers; fiber lengths are on the order of one to ten millimeters.

The mechanical processes employed to extract the fibers from the host matrix, or to further separate (defiberize, open) the aggregates, can impart significant morphological alterations to the resulting fibers. Typically, microscopic observations on mechanically opened fibers reveal fiber bends and kinks, partial separation of aggregates, fiber end-splitting, etc. The resulting product thus exhibits a wide variety of morphological features. The consequences of the peculiar morphology of fiber shapes are difficult to assess, but it is quite obvious that a proper dimensional characterization of these fibers requires a shape factor in addition to diameter and length.

The morphological variance appears more important with chrysotile than with amphiboles. The intrinsic structure of chrysotile, its higher flexibility, and interfibril adhesion allow a variety of intermediate shapes when fiber aggregates are subjected to mechanical shear. Amphibole fibers are generally more brittle and accommodate less morphological deformation during mechanical treatment.

For industrial applications, the fiber length and length distribution are of primary importance because they are closely related to the performance of the fibers in matrix reinforcement. Representative distributions of fiber lengths and diameters can be obtained through measurement and statistical analysis of microphotographs; fiber length distributions have also been obtained recently from automated optical analyzers.

The industrial applications of chrysotile fibers were developed taking advantage of their particular combination of properties: fibrous morphology, high tensile strength, resistance to heat and corrosion, low electrical conductivity, and high friction coefficient. In many applications, the surface properties of the fibers also play an important role; in such cases, a distinction between chrysotile and amphiboles can be observed because of their differences in chemical composition and surface microstructure.

Analytical Methods and Identification

In a general way, the identification of asbestos fibers can be performed through morphological examination, together with specific analytical methods to obtain the mineral composition and/or structure. Morphological characterization in itself usually does not constitute a reliable identification criterion. Hence, microscopic examination methods and other analytical approaches are usually combined.

Fiber Classification and Standard Testing Methods

In the production, or industrial applications, of asbestos fibers, several parameters are considered critically important and are used as standard evaluation criteria: length (or length distribution), degree of opening and surface area, performance in cement reinforcement, and dust and granule content. The measurement of fiber length is important since the length determines the product category in which the fibers will be used and, to a large extent, their commercial value.

The most widely accepted method for chrysotile fiber length characterization in the industry is the Quebec Standard test (QS).

A second industrially important fiber-length evaluation technique is the Bauer-McNett (BMN) classification.

Other classification techniques have been developed which provide some insight on fiber lengths, typically the Ro-Tap test, the Suter-Webb Comb, and the Wash test.

Industrial Applications

Asbestos fibers have been used in a broad variety of industrial applications. In the peak period of asbestos consumption in industrialized countries, some 3000 applications, or types of products, have been listed. Because of recent restrictions, many of these applications have now been abandoned and others are pursued under strictly regulated conditions.

The main characteristic properties of asbestos fibers that can be exploited in industrial applications are their thermal, electrical, and sound insulation; nonflammability; matrix reinforcement (cement, plastic, and resins); adsorption capacity (filtration, liquid sterilization); wear and friction properties (friction materials); and chemical inertia (except in acids). These properties have led to several main classes of industrial products or applications: fire protection and heat or sound insulation, fabrication of papers and felts for flooring and roofing products, pipeline wrapping, electrical insulation, thermal and electrical insulation, friction products in brake or clutch pads, asbestos–cement products, reinforcement of plastics, fabrication of packings and gaskets, friction materials for brake linings and pads, reinforcing agents, vinyl or asphalt tiles, and asphalt road surfacing.

Health and Safety

The relationship between workplace exposure to airborne asbestos fibers and respiratory diseases is one of the most widely studied subjects of modern epidemiology. Asbestos-related health concerns were first raised at the beginning of the century in the United Kingdom, which appears to have been the first country to regulate the asbestos-user industry. It wasn't until the early 1960s, however, that, researchers firmly established a correlation between worker excess exposure to asbestos fibers and respiratory cancer diseases. This finding triggered a significant research effort to unravel important issues such as the influence of fiber size, shape, crystal structure, and chemical composition; the relationship between exposure levels and diseases; the consequence of exposure to asbestos fibers in different types of industries, or from different types of products; and the development of technologies to reduce worker exposure.

The research efforts resulted in significant consensus in some areas, although strong controversies remain in other areas. Typically, it is widely recognized that the inhalation of long (considered usually as >5 μm), thin, and durable fibers can induce or promote lung cancer. It is also widely accepted that asbestos fibers can be associated with three types of diseases: asbestosis: A lung fibrosis resulting from long-term, high level exposures to airborne fibers; lung cancer: Usually resulting from high level exposures and often correlated with asbestosis; mesothelioma: A rare form of cancer of the lining (mesothelium) of the thoracic and abdominal cavities.

A further consensus developed within the scientific community regarding the relative carcinogenicity of the different types of asbestos fibers. There is strong evidence that the genotoxic and carcinogenic potentials of asbestos fibers are not identical; in particular, mesothelial cancer is mostly, if not exclusively, associated with amphibole fibers.

The replacement of asbestos fibers by other fibrous materials has raised similar health issues about substitute materials. However, lung cancer has a latency period of ∼25 years and fiber exposure levels to substitutes are far lower than those that prevailed half a century ago with asbestos. Consequently, the epidemiological data on most substitutes is insufficient to establish statistically significant correlations between exposure and pulmonary disease. A possible exception is slag fibers for which several studies on worker populations are available over extended periods; some results show a substantial increase in lung cancer occurrence. Consequently, the toxicity of asbestos substitute fibers remains a subject of active investigation.

Regulation

The identification of health risks associated with asbestos fibers, together with the fact that huge quantities of these minerals were used ($\approx 5 \times 10^6$ t/yr) in a variety of applications, has prompted strict regulations to limit the maximum exposure of air-borne fibers in workplace environments.

ASCARIS. Parasitic roundworms of relatively large size found in the intestines of humans and other animals.

ASCENT OF SAP. All of the organs of any terrestrial plant are dependent for their existence upon water absorbed from the soil. This water, which always contains traces of solutes and hence is often referred to as sap, moves in a generally upward direction through the plant. In some of the tallest known specimens of redwood trees (*Sequoia sempervirens*) the sap must ascend to heights exceeding 350 feet (105 meters) if the topmost branch is to be kept supplied with water. The upward movement of sap in plants occurs in the xylem, which in trees and shrubs corresponds to the wood. In the trunks or larger branches of trees sap movement is confined to a few of the outermost annual rings of wood. Sap movement occurs only through the vessels and tracheids of the woody tissue.

The earlier theories of the upward movement of sap in plants mostly invoked some vaguely conceived vital activity of the cells as furnishing the motive power for sap movement. Although the vessels and tracheids through which the water moves are dead, they are always in intimate contact with living wood parenchyma and wood ray cells and it is not inconceivable that these cells might in some way motivate the upward movement of sap. However, such theories receive very little support at the present time.

It is a common observation that sap may flow from the severed stems of many kinds of plants and that this flow ("bleeding") may continue for some time. This exudation of sap results from a pressure originating in the root called *root pressure*, and the exuded sap comes from the xylem tissues. Root pressures are also present in intact plants. For several reasons, however, root pressure can be considered only a secondary mechanism of water transport in plants. In the first place, there are many species in which the phenomenon does not occur. In the second place the magnitude of measured root pressures seldom exceeds two atmospheres which could not cause a rise of sap of more than about 60 feet (18 meters). In the third place known rates of sap flow under the influence of root pressure are inadequate to compensate for many known rates of transpiration. And finally, in woody plants at least, root pressures are usually present only in the early spring; during the summer period when transpiration rates and hence rates of sap movement are greatest, root pressures are negligible or nonexistent.

The principal mechanism motivating the ascent of sap in plants is thought by most present day botanists to be dependent upon the property of *cohesion* in water. The cohesive forces between water molecules are very great. The evaporation of water from the mesophyll cells of the leaf during transpiration results in the movement of water molecules into these cells from the xylem (water-conducting tissue) of the veins. The xylem of the leaves is continuous with that of the stems, which in turn is continuous with that of the root system out almost to the very tip of every rootlet. The water is apparently present in the cells and vessels of the xylem as continuous threadlike columns. As water molecules pass out of these water columns into the mesophyll cells the threads of water become taut throughout the plant. Eventually a tension of considerable magnitude may be set up in them which is transmitted from the top to the bottom of the plant. The water columns can sustain this tension only because of the high cohesive force of water. When the water in the xylem of the younger roots passes into a state of tension, movement of water from the root cells into the xylem cells is induced. Loss of water from the root cells in turn causes absorption of water from the soil. Movement of water through the entire plant is thus brought about. Whenever transpiration rates are appreciable, water does not, as a rule, enter the lower ends of the xylem ducts from adjacent root cells as fast as it passes from the upper ends into the mesophyll cells: hence, the water is continuously under tension during periods of rapid transpiration and upward movement of sap. Calculations indicate that a cohesive force of between 30 and 50 atmospheres would be adequate to permit translocation of water to the very top of the tallest known trees by this mechanism. Experimentally determined values of the cohesive force of water are in excess of 300 atmospheres.

See also **Tree**.

ASCIDIACEA *(Chordata, Tunicata)*. The tunicates, sea squirts, or ascidians (Ascidiacea), constituting a class of the subphylum *Tunicata*. They begin life as larvae that resemble tadpoles in form and later become sessile animals invested in a covering called the test or tunic. Some species are solitary and others form colonies. See Fig. 1.

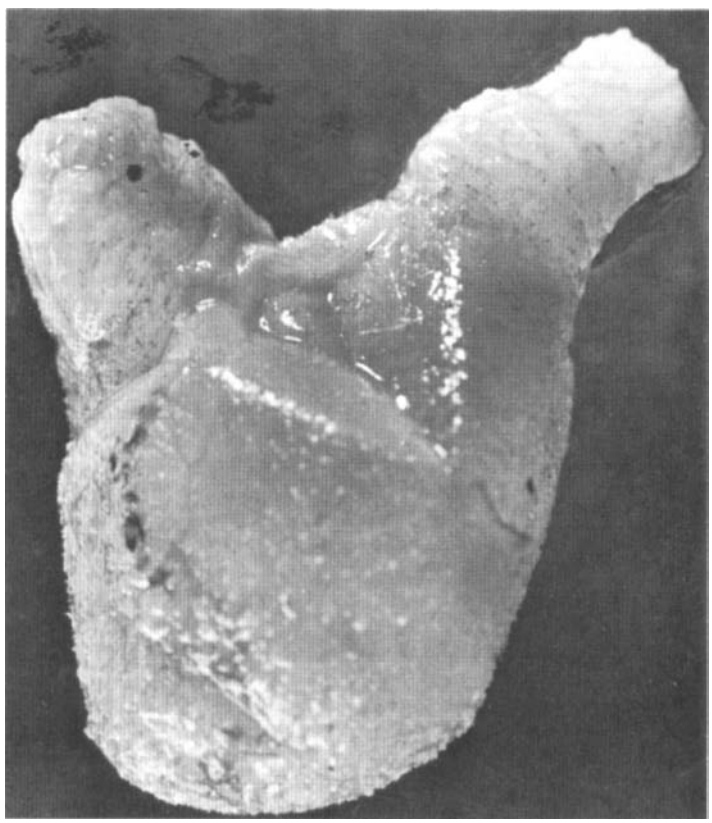

Fig. 1. *Ascidiacea*; sea squirt. (*A.M. Winchester*.)

The class contains two orders:
Order *Enterogena*.
Order *Pleurogena*.

ASCITES. An abnormal accumulation of fluid in the abdominal cavity. Chronic heart failure will lead to blood being dammed up in the liver with resultant increase in its size. As a result of this congestion of the liver, the abdominal cavity may become filled with fluid (*ascites*). This fluid at times may enormously distend the abdomen. The fluid may be drained by a needle passed through the abdominal wall, or the kidneys may be forced to eliminate the fluid by the administration of diuretics.

Ascites is also common in patients with tuberculous infection of the peritoneum and in those with cancer which has spread through the peritoneal cavity. Tubercular ascites will disappear with eradication of the disease. Ascites is also a complication of portal cirrhosis; and occurs in connection with right-sided congestive heart failure.

ASCOMYCETES (Sac Fungi; Fungi). Many of the 40,000 species of fungi comprising the Ascomycetes are very common plants, but few are conspicuous. Most of the species are small, often minute, while a few attain heights of 3 or 4 inches (7.6 or 10.2 centimeters), with a diameter of 1–2 inches (2.5 to 5.1 centimeters). Occasional individuals are even larger. All are characterized by the ascus, or spore-sac, commonly an elongate cylindrical body containing eight spores. In some species the ascus is spherical, or short cylindrical, while the number of spores may

vary from two to many. Usually the asci are grouped together in a dense layer, called the hymenium. This may be composed entirely of asci, or may contain in addition numerous slender sterile filaments, called paraphyses. In some cases at least it seems the function of the paraphyses is to protect the asci, since the outer tip of each paraphysis is a flattened cap which partially covers the ascus. Ascomycetes are found wherever suitable food-yielding materials exist. Many species are parasites, living on living plants; among these are species of great economic importance. Other species are saprophytes, wood-destroying species being particularly numerous. See also **Fungus**.

The life history of an Ascomycete comprises the mycelium composed of slender branching septate hyphae which penetrate throughout the substratum, and the fruiting stage in which the asci are formed. Two types of reproduction occur. One of these is the asexual type, in which asexual cells called conidia are cut off in various ways from the tips of hyphae, known as conidiophores. These conidia are single-celled spores that are disseminated by air currents. The other method of reproduction is sexual, and leads to the formation of asci. In *Pyronema confluens* this process has been carefully studied, and may be considered as typical in the main details for the process as it occurs in all the fungi of this class. The first step in this process is the formation of a multinucleate much-branched structure, which presently becomes septate. Some of the tips of this structure enlarge and become oögonia, called in this case ascogonia, while other tips become antheridia. From the oögonium a slender curved body called the trichogyne grows out. This is separated from the oögonium by a cross-wall. Since the oögonia and antheridia develop close together, the trichogyne comes in contact with the antheridium. All three bodies, oögonium, antheridium and trichogyne, are multinucleate. When the trichogyne comes in contact with the antheridium the walls between them at once break down, as does the wall between the trichogyne and the oögonium. The nuclei of the antheridium pass into the trichogyne, through it and into the oögonium. After this a new wall forms separating the trichogyne from the oögonium. In the oögonium the nuclei from the antheridium pair up with the nuclei of the oögonium, the nuclei of the trichogyne disintegrating early in the period of nuclear migration. Following the pairing of the nuclei in the ascogonium, coarse hyphae grow out from the latter. Into these the paired nuclei migrate. These coarse hyphae are the ascogenous hyphae, from which the asci eventually develop. In many Ascomycetes this process is considerably shortened, the ascogenous hyphae arising directly from the mycelium, no sex cells being formed; while other species have sex cells but no fusion, the oögonium alone developing.

The life cycles of the various ascomycetes are remarkably uniform, suggesting that they are all derived from a common ancestor. Botanists hold two different views of what the ancestral form may have been. According to one group, they are derived from red algae; favoring this view is the very great similarity in the development of the ascogonium and that of the carpospore formation in the algae; another favorable point is the presence of the trichogyne and the behavior of the antheridial nuclei. The other group holds, however, that the ancestors of the Ascomycetes are to be found in the Phycomycetes, basing this contention on the similarity of the Phycomycete sporangium and the ascus, the latter being merely a sporangium in which the number of spores has been greatly reduced, becoming stable at eight in most species.

Many members of this class of fungi are of great importance to humans because of their destructive parasitic habit. A few species are of value as food, or in the production of foodstuffs, and other products used by humans.

Importance of Ascomycetes

Among the injurious species may be mentioned the Chestnut Blight fungus, *Endothia parasitica*, a disease probably introduced from China at the beginning of the twentieth century. In China the native chestnut trees had developed immunity; American trees did not have this immunity, so the fungus, which attacks the cambial tissue, was particularly destructive, nearly wiping out the native chestnut trees in a few years. See also **Chestnut Trees**. Another disease caused by an Ascomycete is the Brown Rot of stone fruits, caused by *Sclerotinia cinerea*. This fungus is particularly destructive in wet seasons. Often infected fruits become shriveled up and dry, in which condition they are known as "mummies." A large group of Ascomycetes are known as Powdery Mildews, because of the abundant conidiophores, which are formed by the mycelium on the surface of the leaves of infected plants. Often these are so abundant as seriously to impair the functional efficiency of the leaf.

Another group of Ascomycetes contains species that are destructive and also those which are commercially of great value; these are the ubiquitous blue and green molds, species of *Aspergillus* and *Penicillium*. The destructive species attack foodstuffs everywhere, causing rotting and spoilage. Citrus fruits become covered with the bluish-green conidial masses; as does moist bread, pie crusts and many other foodstuffs. Species of the genus *Penicillium* give to Camembert and Roquefort cheese their characteristic properties. Other species of this group are the causal organisms for skin diseases of animals, including man. Another species of this genus, *Penicillium notatum*, is the source of the important drug penicillin. See also **Antibiotic**.

Among the largest of the Ascomycetes are species of truffles and morels, which are considered by mushroom fanciers to be particularly finely flavored. Truffles are fruit-bodies of the order *Tuberales*, and grow entirely underground. This makes it a matter of some difficulty to find them. Since they do not lend themselves to artificial cultivation, truffles must be sought in their wild habitat. To aid in locating them, dogs and pigs have been trained to find them using their superior sense of smell.

Another important Ascomycete is the genus *Claviceps*, which is parasitic on many grasses, including several cereal grains. This fungus forms a hard black sclerotium which is known as ergot, and which completely replaces the grain in the infected flower. The sclerotia are poisonous to livestock, causing the animals that have eaten them to become emaciated and covered with sores; another result is abortion in females. See also **Ergot**.

Another very important group of Ascomycetes is the Yeasts. See also **Yeasts and Molds**.

ASCORBIC ACID (Vitamin C). Infrequently referred to as the anti-scorbutic vitamin and earlier called cevitamic acid or hexuronic acid, the present terms, *ascorbic acid* and *vitamin C*, are synonymous. Ascorbic acid was one of the first (if not the first) nutrients to be associated with a major disease. Lind first described *scurvy* in 1757. However, this vitamin C deficiency disease had been recognized by Hippocrates in the 13th century and was a curse during the time of the Crusaders. In time of war, the disease killed untold numbers in armies, navies, and besieged towns. During the early days of the sailing ships, often requiring months between port calls accompanied by a lack of fresh food for long periods, the disease affected the crew as a plague. Scurvy was of some importance as recently as World War II. Currently, the disease is of prime concern in pediatrics. It is rarely seen in breast-fed children, but pasteurization of cow's milk degrades the vitamin and an addition to the diet of ascorbic acid must be provided for infants under 1 year of age.

Scurvy was first produced experimentally by Holst and Frolich in 1907. About 6 months were required to produce scurvy experimentally, as individual susceptibility and the quantity of vitamin C previously stored in the body affects the onset of scurvy. The earliest sign of scurvy is usually a sallow or muddy complexion, a feeling of listlessness, general weakness, and mental depression. Soon the bones are affected and increasing pain and tenderness develop. Teeth easily decay and become loose and often fall out, while the gums bleed easily and are sore. Changes in the blood vessels occur, producing hemorrhages in different parts of the body. In infants, irritability, loss of appetite, fever, and anemia also occur. An infant between 6 and 12 months of age, who has not had sufficient intake of vitamin C (as from fruit juices, supplements, etc.) may show abnormal irritability and tenderness and pain in the legs, often accompanied by pain and swelling of joints (elbows and knees). Immediate administration of vitamin C is indicated in such cases.

In 1928, Zilva first described antiscorbutic agents in lemon juice, although the importance of fresh fruit or vegetables for preventing scurvy had been established a century or more earlier. Also in 1928, Szent-Györgyi isolated hexuronic acid (vitamin C) from lemon juice. In 1932, Waugh and King identified hexuronic acid as an antiscorbutic agent. Haworth, in 1933, established the configuration of hexuronic acid and, in that same year, Reichstein first synthesized hexuronic acid. Later in that year, Haworth and Szent-Györgyi changed the name of hexuronic acid to ascorbic acid.

In 1950, King et al., by the use of glucose labeled with radiocarbon in known positions, traced glucose through intermediate steps in the formation of ascorbic acid in plant and animal tissues; then, by using ascorbic acid with radiocarbon-labeled positions, it was possible to determine with considerable accuracy the metabolic distribution, storage, and chemical changes characteristic of the vitamin molecule. That experimentation made it clear that the carbon atoms in glucose or galactose all retain their original positions, along the carbon chain in the vitamin when it is formed biologically. No rupture or replacement in the chain during conversion was noted. It was also found that the synthesis can be considerably enhanced by feeding livestock small amounts of *chloretone* or any of a score or more of organic compounds. Reactions just described are indicated below.

Biological Role of Ascorbic Acid. Apparently all forms of life, both plant and animal, with the possible exception of simple forms, such as bacteria that have not been studied thoroughly, either synthesize the vitamin from other nutrients or require it as a nutrient. Dormant seeds contain no measurable quantity of the vitamin, but after a few hours of soaking in water, the vitamin is formed.

Ascorbic acid is easily oxidized to dehydroascorbic acid. The latter is less stable than ascorbic acid and tends to yield products, such as oxalate, threonic acid, and carbon dioxide. When administered to animals or consumed in foods, dehydroascorbic acid has nearly the same antiscorbutic activity as ascorbic acid, and it can be quantitatively reduced to ascorbic acid.

In its biochemical functions, ascorbic acid acts as a regulator in tissue respiration and tends to serve as an antioxidant in vitro by reducing oxidizing chemicals. The effectiveness of ascorbic acid as an antioxidant when added to various processed food products, such as meats, is described in entry on **Antioxidants**. In plant tissues, the related glutathione system of oxidation and reduction is fairly widely distributed and there is evidence that electron transfer reactions involving ascorbic acid are characteristic of animal systems. Peroxidase systems also may involve reactions with ascorbic acid. In plants, either of two copper-protein enzymes are commonly involved in the oxidation of ascorbic acid.

In animal tissues, it is easily demonstrated that, as the vitamin content of tissues is depleted, many enzyme systems in the body are decreased in activity. Full explanation of these decreased activities still requires further research. In the total animal and in isolated tissues from animals with scurvy, there is an accelerated rate of oxygen consumption even though the animal becomes very weak in mechanical strength and many physiologic functions are disorganized. With the onset of scurvy, the most conspicuous tissue change is the failure to maintain normal collagen. Sugar tolerance is decreased and lipid metabolism is altered. There is also marked structural disorganization in the odontoblast cells in the teeth and in bone-forming cells in skeletal structures. In parallel with the foregoing changes, there is a decrease in many hydroxylation reactions. The hydroxylation of organic compounds is one of the most characteristic features disturbed by a vitamin C deficiency. These reactions relate to the vitamin's regulation of respiration, hormone formations, and control of collagen structure.

A partial list of physiological functions that have been determined to be affected by vitamin C deficiencies includes: (1) absorption of iron; (2) cold tolerance, maintenance of adrenal cortex; (3) antioxidant; (4) metabolism of tryptophan, phenylalanine, and tyrosine; (5) body growth; (6) wound healing; (7) synthesis of polysaccharides and collagen; (8) formation of cartilage, dentine, bone, and teeth; and (9) maintenance of capillaries.

Requirements. Species known to require exogenous sources of ascorbic acid include the primates, guinea pig, Indian fruit bat, red vented bulbul, trypanosomes, and yeast. Species capable of endogenous sources include the remainder of vertebrates, invertebrates, plants, and some molds and bacteria. The estimation of requirements of vitamin C by humans has been approached in several ways: (1) direct observation in human studies; (2) analogy to experimentation with guinea pigs; (3) analogy to experimental studies in monkeys and other primates; and (4) analogy to animals, such as the albino rat, that normally synthesize the vitamin in accordance with physiological need. It is relatively easy to maintain intakes at recommended levels by use of mixed practical dietaries that include nominal quantities of fresh, canned, or frozen vegetables or fruits. Generally, ascorbic acid is considered as nontoxic to humans. Possible exceptions include kidney stones (in gouty individuals); inhibitory in excess doses on cellular level (mitosis inhibition) possible damage to beta-cells of pancreas and decreased insulin production by dehydroxyascorbic acid.

Distribution and Sources. Natural sources of vitamin C include the following:

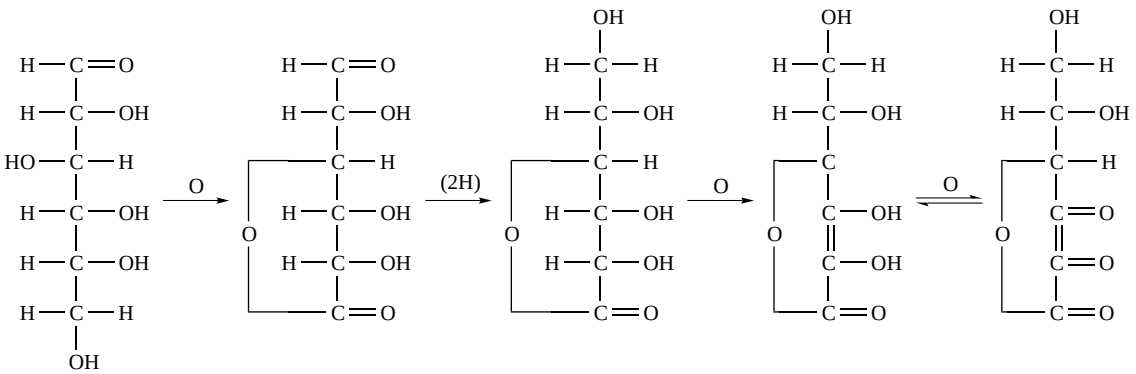
High ascorbic acid content (100–300 milligrams/100 grams)
Broccoli, Brussels sprouts, collards, currant (black), guava, horseradish, kale, parsley, pepper (sweet), rose hips, turnip greens, walnut (green English)

Medium ascorbic acid content (50–100 milligrams/100 grams)
Beet greens, cabbage, cauliflower, chives, kohlrabi, lemon, mustard, orange, papaya, spinach, strawberry, watercress

Low ascorbic acid content (25–50 milligrams/100 grams)
Asparagus, bean (lima), cantaloupe, chard, cowpea, currant (red and white), dandelion greens, fennel, grapefruit, kumquat, lime, loganberry, mango, melon (honeydew), mint, okra, onion (spring), passion fruit, potato, radish, raspberry, rutabaga, soybean, spring greens, squash (summer), tangerine, tomato, turnip

For the species where the ascorbic acid is synthesized endogenously, the precursors include *d*-mannose, *d*-fructose, glycerol, sucrose, *d*-glucose, and *d*-galactose. Intermediates include uridine diphosphate glucose, *d*-glucuronic acid, gulon acid, *l*-gulonolactone, (Mn^{2+} cofactor). Production sites in animals are the kidney and liver in most instances. In rats, it is the intestinal bacterial supply. In plants, the production sites are found in green leaves and fruit skins. Cell sites include microsomes, mitochondria, and golgi.

Supplements. Commercially available ascorbic acid still includes isolation from natural sources, such as rose hips, but large-scale production will involve the microbiological approach, i.e., *Acetobacter suboxidans* oxidative fermentation of calcium *d*-gluconate; or the chemical approach, i.e., the oxidation of *l*-sorbose.



(**1**)

Bioavailability of Ascorbic Acid. The general causes of reduced availability of vitamin C include damage to adrenal cortex, presence of antagonists, and food preparation practices (oxidation, storage, leaching, cooking). Excepting the use of supplements, the almost universal requirement for fresh foods as a source of vitamin C is readily explained by the sensitivity of the vitamin to destruction by reaction with oxygen. This is accelerated by the presence of minute quantities of enzymes that occur in most living tissues, in which copper or iron is combined with a protein to form a catalyst for the oxidation reaction. Other chemicals, such as quinones or high-valence salts of manganese, chromium, and iodine can also oxidize the vitamin readily in aqueous solutions. Most of these reactions increase rapidly in proportion to exposure to air and rising temperature. In the dry crystalline state, however, and in many dried plant tissues, particularly if acidic in reaction, the vitamin is quite stable at room temperature over a period of several months.

Freshly cut oranges or their juices may be exposed in an open glass for several hours without appreciable loss of the vitamin because of the protective effect of the acids present and the practical absence of enzymes that catalyze its destruction. In potatoes, when baked or boiled, there is a slight loss of the vitamin, but if they are whipped up with air while hot, as in the production of mashed potatoes, a large fraction of the initial vitamin content usually will be lost. In freezing foods, it is common practice to dip them in boiling water or to treat them briefly with steam to inactivate enzymes, after which they are frozen and stored at very low temperatures. In this state, the vitamin is reasonably stable. Vitamin C degradation in dehydrated food systems is described shortly.

Factors which increase the bioavailability of ascorbic acid include the presence of antioxidants and synergists in the diet.

Numerous studies have been conducted concerning vitamin C degradation during food processing, including dehydrated food systems. In the latter, the degradation is dependent upon water activity, moisture content, and storage temperature (for example, in containers with no headspace). Ascorbic acid destruction is dramatically increased in the presence of oxygen. See Structure 1.

ASEXUAL REPRODUCTION. In asexual reproduction, a part of the parent organism becomes an organism identical with the parent.

Different types of asexual reproduction can be found in the different groups of plants. In bacteria, fission, a simple splitting into two equal parts, is the asexual method of reproduction. In green algae the characteristic method is by the formation of zoospores, which are unicellular motile bodies formed from the protoplast of a single cell. Each zoospore, after swimming around for a time, becomes quiet and grows to form a new individual of the parent type. In flowering plants there are many methods of asexual reproduction, some of great importance to humans. A common type is found in the strawberry, where long slender branches grow out from the short stem of the plant and take root at their tip. There a new plant forms. This reproductive structure is called a stolon. Many other plants produce similar branches that run along the surface of the ground (runners) or just beneath it (rhizomes), and send up one or more new plants from the nodes. Other plants, like the tiger lily, bear small buds in the axils of their leaves: the buds or bulblets are easily detached and readily grow to form new plants. Similar bulblets are formed at the base of many bulbs. Another very common method of asexual reproduction is through the formation of suckers, branches formed at the base of the parent plants, and gradually growing to replace them. Growers propagate date palms, pineapples, and bananas, for example, by means of suckers. The familiar potato tuber, the swollen tip of a rhizome, is another type of asexual reproduction that is of tremendous economic value.

All the methods so far enumerated are from the stem of the plant. However, any part of the plant may be a means of asexual renewal. Many plants are known which reproduce by means of the leaves. Several of these are now cultivated extensively as objects of beauty or of curiosity. For example, the African violet, *Saintpaulia*, and many of the ornamental begonias, are readily propagated by leaves. Less widely known but equally interesting are species of *Bryophyllum* and *Kalanchoe*. In the notches of the leaves of these plants, while still attached to the parent plant or after being severed therefrom, tiny plants readily form and grow.

Many plants readily root when cut up into segments. Most people are familiar with the habit of the willow twig of striking root and growing when stuck in the ground. Equally well known is the geranium cutting, which is merely a branch removed from the parent plant and placed in a favorable environment.

Asexual reproduction is of much economic importance. New and improved forms of plants are constantly being made: by asexual means they are reproduced in the great quantities necessary for commercial use. Without such reproduction their formation in quantity would be practically impossible. (See **Grafting and Budding**.)

Asexual reproduction is also found in animals although it is restricted to some of the simpler phyla. Fission, a splitting in half, occurs in most of the *Protozoa*, such as *Amoeba* and *Paramecium*. In the class of *Protozoa* known as *Sporozoa*, one cell may break up into many reproductive bodies, which may be called *merozoites* or *sporozoites*. The nucleus within a cell first divides many times and a plasma membrane forms around each nucleus and the surrounding cytoplasm, and the original cell breaks open liberating the "spores." The malarial parasite, *Plasmodium*, is a good example; merozoites are formed in red blood cells and sporozoites are formed in a mosquito.

Budding is a means of asexual reproduction found in sponges and in certain coelenterates, such as Hydra. Many of the simpler metazoans also have the power of regeneration; if cut into two or more parts, each part can grow back the missing parts, thus forming two or more complete animals. See Figs. 1 and 2.

ASH.

1. Airborne particulates produced as a combustion product. These affect air quality, and their emission and ambient concentration is often regulated. For example, coal ash can consist of oxides of silicon, aluminum, iron, calcium, magnesium, sodium, potassium, sulfur, and titanium.
2. The unburnable solid remains of a fire.
3. Airborne particulates produced by a volcano (Volcanic ash). These are often fine particles of rock with very sharp edges, which cause great abrasion and wear when ingested in the air intake of an engine, and can quickly lead to engine failure.
4. In analytical chemistry, one of the components in the proximate analysis of biological materials, consisting mainly of carbonates and bicarbonates of metals.

ASH DEVILS. Dust devils made visible by loose ash from the earth's surface that is picked up or entrained by the rotating column of air.

For example, after the eruption of the Mount St. Helens volcano in western Washington State during May 1980, ash devils were frequently observed in the eastern Washington boundary layer during the subsequent summer.

See also **Dust Devil**.

ASH TREES. The timber and shade trees called *ashes* are members of the family *Oleaceae* (olive family); whereas the mountain ashes are members of the family *Rosaceae* (rose family). The so-called prickly ash (toothache-tree), the southern prickly ash, and the hop tree (sometimes referred to as the wafer ash) are members of the family *Rutaceae* (citrus family).

The olive ashes are of the genus *Fraxinus* and are deciduous trees (a few may be considered shrubs). Important species include:

Afghan ash	*Fraxinus xanthoxyloides*
Biltmore ash	*F. biltmoreana*
Black ash (or hoop ash)	*F. nigra*
Blue ash	*F. quadrangulata*
Carolina ash (or water ash)	*F. caroliniana*
Chinese ash	*F. chinensis*
European common ash	*F. excelsior*
Flowering ash (or Marie's ash)	*F. mariesii*
Green ash	*F. pennsylvanica lanceolata*
Manna ash	*F. ornus*
Narrow-leaved ash	*F. angustifolia*
Oregon ash	*F.latifolia*
(Oxycarpa)	*F. oxycarpa*
Pumpkin ash	*F. profunda*
Red ash (or brown or river ash)	*F.pennsylvanica*
Texas ash	
(Tomentosa)	*F.tomentosa*
Velvet ash	*F. velutina*
Wafer ash (or hop tree)	*Ptelea trifoliata*
Weeping ash	*F. excelsior latifolia*
White ashF. texensis	*F. americana*

The mountain ashes are of the genus Sorbus and are deciduous trees or shrubs. Important species include:

American mountain ash	*Sorbus americana*
European mountain ash (or Rowan)	*S.aucuparia*
Western mountain ash	*S. scopulina*
Notable Asian Species	
Embley mountain ash	*S. discolor*
Folgner mountain ash	*S. folgneri*
(Harrowiana)	*S.harrowiana*
(Hupehensis)	*S. hupehensis*
(Insignis)	*S. insignis*
Japanese mountain ash	*S. commixta*
Kashmir mountain ash	*S. cashmiriana*
(Pohuashaenensis)	*S. pohuashaenensis*
Sargent's mountain ash	*S. sargentiana*
Vilmorin's mountain ash	*S. vilmorinii*

As will be noted from Table 1, of record ash trees, the white ash is a large tree and valuable for its timber. The white ash prefers moist and rich soil in a cool woods environment and particularly favors locations along rivers. The tree ranges from Newfoundland and Nova Scotia westward into Ontario and Minnesota, and southward to northern Florida and southwestward into Oklahoma and Texas. The tree frequently occurs scattered but there are large concentrations in Maine. The wood is excellent for furniture, interior finish, and implements of various types. The color ranges from pale to medium brown. The grain is close although not considered fine-grained. Commercial white ash in the green condition has a moisture content of about 43% and weighs 48 pounds per cubic foot (767 kilograms per cubic meter). After air-drying to 12% moisture content, the wood weighs 41 pounds per cubic foot (657 kilograms per cubic meter) and 1,000 board-feet (2.36 cubic meters) of nominal sizes weigh 3,420 pounds (1551 kilograms). Crushing strength of the green wood with compression applied parallel to the grain is 4,060 psi (28 MPa); of the dried wood, it is 7,280 psi (50.2 MPa). The tensile strength of the green wood with tension applied perpendicular to the grain is 580 psi (4 MPa); of the dry wood, 850 psi (5.8 MPa).

The leaves of the white ash are compound and from 7 to 12 inches (18 to 30 centimeters) long. They are of a lusterless light green, lighter and a silver−green underneath. The flowers are green and without petals. The fruit occurs in clusters and is winged. The seed chamber is about 3/8-inch (0.9 centimeter) long and remains on bare branches well into mid-winter.

The green ash prefers the peripheries of streams and damp lowlands. It is found from Vermont southward along the mountains as far as northern Florida. Its range reaches westward to the eastern foothills of the Rocky Mountains. As shown by the Table 1, the pumpkin ash attains great heights, normally between 60 and 100 feet (18−30 meters) for average trees. It is a slender tree with a trunk diameter usually of 3 to 4 feet (0.9 to 1.2 meters). The tree has a distinctively swollen appearing trunk at the base, giving rise to its unusual name. This species likes swamps and wet areas around ponds. It ranges from western New York, west to Missouri and Arkansas, and southward to Florida.

The black ash, also known as hoop ash, is also a slender, very tall tree, averaging from 50 to 65 feet (15 to 19.5 meters) in height and a trunk diameter of only 1 to 2 feet (0.3 to 0.6 meter). This tree also prefers swampy country. The blue ash is valuable for timber and is found generally in the western and southwestern states. See Fig. 1. It can attain a height of close to 100 feet (30 meters), with a trunk diameter up to about 30 inches (76 centimeters), making it a slender tree. This tree is found in damp woods and prefers limestone hills. The tree occurs throughout middle America, ranging from Michigan southward into Alabama and Arkansas.

The American mountain ash is a very pretty tree, seldom exceeding 20−25 feet (6 to 7.5 meters) in height, with a trunk of from 8 to 15 inches (20.3 to 38 centimeters) in diameter. At high altitudes, it may be reduced to the status of a shrub. The tree flowers white in early spring. The fruit ranges in color from a coral red to deep scarlet. In nature, the tree is found in cool woods and along river banks, and also in swamps. The range is from Newfoundland west to middle-Canada and southward through the region of the Great Lakes and into Tennessee. The tree occurs on the mountain slopes in New England's White and Green Mountains and all along the Alleghenies as far south as North Carolina. The tree is used in landscaping.

The European mountain ash, sometimes called Rowan Tree, is used widely in parks and gardens in North America. The tree has narrow, oblong leaflets, the undersides covered with a white, hairy down. The fruit is of a bright scarlet color and is about 3/8-inch (0.9 centimeter) in diameter. There is considerably more variety in the European ashes with different colorations of bark and shape of leaves. There is a weeping ash (*Fraxinus excelsior* "Pendula") and the manna ash (*F. ornus*) which occurs in Southern Europe is known for its showy cream-colored flowers. The *F. excelsior* "Diversifolia" has a dandelion-color bark.

Several mountain ashes are native to Asia, including *Sorbus hupehensis* and *S. cashmiriana*. The *S. discolor* is well known as an excellent street tree because of its branches which point sharply upward. It has attractive large red leaves and fruit. The Chinese mountain ash, *S. vilmorinii*, is well known for its beauty of autumn coloration, with a full range from orange to purple.

The whitebeams are also of the genus *Sorbus* and thus closely related to the mountain ashes. A few highlights of the whitebeams include:

TABLE 1. RECORD ASH TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
GENUS: *Fraxinus*							
Berlandier ash (1995) (*Fraxinus berlandierana*)	234	594	65	19.8	78	23.8	Texas
Blue ash (1994) (*Fraxinus quadrangulata*)	185	470	86	26.2	66	20.1	Kentucky

[2]At 4.5 feet (1.4 meters).

Fig. 1. Blue ash located at Danville, Kentucky. (*Kentucky Division of Forestry*.)

S. alinfolia is found in Japan, crimson fruit, red-orange autumnal colors, attains a height of about 25 feet (7.5 meters); *S. aria*, a whitebeam of Europe, fragrant dull-white flowers, red fruit, brown autumnal colors, attains a height of from 30 to 45 feet (9 to 13.5 meters); *S. cuspidata*, a whitebeam of the Himalayas, white flowers, round, green fruit, large ovate leaves, attains a height up to 35 feet (10.5 meters); *S. domestica*, the service tree, occurs in southern Europe as well as western Asia and north Africa — pinnate leaves, small flowers, bears a pear-shaped fruit, may reach a height of 60 feet (18 meters); *S. hybrida*, also known as the bastard service tree, occurs in Scandinavia, white flowers, red fruit, reaches a height of 20 to 40 feet (6 to 12 meters); *S. intermedia*, the Swedish whitebeam, occurs in northwestern Europe, off-white flowers, clustered oval fruit of red coloration, attains height of about 20 feet (6 meters); *S. latifolia*, known as the service tree of Fontainebleau, ranges from Portugal to southern Germany. Rises to about 60 feet (18 meters), white flowers, brown fruit, shaggy bark; and *S. thibetica*, a whitebeam of Tibet.

ASM (International). The American Society for Materials is an organization with the mission of gathering, processing, and disseminating technical information pertaining to the understanding and application of engineered materials, their research, design, manufacture, and use, stressing economic and social benefits. These objectives are accomplished by way of a global information-sharing network of interaction among members in forums, meetings, and educational programs, through publications, such as the monthly *Advanced Materials and Processes*, and by use of electronic media. Headquarters of the ASM (International) is in Materials Park, OH, *http://www.asm-international. org/*.

ASPARAGINE. See **Amino Acids**.

ASPARAGUS. Of the family *Convallariaceae* (lily-of-the-valley family), genus *Asparagus*, the familiar asparagus plant is one of about 125 species in the genus. The plant is native to temperate and tropical regions of the Old World, but widely cultivated in suitable climes throughout the world. Members of the genus are characterized by having the leaves reduced to minute scales or bristles, while small, often very leaflike branches called cladophylls function as leaves. The flowers are small, yellowish or white in color, and the fruit is a berry that is often brightly colored. *Asparagus officinalis*, a native of the marshes of Europe, is the cultivated garden form with thick and fleshy young stems. Other species are widely grown for their delicate beauty, as the familiar Asparagus ferns, *Asparagus plumosus* and *Asparagus sprengeri* (which are not properly ferns at all), and the florist's smilax, *Asparagus asparagoides*. See Fig. 1.

Fig. 1. Bunches of asparagus placed on damp moss in flat to keep them fresh for market. (*USDA photo.*)

ASPARAGUS BEETLE *(Insecta, Coleoptera).* An introduced European beetle, *Crioceris asparagi*, which is sometimes an important pest on asparagus. A related species, also introduced from Europe, is known as the 12-spotted asparagus beetle. They are held in check by handpicking and by dusting plants with lime or other control chemicals.

ASPERA-3 MISSION. See **Discovery Program**.

ASPERGILLOSIS. An infection produced by fungi of the genus *Aspergillus* of which *A. fumigatus* is the main infecting species, with *A. flavus* causing an invasive disease and *A. niger* an intracavity fungus ball of aspergilloma. The group of fungi is of low pathogenicity for humans unless resistance is overcome by an overwhelming inoculum, debilitating illness, or in immunocompromised individuals. There is no predisposition by race, age, or sex to *Aspergillus* infections.

Aspergilli are usually found as saprophytes on decaying vegetation, and pigeon excreta have also been found to harbor the organism. Marijuana also provides a site of growth and aspergillus precipitins have been found in the sera of more than 50% of marijuana smokers. The organisms assume a mycelial form both in culture and infected tissues.

Primary infections of the lung sometimes develop after inhalation of massive numbers of spores from mycelia growing on grain. Secondary pulmonary infection may be superimposed on tuberculous cavities, bronchiectases, and the like. The destructive paranasal granuloma normally caused by *A. flavus* is most often seen in the tropics or in patients who originate from those areas.

Allergic bronchopulmonary aspergillosis is associated with persistent endobronchial growth of the fungus — usually *A. fumigatus*. Symptoms of reversible airway obstruction are seen in early cases which develops into breathlessness and a chronic productive cough as the bronchial damage increases; mycelia of the fungus may be found in the sputum in such cases and x-rays show scattered linear shadows in the peripheral lung fields. Treatment is difficult, particularly in the late cases. Removal of the organism from the airways using antifungal drugs is normally of only temporary benefit. Therapy is therefore aimed at the inflammatory response by use of bronchodilators or corticosteroids.

The development of a fungal ball (aspergilloma) in a preexisting pulmonary cavity frequently presents no symptoms apart from intermittent cough associated with hemoptysis of varying severity. The condition is diagnosed by positive cultures and high titers of specific antibodies. Radiologically an opacity can be demonstrated in a cavity. The most reliable approach is surgical excision.

In severely compromised individuals, *A. fumigatus* or *A. flavus* may invade tissues and this is the most lethal form of the infection. Pulmonary vessels may be invaded, occluded, or even destroyed producing hemorrhage or infarction with rapid extension of the invasion through blood vessels to the brain, heart, kidneys, liver, and spleen. Where biopsy culture and serology confirm this form of the infection, treatment should not be delayed. Intravenous amphetericidin B in full dosage is usually suggested. The mortality of all invasive forms of aspergillosis, even with treatment, is high.

R.C. VICKERY, M.D.; D.Sc.; Ph.D.; Blanton/Dade City, FL

ASPHALT (or Asphaltum). A semisolid mixture of several hydrocarbons, probably formed because of the evaporation of the lighter and more volatile constituents. It is amorphous, of low specific gravity, 1–2, with a black or brownish-black color and pitchy luster. Notable localities for asphaltum are the Island of Trinidad and the Dead Sea region, where Lake Asphaltites were long known to the ancients. See also **Coal Tar and Derivatives**; and **Petroleum**.

Web References

Asphalt Institute, http://www.asphaltinstitute.org

ASPHERIC SURFACE. A surface of a lens or mirror that has been changed slightly from a spherical surface as an aid in reducing aberrations. Parabolic mirrors for telescopes and the Schmidt objective are common aspheric surfaces.

ASPHYXIA. Suffocation, the consequences of interference with the aeration of the blood, usually from interference with respiration, whether by mechanical means or by the inhalation of gases containing insufficient oxygen, although it may result from other causes which would depress the respiratory center or result in a deficiency of hemoglobin in the blood. The effects are cyanosis, increased blood pressure, violent respiratory efforts, ultimately leading to unconsciousness and death if the cause is not removed. The effects are partly due to anoxemia and partly to excess of carbon dioxide in the blood. When the blood supply to a limited portion of the body is temporarily interrupted, the term local asphyxia sometimes is used. See also **Anoxemia**.

ASPIRIN. [CAS: 50-78-2] A drug used for nearly a century to relieve headaches and general aches and pains and to reduce the swelling and pain associated with joints (gout, ague, rheumatoid arthritis). In recent years, attention to aspirin for its apparent role in reducing heart attacks (coronary thrombosis) and strokes has increased. Trial studies also are underway for its use in reducing the risk of fatal colon cancer.

As early as 1763, the Rev. Edward Stone of Chipping-Norton, Oxfordshire (England), reported to the Royal Society that the bark of the willow tree (*Salix alba*) was found to be effective by his local constituents for treating ague. He reported his findings to the Royal Society, creating much interest. Medical historians also report that Hippocrates as well as some North American Indian tribes were aware of the analgesic effects of the bark of certain trees. Ways were sought to prepare what chemists at the time referred to as *salicin* by extracting the active ingredient from the willow bark. To produce very small amounts of salicin required several pounds of bark, causing the price to be quite high. However, with further efforts, the extraction process was improved, lowering the price. Ague and gout occurred widely, and the extract market became quite large — sufficiently

large to interest early European pharmaceutical firms to find a way to synthesize the product. The Germans, who during the mid-1800s excelled in organic chemistry due to their synthesizing important dye chemicals, finally found a way to synthesize salicylic acid. Ironically, however, chemists in France were first to name the product, *l'acide salicylique* (salicylic acid).

It was found that salicylic acid in its pure form had a number of deficiencies, and for a number of years chemists sought a salicylic acid–based compound that would be effective yet less harsh and that could counteract pain with smaller dosages. This process ended in 1898 with the introduction by Bayer of acetylsalicylic acid, which has the formula $C_6H_4(COOH)CO_2CH_3$ and since then has been commonly referred to as *aspirin*.

The market for aspirin grew at a rapid rate, with sales in the United States reaching $2 billion/year in 1990. This represents 1600 tons of the drug, or 80 million tablets. Within recent years, some aspirin has been formulated with other materials. These include buffers for reducing stomach irritation experienced by some people who consume aspirin. Also within the last decade or so, other nonsteroidal anti-inflammatory drugs (NSAIDs) have been introduced into this highly competitive marketplace.

In recent years aspirin has been subjected to some negative publicity. In a minority of the population, aspirin can induce hypersensitivity syndrome. Obviously, persons who exhibit an allergic reaction to the drug are not candidates for it and should turn to other NSAIDs. Needless to say, aspirin must be used with moderation. A most unusual situation was reported by Thibault (1992) in one of the publications listed. A middle-aged man, who had a psychiatric history, complained at an emergency center of nausea, vomiting, shortness of breath, and hallucinatory hearing. It was learned that the patient had consumed four aspirin tablets every 2 to 4 hours for a period of 2 weeks. Obviously, this defines *extreme immoderation* in terms of the drug's use. However, with treatment, the patient's symptoms disappeared within 2 days. Fortunately, such findings of the abuse of aspirin are rare, but the case does emphasize, in perspective, the relative safety of the drug when properly administered.

Probably the most negative situation involving aspirin arose about a decade ago, in connection with the appearance of Reye's syndrome. The biochemistry of this connection has not been fully elucidated, but based upon clinical findings, the general medical community stipulates that aspirin not be used (particularly with young children) where there any symptoms or suspicions that influenza may be present. See also **Reye's Syndrome**. Also, as a result of this incident, aspirin was removed from the World Health Organization's list of essential drugs, representing a decision that was not universally accepted by medical professionals.

Biochemistry of Aspirin: The biochemical paths and actions by which aspirin and other salicylates achieve their therapeutic effects were poorly understood until at least a partial mechanism was proposed by Sir John Vane in 1971. Vane, who later received a Nobel Prize for his efforts (1982), found that NSAIDs, including aspirin, block the production of prostaglandins by cells and tissues. During the same time frame, Vane and other researchers also confirmed the inhibitory effects of aspirin on platelet aggregation, this caused by interference with the ability of platelets to synthesize prostaglandins, notably thromboxane A_2. The complexities of the topic go well beyond the scope of this volume, but are well ventilated in the Vane (1971), the Smith-Willis (1971), and the Weissmann (1991) articles listed. See also **Prostaglandins**.

Much current research relating to aspirin and heart attacks and strokes is going forward, principally in the form of trial study groups, with emphasis on the effects of dosage. The findings of aspirin's advantage in connection with fatal colon cancer are in their early and debatable study phases.

ASSASSIN BUG *(Insecta, Hemiptera)*. Any bug of the large predacious species constituting the family *Reduviidae*. The assassin bug is found in the southern part of the United States and in the West Indies. Throughout the world, it is estimated that there are about 2500 species. Some species pounce upon their prey; other species stick their legs into resin from a tree and hold the sticky limbs aloft, awaiting a likely victim to come along. Some assassin bugs secrete a fluid that other insects find attractive, but the fluid has an intoxicating effect on likely victims, thus making them easy prey. An oily hair on the legs of the assassin bug helps in holding prey. The thorax of the assassin bug also produces a poisonous venom which, when injected into prey, assists in reducing the tissues of the victim to a thick juice ready for convenient consumption and assimilation.

ASSEMBLER (Computer System). A computer program which operates on symbolic input data to produce machine instructions by carrying out such functions as (1) translation of symbolic operation codes into computer instructions, (2) assigning locations in storage for successive instructions, or (3) assignment of absolute addresses for symbolic addresses. An assembler generally translates input symbolic codes into machine instructions item for item, and produces as output the same number of instructions or constants defined in the input symbolic codes.

Assembler language may be defined as computer language characterized by a one-to-one relationship between the statements written by the programmer and the actual machine instructions performed. The programmer thus has direct control over the efficiency and speed of the program. Usually, the language allows the use of mnemonic names instead of numerical values for the operation codes of the instructions and similarly allows the user to assign symbolic names to the locations of the instructions and data. For the first feature, the assembler contains a table of the permissible mnemonic names and their numerical equivalents. For the second feature, the assembler builds such a table on a first pass through the program statements. Then, the table is used to replace the symbolic names by their numerical values on a second pass through the program. Usually, some dummy operation codes (or pseudocodes) are needed by the assembler to pass control information to it. As an example, an origin statement is usually required as the first statement in the program. This gives the numerical value of the desired location of the first instruction or piece of data so that the assembler can, by counting the instructions and data, assign numerical values for their symbolic names.

The format of the program statements is usually rigidly specified and only one statement per input record to the assembler is permitted. A representative statement is: symbolic name, operation code (or pseudocode), modifiers and/or register addresses, symbolic name of data. The mnemonic names used for the operation codes usually are defined uniquely for a particular computer type with little standardization between computer manufacturers even for the most common operations. The programmer must learn a new language for each new machine with which he works.

An example of a program prepared in an assembler language is given Fig. 1. The explanatory comments following the REM (remarks) mnemonic and those to the right of the other program statements are ignored by the assembler program and thus do not affect execution of the program. Fig. 1. Assembler program.

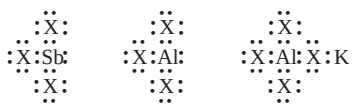
reversible. Association is characterized by reversibility or ease of disassociation, low energy of formation (usually about 5 and not more than 10 kcal per mole), and the coordinate covalent bond which Lewis called the acid-base bond. Association takes place between like and unlike species. The most common type of this phenomenon is hydrogen bonding. Association of like species is demonstrable by one or more of the several molecular weight methods. Association between unlike species is demonstrable by deviation of the system from Raoult's law.

The strength of the coordinate covalent bond is a function of polarity of the associating molecules. Hence, associated molecules vary in stability from very unstable to very stable. The argon-boron trifluoride complex is quite unstable, whereas calcium sulfate dihydrate (gypsum) is very stable. The bond strength associated with stability has been measured for a number of combinations. The strengths of some hydrogen bond types decrease in the order FHF, OHO, OHN, NHN, CHO, but they are dependent upon the geometry of the combination and upon the acid-base characteristics of the group. Steric effects can have a marked effect on the strength of the coordinate covalent bond. This was demonstrated by a study of the strength of the series NH_3, $C_2H_5NH_2$, $(C_2H_5)_2NH$, $(C_2H_5)_3N$ as bases toward an acid in solution and in the gaseous state and the comparison of the base strength of triethylamine and quinuclidine. The latter is, in effect, triethylamine in which the two-carbon atoms of each ethyl group are tied together by another carbon. The geometry of the ethyls around the nitrogen is drastically changed, and the cyclic is a stronger base than the triethyl compound. The factors affecting the strength of the hydrogen bond also influence the degree of association.

Association within the same species accounts for the high boiling points of water, ammonia, hydrogen fluoride, alcohols, amines, and amides. Ethyl ether and butanol contain the same number of atoms of each element, but butanol has a boiling point of 83 °C above that of ethyl ether as a result of more extensive hydrogen bonding. Some substances associate completely to two or more formula weights per molecule. Carboxylic acid, by a hydrogen-to-oxygen association, form dimers with a six-membered ring. N-unsaturated amides dimerize in the same manner, whereas N-substituted amides dimerize in a chain form in a *trans* configuration.

Hydrogen bonding is so common that coordinate bonds between other elements are sometimes overlooked. Antimony(III) halides form very few complexes with other halides, whereas aluminum halides readily form complexes. The octet of electrons is complete in all atoms of the antimony halides, but is incomplete in the aluminum atom of aluminum halides:



(**a**) (**b**) (**c**)

Aluminum can accept two electrons to complete its octet. The pair of electrons is available from the halogen. An alkali halide can supply the electrons and form a complex (c), or the electron pair may come from the halogen of another aluminum chloride. Association with other aluminum halides accounts for the higher melting point of aluminum halides over antimony(III) halides which have a formula weight of 95 or more. The association of aluminum sulfate, alkali metal sulfate, and water to form the stable alums is one of the more complex examples.

The formation of solvates is association between unlike species. Solvation is more frequent between substances of high polarity than those of low polarity. This is illustrated by the decrease in the tendency to form solvates with decrease in dipole moment and dielectric constant (shown in parentheses) for N-methylacetamide (3.59; 172), to water (1.84; 78.4), to ethanol (1.70; 24.6); to ammonia (1.48; 78.4); to ethanol (1.70; 24.6); to ammonia (1.48; 17.8); to methylcyclohexane (0; 2.02) for which few associations are known.

J. A. RIDDICK, Baton Rouge, Louisiana

ASSOCIATION (Coefficient of). In statistical theory, this word is used (a) in a general sense, to denote the degree of dependence between two variables; and (b) especially to denote the relationship between two variables that are simply dichotomized. For example, if a set of n numbers is classified as A or not $-A$, and as B or not $-B$, an association table is of the following kind:

	A	NOT$-A$	TOTALS
B	a	b	$a+b$
not$-B$	c	d	$c+d$
Totals	$a+c$	$b+d$	$a+b+c+d=n$

A coefficient of association Q is defined by

$$Q = \frac{ad - bc}{ad + bc}$$

It can vary from -1 to $+1$ according to the strength of the association. Other coefficients are sometimes used.

SIR MAURICE KENDALL, International Statistical Institute, London

ASSOCIATION (Ecology). Central to certain concepts of ecology is the interaction between various otherwise unrelated species in a way that is beneficial to the participating parties, but not always indispensable. Ants and plant lice are sometimes associated in this way. The plant lice are guarded by the ants and sometimes carried to a good food supply whereupon the ants receive the sweet honey dew secreted by their charges. So-called cleaner fishes play useful roles in removing barnacles and other deposits from larger fishes, and, in recognition for these services, are not eaten by the larger fishes. This type of association is also sometimes termed *commensalism.*

Plants. It is well established that plants are not distributed in nature in a haphazard fashion, but in habitats in which when certain species are present certain others usually occur also. Each such community of plants, composed of more or less the same group of species, is called a plant association. Some plant associations, such for example as the marginal rush or cattail association around a pond, may occupy only localized areas. Other associations, such as some of the grassland or desert shrub associations of western North America may occupy vast continuous areas. In general, however, plant associations are the smaller units of vegetation occurring within a plant formation (see below) and their distribution is largely controlled by local soil and climatic conditions. Local differences in climate, in turn, are largely a function of topography. Some plant associations, such as a lichen association on a rock cliff, are relatively simple in organization. Others are relatively complex. The oak-hickory association of the eastern United States, for example, is named for the two prominent genera of trees present. Associated with the oaks and hickories, however, are occasional other large trees. In addition there are usually present smaller kinds of trees, species that constitute a shrub layer, and herbaceous species which constitute a more or less continuous ground cover.

A larger unit of vegetation than the association is the formation. A *plant formation* usually occupies very large regions and its limits are controlled primarily by climatic conditions. Some of the major plant formations of North America are the tundra, the boreal forest, the hemlock-hardwood forest, the deciduous forest, the grasslands, the western coastal forest, the western mountain forest, the semi-deserts, and the tropical forests. Within each formation there are usually many different plant associations. Most plant associations are not permanent, but in the phenomenon of plant succession one association gradually replaces another. Many successions are in progress in any plant formation. The end result of the successive replacement of one plant association in turn by another is, if the process goes to completion, the establishment of a *climax association*. Such an association is a stable plant community and is not succeeded by any other association; it is the apex of the process and, barring changes of climate, will continue to reproduce itself indefinitely.

Animals. While most animals are solitary, associating with others of their kind only incidentally or during the breeding season, others normally live in some relationship with members of the same or of other species.

The simplest association of members of the same species is gregariousness. Gregarious animals are not bound by the association, but profit by it. Examples are the great herds of herbivorous animals such as the bison and the packs of predacious animals, such as wolves.

Colonial association may be accompanied by structural union between individuals, as in many marine polyps, or may be based on behavior, as in the social insects. The term merges with social organization. This type of association is accompanied by structural specialization of individuals for special tasks, except in human society where it depends on specialized training.

The association of individuals of different species may be the relatively loose type called commensalism in which both forms benefit but not in an essential way, or the indispensable symbiosis in which neither organism can persist without the other. An excellent example of symbiosis is the relation of termites with the protozoa found in their intestine; neither can live without the other.

An association in which one individual lives at the expense of the other is called parasitism.

Slavery is an association practiced by some of the social insects and, at one time, by people; among the insects the slaves are of a different species.

Such relations as symbiosis and parasitism also occur among plants, where they are exemplified by the combining of algae and fungi to form lichens and by the mistletoe, which is parasitic on trees. Symbiotic relations between animals and plants also occur.

ASTATIC. A term that means: "without orientation or directional characteristics".

ASTATINE. [CAS: 7440-68-8] Chemical element, symbol At, at. no. 85, at. wt. 210 (mass number of the most stable isotope), periodic table group 17, classed in the periodic system as a halogen, mp 302 °C, bp 337 °C. All isotopes are radioactive. This element occurs in nature only in minute amounts, as a result of minor branching in the naturally occurring alpha decay series: ^{218}At($t_{1/2}$ = ca. 2 sec); it is produced to the extent of 0.03% by the beta decay of ^{218}Po(radium A), 99.97% going by alpha decay to ^{214}Pb(RaB); ^{216}At($t_{1/2} = 3 \times 10^{-4}$sec.) and 0.013% by beta decay from ^{216}Po(thorium A);

$$^{215}\text{At}(t_{1/2} = 0.018 \text{ sec.})$$

0.0005% by beta decay from ^{215}Po (actinium A). Astatine-217 ($t_{1/2}$ = 0.020 sec.) is a principal member of the neptunium ($4n + 1$) series, all members of which occur only to that extent to which the parent ^{237}Np is produced by naturally occurring slow neutrons from uranium.

The first isotope to be discovered was ^{211}At made by Carson, Mackenzie, and Segrè by bombardment of a bismuth target with α-particles from the 60-inch cyclotron at Berkeley in 1940. The reaction is ^{209}Bi(α, $2n$)^{211}At. The half-life of ^{211}At is 7.2 hr. It decays in two modes, 60% by K-electron capture and 40% by α-particle emission. The longest-lived isotope is ^{210}At($t_{1/2}$ = 8.3 hr.); other isotopes having half-lives longer than 1 hr are 206, 207, 208, and 209. Some of the collateral radioactive series involving bombardment reactions contain other astatine isotopes, such as ^{214}At and ^{216}At. All these isotopes have half-lives that are only fractions of a second. The total number of isotopes is at least nineteen, including spallation reaction products as well as bombardment ones. They also include two short-lived isotopes, ^{215}At and ^{218}At, occurring in very small amounts in the branched β-disintegration of ^{215}Po(actinium A) and ^{218}Po(radium A), respectively, as noted above.

The chemistry of astatine determined by tracer techniques, is in keeping with the regular transition of properties of the halogens. The acid properties of astatine are less marked than are those of iodine, while its electropositive character is more marked than that of iodine. After reduction by SO_2 or metallic zinc, the astatine activity is carried by silver iodide or thallium iodide, so it evidently forms insoluble silver and thallium salts. This represents astatine in the univalent negative state characteristic of the halogens. However, astatine is very readily oxidized by bromine and ferric ions, giving indications of two higher oxidation states. Although there is no evidence from migration experiments of the presence of positive ions in the solution, astatine deposits on the cathode, as well as on the anode, in the electrolysis of oxidized solutions. Elemental astatine can be volatilized, although not so readily as iodine, and it has a specific affinity for metallic silver. The similarity to iodine is also shown by the observation that astatine concentrates in the thyroid glands of animals.

A-STATION. In loran, the designation applied to the transmitting station of a pair, the signal of which always occurs less than half a repetition period after the next preceding signal and more than half a repetition period before the next succeeding signal of the other station of the pair, designated a *B-station*.

ASTERISM. One of the characteristic effects sometimes observed in x-ray spectrograms. It has, roughly, the shape of a star, and commonly indicates the presence of internal stress in the material under investigation.

ASTEROIDEA. A class of the phylum *Echinodermata*. The starfishes.

The starfishes are distinguished from other echinoderms by the presence of radiating arms or rays, usually five or in multiples of five, which contain part of the internal organs and are usually not sharply separated from the central disk. See Fig. 1. There are many species but the economic importance of the group is limited. They are sometimes serious pests in oyster beds since they feed largely on shellfish.

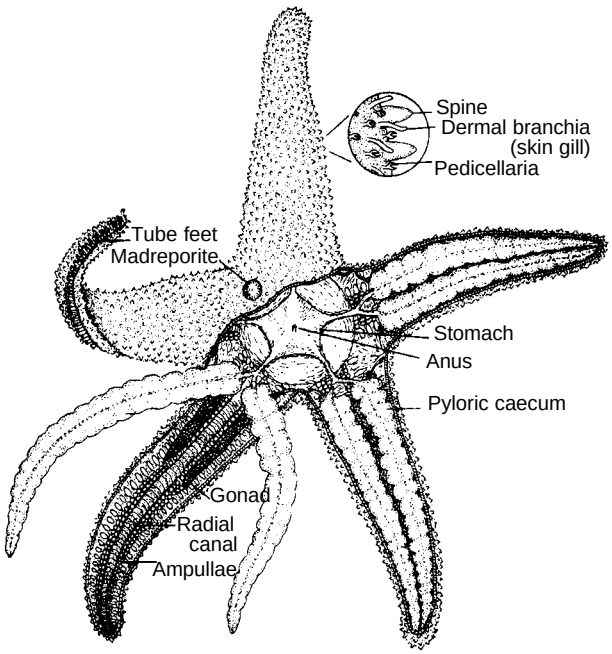

Fig. 1. Common starfish. (*Winchester and Lovell, "Zoology," Van Nostrand Reinhold.*)

The class is divided into three orders: *Phanerozonia*, *Spinulosa*, and *Forcipulata*; in addition two orders — *Platyasterida* and *Hemizonida* — contain extinct asteroids.

ASTEROID (Mathematics). A higher plane curve, which is a special case of a hypocycloid. The curve is generated by a point on the circumference of a circle of radius r, which rolls around the inside of a fixed circle of radius $R = 4r$. Its parametric equations are $x = R\cos^3\phi$, $y = R\sin^3\phi$, and its equation in Cartesian coordinates is

$$x^{2/3} + y^{2/3} = R^{2/3}$$

The curve is symmetric to both coordinate axes. There are cusps of the first kind at the four points $(\pm R, O)$, $(O, \pm R)$, where the corresponding tangents are the X- and Y-axes. The evolute of an ellipse, which has the equation $(rx)^{2/3} + (Ry)^{2/3} = (r^2 - R^2)^{2/3}$ and the same general shape with four cusps, is sometimes also called an asteroid. The spelling astroid is often given. See Fig. 1.

See also **Evolute**; and **Hypocycloid**.

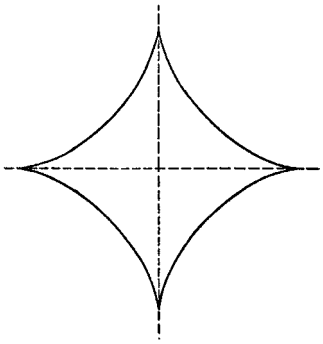

Fig. 1. Asteroid.

ASTEROIDS. Asteroids are small members of the solar system in heliocentric orbits concentrated between Jupiter and Mars. Since most of them have orbits that are roughly similar to those of the planets (low inclination and eccentricity), they have sometimes been called minor planets. More important is the distinction between asteroids and comets, where the primary difference is one of composition. Asteroids are metallic rocky bodies without atmospheres that orbit the Sun, and composed of the same sorts of materials as the inner planets. Comets, in contrast, contain a substantial quantity of water ice and other frozen volatiles in addition to silicates and organic compounds. However, there are ambiguities in terminology. Comets that make frequent passes around the Sun may lose their volatiles and become indistinguishable from rocky asteroids. In addition, there are many volatile-rich objects being discovered in the outer solar system (beyond Neptune) that resist classification as either asteroids or comets. These are the Kuiper Belt Objects (KBOs).

During the 19th century and much of the 20th century, asteroids were considered to be made up of the debris that resulted from the shattering of one or more ancient planets, giving rise to the term *minor planets*. This earlier theory, however, did not postulate what may have caused one or more ancient planets to shatter. The most recent and widely accepted theory considers the asteroids to be remnants of early planetary material that failed to coalesce into a planetary body. The newer theory presents a major difference in the perspective of asteroid scholars.

The first few asteroids to be discovered (1801–1807) were considered to be minor planets. These are the larger of the asteroids known today — *Ceres*, *Pallas*, *Juno*, and *Vesta*. Today, the asteroid population is estimated in the millions, ranging widely in mass and dimension. Even then, collisions among asteroids of any appreciable size are rare because of the immense emptiness that exists between planets of the solar system.

Search for the "Missing Mass": As early as 1766, Titius, a German astronomer, studied the relative spacing of the planets and from his calculations observed a "missing planet" that should be found between the orbits of Mars and Jupiter. This inspired European astronomers to search for the missing planet, and, as previously mentioned, Ceres, Pallas, Juno, and Vesta were observed by 1807.

Also regarded as minor planets by Herschel, he suggested that they be given a special group name, *asteroids*, from the Greek "starlike," because they appeared through the telescope more like distant stars than distant planets, such as Uranus, which had been discovered by Herschel in that time period.

Early Discoveries of Asteroids

Asteroids are too faint to be visible to the unaided eye, so their discovery belongs to the era of telescopic astronomy. On New Year's Day in 1801, Giuseppe Piazzi at Palermo Observatory found the first asteroid, which he named Ceres for the Roman patron goddess of Sicily. This faint object (now known as the largest asteroid) orbited the Sun at a distance of 2.8 astronomical units (AU); strong support was given by it to Bode's relation. See also **Bode's Relation**. It was at first hailed as the "missing planet" in the large gap between the orbits of Mars and Jupiter. In the following few years, three more asteroids — Pallas, Juno, and Vesta — were found, also orbiting between Mars and Jupiter. These were even smaller than Ceres, although Vesta is slightly brighter due to its more reflective surface. Even combined, the masses of these four objects came nowhere near that of a real planet. Most of the asteroids are located in what is defined as the main asteroid belt, at distances from the Sun are between 2.2 and 3.3 AU, corresponding to orbital periods between 3.3 and 6.0 years.

Continuing Discoveries

The next asteroid was not discovered until 1845, but from then on, they were found regularly by visual observers who scanned the sky looking for them. By 1890, the total number had risen to 300. See Table 1. for a listing of the dozen largest Asteroids by year of discovery. At that time, photographic patrols began, and the number of known objects rapidly increased and reached 1000 in 1923, 3000 in 1984, 5000 in 1990, and 20,000 in 2001. To be entered on the official list of asteroids, an object must be well enough observed to establish its orbit and permit its motion to be accurately calculated many years into the future. The responsibility for cataloging asteroids and approving new discoveries is assigned to the International Astronomical Union Minor Planet Center in Cambridge, Massachusetts. It is an interesting indication of growing interest that 198 years were required to find the first 10,000, but only two years were needed

TABLE 1. THE LARGEST ASTEROIDS

Name	Year of discovery	Class
Ceres	1801	C
Pallas	1802	C
Vesta	1807	V
Hygeia	1849	C
Ineramnia	1910	C
Davida	1903	C
Cybele	1861	C
Europa	1868	C
Sylvia	1866	C
Juno	1804	S
Psyche	1852	M
Patientia	1899	C

to find the second 10,000. Most recent discoveries are a by-product of the Spaceguard Survey, a concerted search for near-Earth Asteroids (NEAs).

Designating Asteroids

When an asteroid is first discovered, it is designated first by the year of discovery, then by two letters that indicate the half of the month in which the object was found, and last by the chronological order of discoveries within that half-month. After the orbit of the object has been determined, and if it proves to be a new asteroid, it is assigned a permanent number, in chronological order of discovery, and the discoverer is privileged to name the object as he may choose. In addition to numerical designations (e.g., 4 Vesta, 1000 Piazzia), which are given in chronological order of determination of an adequate orbit, most asteroids have names, usually suggested by the discoverer. Initially, these were the names of Greek and Roman goddesses, such as Ceres and Vesta, and later expanded to include female names of any kind. When masculine names were applied, they were given the feminine Latin ending. More recently, the requirement of female gender has been dropped, and today asteroids are named for a bewildering variety of persons and places, famous or obscure.

Physical Characteristics of Asteroids. In the Table 2 are summarized key physical parameters of the larger and better-known asteroids. It is well known that the reflected sunlight from many of these objects varies in a periodic manner that can be explained adequately only on the basis of rotation of the object. In the case of Eunomia, it has been shown definitely that the object must be close to spherical and that the variation in light is due to different reflecting powers of different parts of the surface. On the other hand, Eros has been shown to have a brick-like shape, with the light variations due to rotation of this irregular object. Several techniques in recent years have contributed to improved asteroid imagery, including radar observations. In terms of estimating total size of an asteroid, thermal (infrared) methods are used. On the average it appears that surface temperatures of asteroids are approximately 200 kelvins. This, of course, varies with the albedo of the object and its diameter and distance from the sun. An interesting laboratory technique that can be used to model asteroid shapes is described by Binzel, et al. 1989. This system creates synthetic light curves for varying object shapes.

TABLE 2. REPRESENTATIVE ASTEROIDS

Asteroid	Diam. (km)	Mass (10^{15}g)	Period (d)	a(A.U.)	e	i(deg.)
Ceres	940	60×10^7	1681	2.767	.08	10.6
Pallas	540	18×10^7	1684	2.767	.24	34.8
Juno	265	2×10^7	1594	2.670	.26	13.0
Vesta	510	10×10^7	1325	2.361	.09	7.1
Hebe	220	20×10^6	1380	2.426	.20	14.8
Iris	200	15×10^6	1344	2.385	.23	5.5
Hygiea	410	60×10^6	2042	3.151	.10	3.8
Eunomia	280	40×10^6	1569	2.645	.18	11.8
Psyche	265	40×10^6	1826	2.923	.14	3.1
Nemausa	80	9×10^5	1330	2.366	.06	9.9
Eros	14	5×10^3	642	1.458	.22	10.8
Davida	310	3×10^7	2072	3.182	.18	15.7
Icarus	1.4	5	408	1.077	.83	23.0
Geographos	3	50	507	1.244	.34	13.3

Note: In the main asteroid belt between Mars and Jupiter, there are approximately 1000 asteroids that are larger than 30 km in their longest direction. Of these, about 200 are larger than 100 km across. Researchers estimate from calculations, that there must be a million or more asteroids having a longest direction of 1 + km. With numerous asteroids, the term *diameter* is inappropriate because of their odd, nonspherical shape. All of the values for mass and many of the diameter values are only rough estimates.

Asteroid Locations (Belts)

The greater number of asteroids observed and cataloged lie in what is commonly called the "main belt," located between Mars and Jupiter.

The orbits of asteroids have been studied carefully ever since the discovery of Ceres. See Fig. 1.

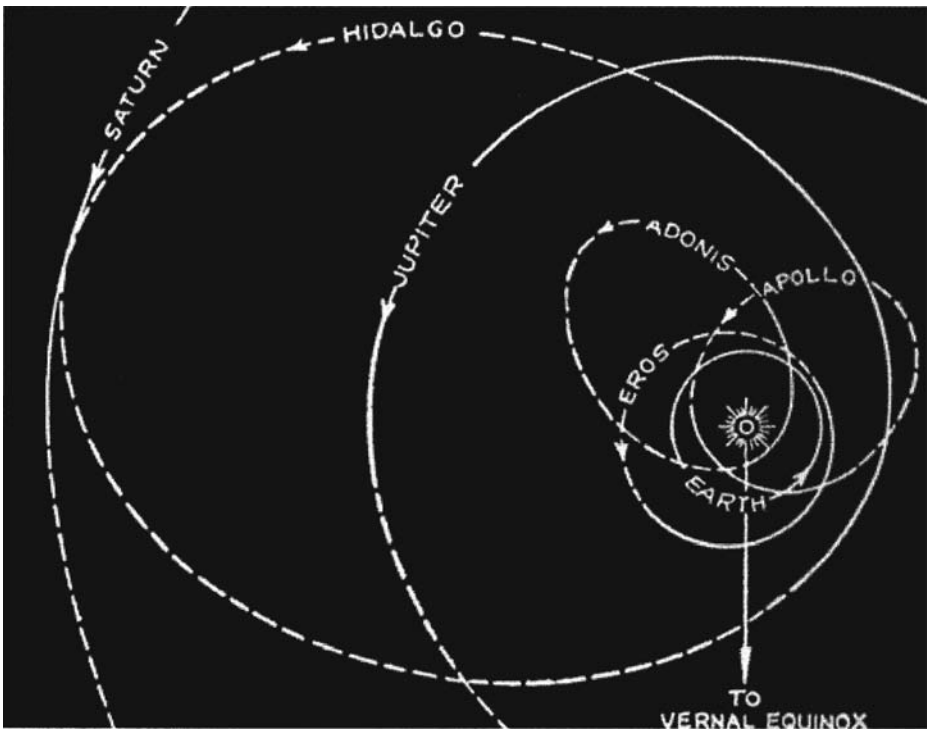

Fig. 1. Orbits of four unusual asteroids. Broken lines represent parts of the orbits south of the plane of the ecliptic.

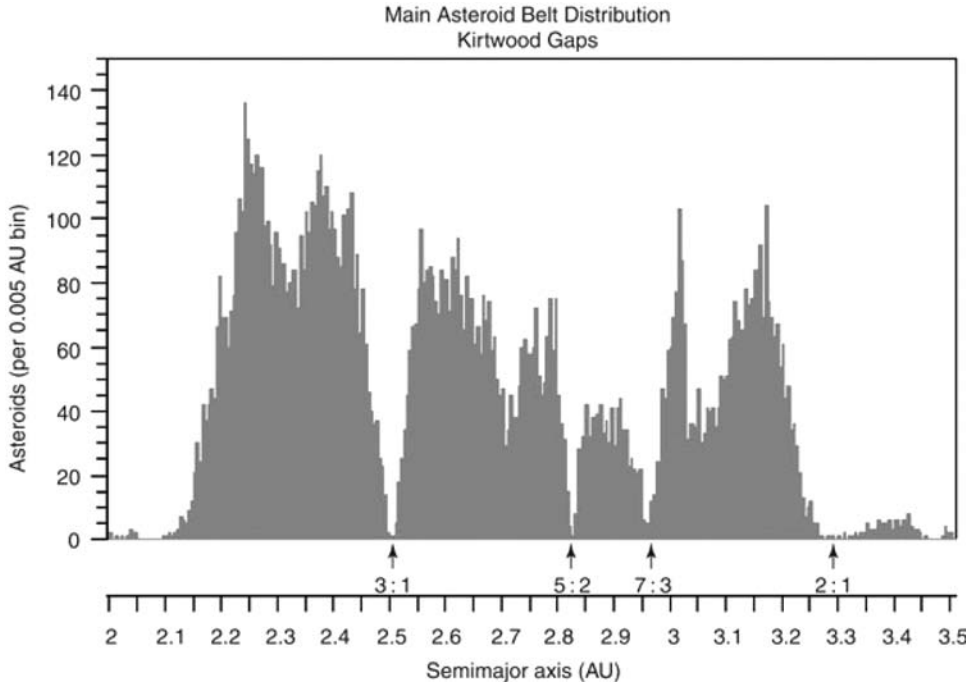

Fig. 2. Histogram of orbital periods of the known asteroids. The deep minima are the Kirkwood gaps that correspond to periods that are in resonance with Jupiter (courtesy of Jet Propulsion Laboratory (JPL) and NASA)

The orbits of the belt asteroids are for the most part stable, their eccentricities are less than 0.3, and inclinations are below 20°. In the past, when presumably there were more asteroids, collisions may have been common, but by now the population has thinned to the point where each individual asteroid can expect to survive for billions of years between collisions. Still, with 100,000 objects 1 kilometer or more in size, a major collision somewhere in the belt is expected every few tens of thousands of years. Such collisions, as well as lesser cratering events, presumably yield some of the fragments that develop Earth-crossing orbits and eventually reach Earth as meteorites. In contrast, Earth-approaching NEAs have unstable orbits and typical dynamic lifetimes of only about 100 million years. Their numbers represent an equilibrium between inward scattering from the main belt and elimination either by colliding with the terrestrial planets or the Sun or by gravitational ejection from the solar system.

Given their history of collisions, there is no reason to expect that most asteroids are monoliths. Many may be rubble piles, consisting of loosely bound, low-density accumulations of debris that has reaccreted after a catastrophic disruption. In general, the energy required to disperse such debris completely is substantially greater than the energy needed to break up a target. One line of evidence for the existence of rubble piles comes from the highly elongated shapes of some small, rapidly spinning asteroids. These shapes are nearly what one might expect for an equipotential fluid and suggest such a reaccretion process. However, conclusive evidence of rubble piles awaited the first close-up spacecraft investigations, as recounted later.

The orbits of asteroids within the main belt are not evenly distributed. As shown in Fig. 2, some orbital periods are preferred, and others are nearly unpopulated. These unpopulated sections of the belt are resonance gaps, also known as the Kirkwood gaps for the nineteenth-century astronomer who discovered them. These gaps occur at orbital periods that correspond to resonances between these periods and the orbital period of Jupiter. Resonance takes place when the orbital period of one body is an exact fraction of the period of another. In this case, the underpopulated asteroid orbits correspond to periods that are one-half, one-third, one-quarter, etc., that of the 12-year orbital period of Jupiter. The Kirkwood gaps provide a clue to the origin of the asteroids or rather to the absence of a single large planet in the region between Mars and Jupiter. Presumably the dominant gravitational presence of Jupiter interrupted the accretionary process and dispersed the planetesimals in this part of the solar system. Most of the material ended up striking the inner planets or was ejected from the system, and only a small remnant remains in the asteroid belt today.

Asteroidal orbits display other patterns in addition to the resonance gaps. An asteroidal family is defined as a group of objects that have similar orbits that suggest a common origin. These were first identified by Kiyotsuga Hirayama early in the twentieth century. About half of the known belt asteroids are members of families, nearly 10% belong to just three: the Koronos, Eos, and Themis families. Although not clustered together in space at present, the members of an asteroid family were all at the same place at some undetermined time in the past. Members of the same family tend to have similar reflectivities and spectra. Apparently, the family members are fragments of broken asteroids, shattered in some ancient collision, and still follow similar orbital paths. According to some estimates, almost all asteroids smaller than about 200 km (124 miles) in diameter were probably disrupted in earlier times, when the population of asteroids was larger. The families we see today may be remnants of the most recent of these interasteroidal collisions.

Amor Asteroids. A group of asteroids with orbits that cross the orbit of Mars (as projected on the ecliptic plane), but do not cross the orbit of the earth. Typical Amor orbits reach from the asteroid belt to a point between the earth and Mars. The group is named after the prototype asteroid, Amor.

Apollo Asteroids. A group of asteroids with orbits that cross the orbit of the earth (as projected on the ecliptic plane). Collisions with the earth are possible and apparently have occurred as described later, but these asteroids generally cross above or below the ecliptic plane, thus minimizing the possibilities of collisions. A substantial number of Apollo asteroids have been observed and their orbits have been calculated. In other instances, some have been discovered and ultimately "lost." Instrumental evidence suggests that they are rocky bodies, generally a few kilometers across. It is believed that most meteorites may be fragments broken off from them.

Trojan Asteroids. A particularly interesting group of dark, distant asteroids is orbitally associated with Jupiter. Although the gravitational attraction of this giant planet generally makes nearby asteroidal orbits unstable, exceptions exist for objects of the same orbital period as Jupiter, while leading or trailing it by 60°. These two stable regions are called the leading and trailing Lagrangian points, named for the mathematician who demonstrated their existence in 1772. While he was mathematically examining the possible motions of three mutually gravitating bodies, Lagrange found two regions where a small object could occupy a stable orbit within the gravitational fields of two larger objects. If the larger objects are Jupiter and the Sun, a small object in one of the Lagrangian points occupies one corner of an equilateral triangle, and the Sun and Jupiter are at the other two points.

The regions of stability around the two Lagrangian points are quite large: each contains several hundred known asteroids. The first of these Lagrangian asteroids was named Hektor when it was discovered in 1907.

All of them are named for the heroes of the *Iliad* who fought in the Trojan War, and collectively they are known as the Trojan asteroids. Their spectra are distinctive, suggesting that they represent a group of special, primitive objects that have been trapped in this region of space since the birth of Jupiter. If we could detect the fainter members of these Trojan clouds, we might find that the Trojan asteroids are nearly as numerous as those in the main asteroid belt.

Material Composition of Asteroids

Spectroscopic measurements yield information on the chemical composition of asteroids. There are several letter-designated classes in terms of materials. This taxonomic system, developed in 1984, has since been refined by astronomers at the University of Hawaii. The system does not commence with S or proceed alphabetically in a logical manner, but rather letters were assigned in order of their observed relative abundance, and thus it is confusing to the uninitiated. To achieve some simplification, asteroids currently are grouped into classes by composition, namely, the *primitive* asteroids, which include types C, D, and P; the igneous asteroids, which encompass the S, M, and E types; and the *metamorphic* asteroids, which contain the F, G, B, and T types.

Primitive asteroids are found in the outlying portions of the main belt. Theoretically, it is suggested that the primordial process that produced them was one of such large temperature gradient that the composition of the asteroids essentially was altered at the time of their origin. Being farthest from the sun, these asteroids are assumed to be rich in carbon and water. Today, they are considered to be representative of the material left over from when the solar system was formed.

Igneous asteroids are found closest to the sun and must have endured severe heating. It is assumed that they formed complex mineral mixtures during melting and solidification. Some researchers suggest that radioactive heating may have been involved. The lack of similarity of materials composing the asteroids also has been attributed by some researchers as "space weathering."

Metamorphic asteroids are found in the central region of the belt. The composition similarities between asteroids and meteorites is mentioned briefly under **Meteorides and Meteorites**.

Similarity with Comets

When observed at great distances, comets have been mistakenly identified as asteroids and vice versa. This proved to be the case of *Chiron*, at first considered an asteroid after its discovery in 1987. *Chiron* was found to have unusual characteristics, including its distant orbit between Saturn and Uranus. Observers now generally agree that *Chiron* is a comet, with the requisite properties required of a comet.

Hirayma Asteroid Families usually are classified as C, S, and M types. They have similar orbits and are suspected to be fragments from collisions between pairs of asteroids. They were observed early in the 20th century (by Hirayama, 1918–1929). The use of reflection spectroscopy, polarimetry, and thermal radiometry have provided information on the composition of these minor planetary bodies, suggesting new insights as to the importance of the Hirayama bodies. If these asteroids are the result of collisions, then the members of a single family should show identical composition, assuming that the parent body was homogeneous. But, on the other hand, if the dynamical families were formed by the collisional focusing of unrelated field asteroids, then one would expect to find only the pattern of compositions that is characteristic of that region of the asteroid belt. A technique known as UBV photometery (U-B ultraviolet-minus-blue and the B-V blue-minus-visual) has shown that the colors of minor planets indicate compositions quite distinct from those of the field population in each of the three Hirayama families. Researchers have observed that the Eos and Koronis families apparently originated from the collisonal fragmentation of undifferentiated silicate bodies and the Nysa group from a geochemically differentiated parent body. Considerable research remains to further refine the postulations concerning the origin of the Hirayama families.

Physical and Chemical Properties

As seen through a telescope without special image compensation (adaptive optics), an individual asteroid is an unresolved starlike point. The word asteroid means starlike. Before about 1970, almost nothing was known about the physical nature of asteroids, and research was confined to discovering and charting orbits and determining rotational rates from observations of periodic variations in brightness. In the past 30 years, however, new observing techniques used with large telescopes have revealed a great deal about the physical and chemical nature of the asteroids. These astronomical observations have been supplemented by key studies of meteorites and by close-up spacecraft observations of a few asteroids, including Gaspra, Ida, Mathilde, and Eros — the latter involved both orbital and landed investigations.

Asteroid sizes and shapes are determined directly from imaging with modern adaptive optics or from the Hubble Space Telescope (although the resolution, even with the largest telescopes, leaves much to be desired). See also **Hubble Space Telescope**. High-precision radar imaging is also a powerful tool if the object comes sufficiently close to Earth. Size can also be measured by timing the passage of an asteroid in front of a star. Because we know exactly how fast the asteroid is moving against the stellar background, measuring how long the star is obscured yields a chord length for the asteroid that can be accurate to a few kilometers. If timings of the same event made from different locations on Earth are combined, the profile of the asteroid can be derived. Unfortunately, however, suitable events are rare, and only a dozen asteroids have been measured successfully by this method.

Most asteroid sizes have been estimated indirectly from their visible or infrared brightness. Given only the apparent visible-light brightness of the object, we can roughly estimate its size by assuming a reflectivity or albedo that is characteristic of average asteroids. Such diameters are typically uncertain by a factor of 2, implying an order-of-magnitude uncertainty in mass. Much more accurate are reflectivities determined by combining visible-band measurement of reflected light with infrared-band measurement of emitted heat radiation. Such diameters are good to 10% or better, and they require no arbitrary assumptions about reflectivity.

It is clear that the asteroids have a variety of surface compositions, as discussed further later. This variety leads to a wide range of surface reflectivity. The majority of the asteroids are very dark, roughly the brightness of charcoal. Other types can have reflectance as high as white terrestrial rocks. To make sense of this diversity of material, one must add information on the spectral reflectance of the asteroids. It is particularly useful to compare the asteroids with extraterrestrial samples that reach Earth as meteorites. A few meteorites come from the Moon or Mars, but the great majority of them are fragments from asteroids. Unfortunately, the chaotic dynamic processes that deliver meteorites to our planet do not include traceable return addresses. One of the major challenges of meteoritics is to connect the samples we have to their parent bodies (or class of parent bodies) among the asteroids.

The use of spectral data to characterize asteroids has yielded preliminary determinations of composition for approximately 1500 objects. These include a few asteroids that have metallic surfaces, presumably representing the surviving cores of objects that melted, differentiated chemically, and subsequently lost their stony crusts and mantles. Most, however, have rocky surfaces, that compare to the majority of meteorites, which are also rocky. Exact identifications are difficult, however, and usually we cannot specify the unique properties that identify an individual. With some notable exceptions, contemporary asteroid research, therefore, tends toward broad statistical studies rather than detailed investigation of particular objects. The exceptions are the handful of asteroids that have been visited by spacecraft or imaged at close range by radar, to be discussed further later.

Most of the well-observed asteroids fall into one of two classes based on their reflectivity. They are either very dark (reflecting only 3–5% of incident sunlight) or moderately bright (15–25% reflectivity). A similar distinction exists in their spectra. The dark asteroids are fairly neutral reflectors and do not have major absorption bands in the visible range to reveal their compositions, although some of them show spectral evidence of chemically bound water in the infrared. Most of the lighter asteroids are reddish and have the spectral signatures of common silicate minerals such as olivine and pyroxene. The dark gray asteroids have spectra similar to the carbonaceous meteorites, so they are called C-type asteroids. The lighter class is named the S-type, indicating silicate or stony composition. A third major group appears to be metallic (like the iron meteorites) and is called the M-type. There is also a variety of subclasses based on spectra and reflectivity, especially among the dark C-type objects. It is also increasingly clear that some process of "space weathering" alters the optical properties of surface materials; it partially masks identification with specific meteorite types on Earth and blurs the distinctions that might otherwise be seen among asteroids of different subgroups.

Using the classification of the asteroids, we can look at the distribution in space of the broad C, S, and M types. At the inner edge of the belt, the S asteroids predominate. Moving outward, the fraction of C-type objects increases steadily, and in the main asteroid belt as a whole, the dark, carbonaceous objects make up 75% of the population, compared to 15% S and 10% of M and other types.

Beyond the main belt, all asteroids are very dark, but their colors are redder than the belt objects, and they do not look like any known carbonaceous meteorite. Because these objects are not represented in our meteorite collections, scientists hesitate to commit themselves concerning their composition. It is generally thought, however, that they are primitive objects and that a fragment from one of them would be classed as a carbonaceous meteorite, although of a kind different from those already encountered.

If the asteroids are still near the locations where they formed, we can use the distribution of asteroid types to map out the composition of the solar nebula, the original circumsolar assemblage of gas and dust from which the planetary system formed. Carbonaceous meteorites formed at lower temperatures than the other primitive stones, so we infer that the concentration of similarly composed C-type asteroids in the outer belt is consistent with their formation farther from the Sun, where the nebular temperatures were lower. It is also possible, however, that the asteroids formed elsewhere and were herded into their present positions by the gravity of Jupiter and the other planets. In that case, the C-type asteroids could have formed far beyond Jupiter and subsequently diffused inward to their present positions in the outer part of the asteroid belt. Similarly, the S-type asteroids near the inner edge of the belt could either have formed where we see them today, or they could have been gravitationally scattered to their present locations from still closer to the Sun. The solar nebula temperatures that we would deduce by applying these two alternative models are quite different. So far, however, we have not been able to settle on which model is preferred for the origin of the asteroids.

Captured Asteroids

The irregular shapes and other unexpected characteristics of Deimos and Phobos, the moons of Mars, as revealed by high-resolution photos obtained by the Viking orbiters, have suggested to a number of specialists that these two bodies are asteroidal satellites. If so, they are the first captured asteroids to be viewed at close range. See Figs. 3 and 4. As of the early 1990s, this postulation has been neither proven nor disproved.

Binary Asteroids

Light curves obtained of 624 Hektor (Fig. 5) have suggested that the asteroid has the shape of a dumbbell or possibly a fat cigar, considerably longer than it is wide. The irregular form of an asteroid like this may result from collisions with other asteroids, but, on the other hand, it is unlikely that a collision would produce an oblong body. Other observers have suggested that Hektor may not be a dumbbell as previously proposed, but rather two asteroids in contact orbiting together. Future spectroscopic observations may reveal whether Hektor is one or two objects.

Star Occulted by Asteroid

In a rare event that occurred on June 7, 1978, a star was eclipsed by the asteroid 532 Herculina. While the total occultation lasted for 20.6 seconds, there were six additional reductions in starlight within 2 minutes of the main eclipse. These ranged from 0.5 to 4 seconds. Since the star was almost four magnitudes, atmospheric interference was ruled out. The longest secondary occultation has been confirmed by an independent observation. This occultation was caused by a secondary body about 50 kilometers in diameter and about 1000 kilometers from Herculina, whose diameter is 220 kilometers. Current thinking is that the six secondary eclipses were caused by six satellites of Herculina. The masses and distances are such that the system would be gravitationally stable.

Asteroids up Close: Current and Past Missions

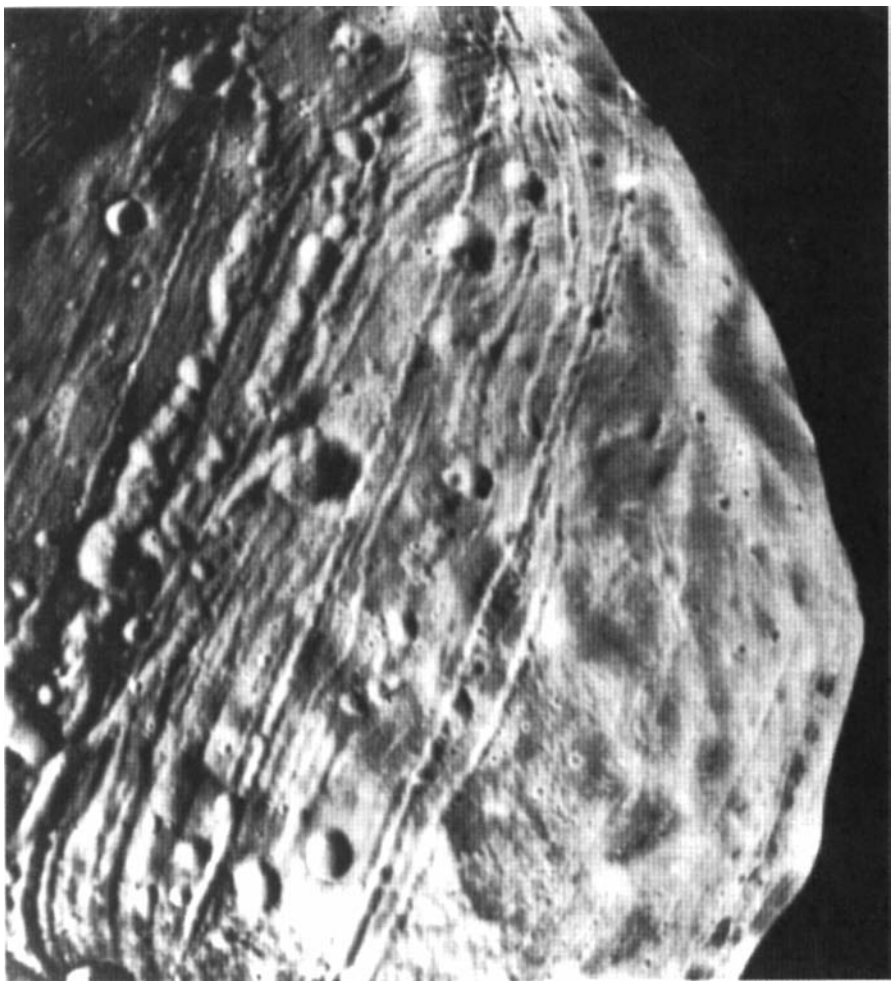

Fig. 3. Phobos, a satellite of Mars, may be a captured asteroid. (*Viking Orbiter 1*.)

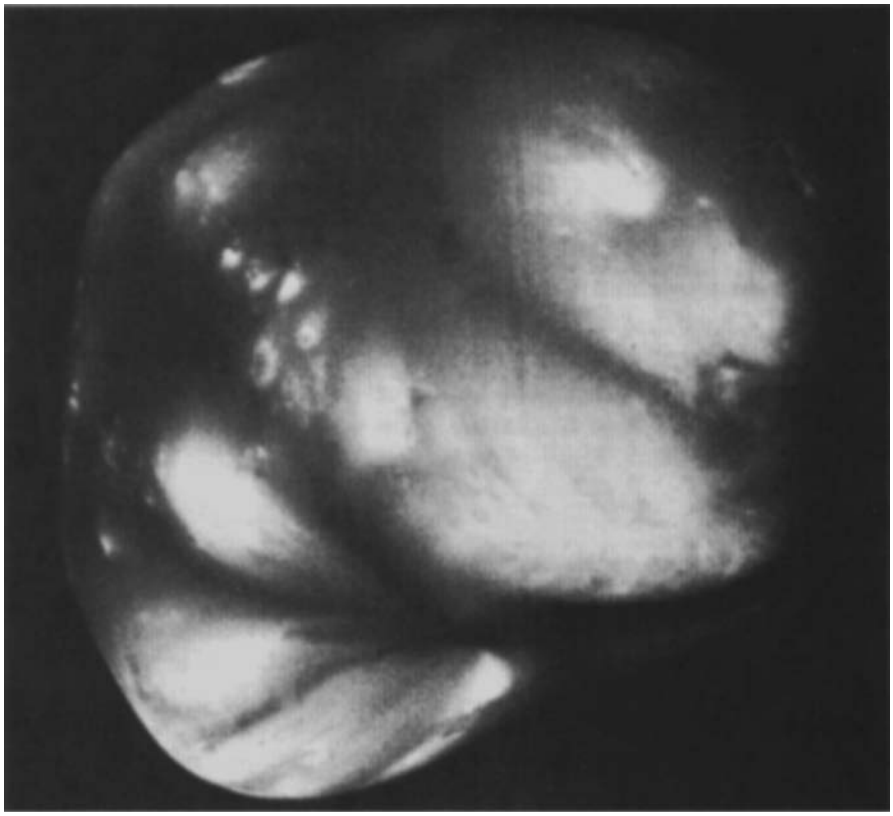

Fig. 4. Deimos, a satellite of Mars, in nearly full phase. This moon may be a captured asteroid. (*Viking Orbiter 2*.)

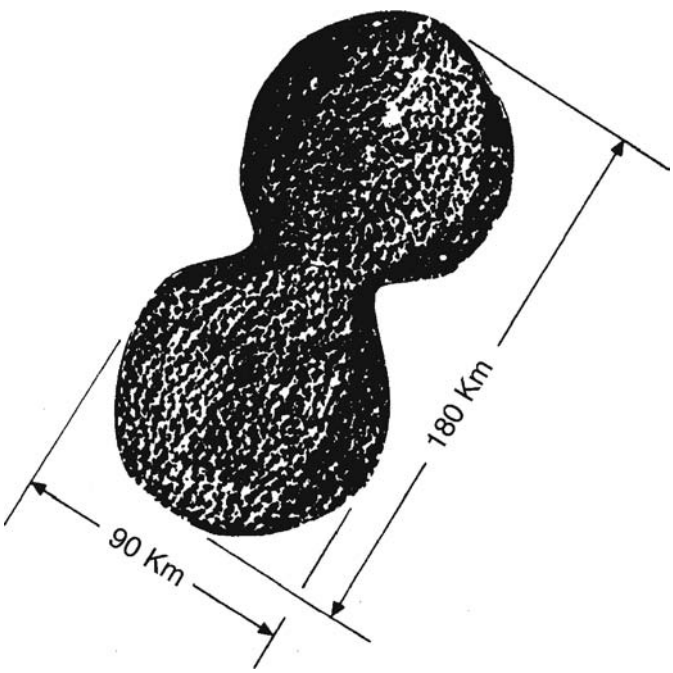

Fig. 5. Light curves indicate that Asteroid 624 Hektor may be a dumbbell shape, as shown here, or it may be two separate bodies (a binary asteroid.)

Investigations

Rendezvous with Galileo

Unless the satellites of Mars (*Deimos and Photos*) prove to be asteroids, the first close-up of an asteroid occurred on October 29, 1991, when the NASA spacecraft *Galileo* returned an image of *Gaspra*, a comparatively small (12× 20 km) asteroid that orbits between Mars and Jupiter. *Gaspra*, a stony S-type asteroid, is oddly shaped, possibly the result of numerous collisions. One researcher estimates *Gaspra*'s age at between 300 and 500 million years, which makes it comparatively young on the basis of the solar system, which is estimated at 4.6 billion years. The spacecraft's ability to transmit additional images will depend upon remotely fixing an antenna. Originally, a resolution of features less than 100 meters across had been planned. See also **Galileo Mission To Jupiter**.

Radar Studies. One of the most powerful tools for investigating asteroids is radar. There are two major planetary radar facilities, both of which were upgraded in the late 1990s. NASA operates the Goldstone (California) planetary radar facility as part of the Deep Space Network, and the 1000- foot Arecibo dish in Puerto Rico is operated by the National Astronomical and Ionospheric Center with NSF and NASA support. The two facilities are complementary — Arecibo has greater sensitivity, but Goldstone has greater sky coverage. Radar allows measuring range and velocity and permits us to define the rotational state precisely and to constrain the object's internal density distribution. In addition, radar astronomers used measurements of echo power in time delay (range) and Doppler frequency (radial velocity) to construct geologically detailed three-dimensional models that sometimes rival the resolution of spacecraft imaging systems. See also **Deep Space Network**.

By 2001, radar had detected more than 120 asteroids, whose sizes are as small as 30 m. These include large objects in the main belt as well as more than 80 of the smaller NEAs. One of the early radar contributions was to search for direct evidence of metallic surfaces for a few asteroids from their high microwave reflectivity. Observations of M asteroids Psyche and Kleopatra provide the best evidence linking the M class to metallic composition. However, these two asteroids have provided numerous surprises. In spite of its apparently metallic surface, Psyche has a density of only about 2 g/cm^3, suggesting that its interior has extremely high porosity if composed of metal. Kleopatra is even stranger; it has a remarkable "dog-bone" shape that suggests reaccretion of material after a catastrophic impact. There is also evidence of a low-density surface of unconsolidated rubble on Kleopatra — again not what we would have expected by comparison with the lumps of iron-nickel in our meteorite collections.

The highest-resolution imaging has been achieved for asteroids that come very close to Earth. The largest of these is Toutatis, (Fig. 6) an elongated lumpy asteroid that provided early evidence that asteroids might not be monolithic. At 5 km (3 miles) long, Toutatis is among the largest of the NEAs. Toutatis is also one of three asteroids found so far that are

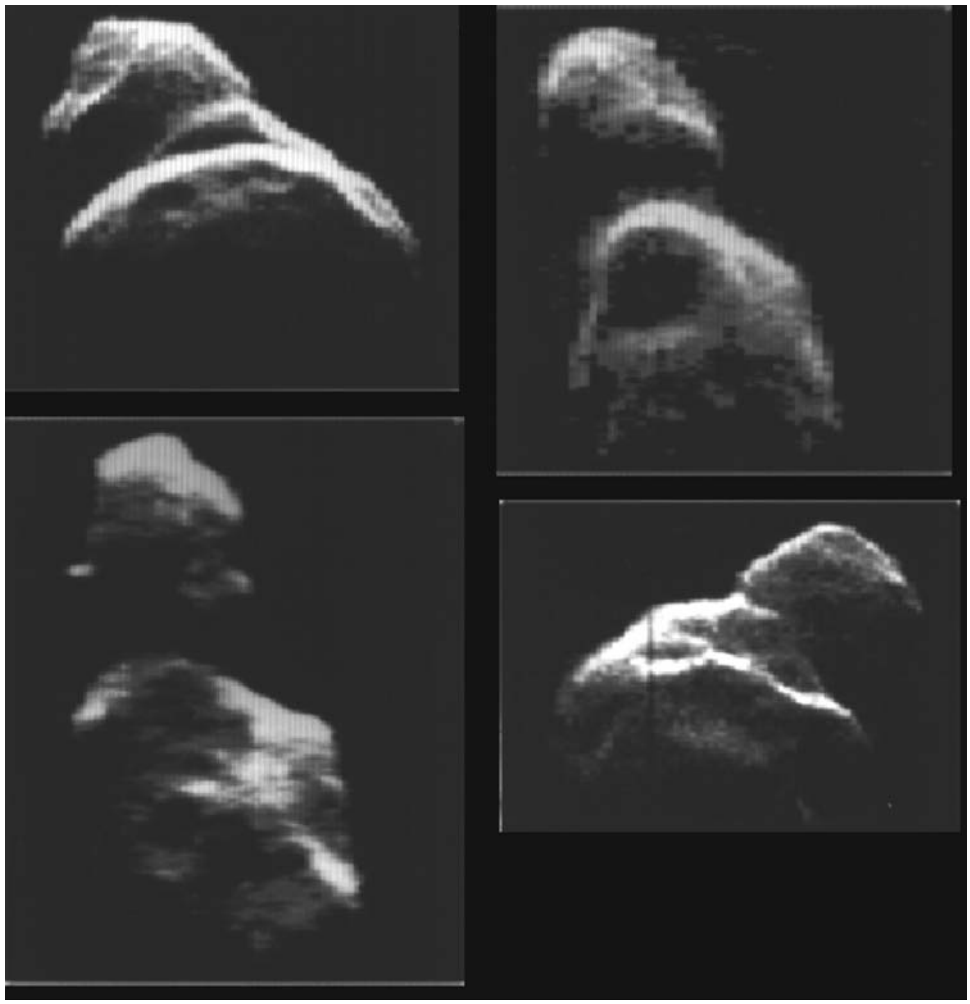

Fig. 6. Four radar images of asteroid 4179 Toutatis created using the Goldstone DSN antennas. These images were made on 8,9,10, and 13 December 1992 when Toutatis made a closest approach (approx. 4 million km) to Earth. The radar illumination is from the top in each image, and each shows the asteroid in a different orientation. Toutatis is an irregularly shaped body roughly 4.6× 2.4× 1.9 km, which appears to consist of 2 bodies in contact. The large crater in the 9 December image (2nd from top) is about 700 m in diameter. (*NASA Goddard Space Flight Center*)

in slow, non-principal-axis spin states — perhaps evidence that they have received recent impacts. Among the interesting results of radar has been the discovery of three bifurcated objects (Castalia, Mithra, and Bacchus) that appear to be contact binaries. In several other cases, there is evidence of satellites orbiting asteroids. Satellites provide a way to calculate densities of the primary objects. Since the late 1990s, several asteroidal satellites (including the large C-type main-belt asteroids Eugenia and Antiope) have been discovered by using ground-based optical telescopes, and densities have also been measured for three of the asteroids visited by spacecraft. Most of the densities turn out to be surprisingly low (less than 2 g/cm^3), suggesting rather high interior porosity.

Spacecraft Flybys. Table 3 summarizes the four detailed spacecraft studies of asteroids. The main-belt asteroids Gaspra and Ida were flyby targets for Galileo on its way to Jupiter, and Mathilde was visited by the NEAR-Shoemaker spacecraft on its way to its primary target, Eros. The NEAR studies of Eros are discussed in the next subsection. Figure 7 illustrates these spacecraft targets on the same scale.

TABLE 3. SPACECRAFT ENCOUNTERS WITH ASTEROIDS

Asteroid	Class	Date	Dimensions, km	Density, g/cm^3	Best resolution, m
Gaspra	S	1991	18 × 11 × 9	—	50
Ida	S	1993	60 × 25 × 19	2.6	25
Mathilde	C	1997	66 × 48 × 46	1.3	160
Eros	S	2000	31 × 13 × 13	2.67	0.1

The Galileo flybys of two main-belt S-type asteroids revealed that both are highly irregular in shape, heavily cratered, and have only slight differences in color or reflectivity across their surfaces. Gaspra is undersaturated with craters, indicating a relatively young age (where age is the time since the last global-scale impact). In contrast, Ida is saturated with craters, and it appears to have a broken-up surface layer (a regolith) that is tens of meters thick (similar to that of the Moon). The discovery of a small satellite (Dactyl) in orbit around Ida permitted measuring its mass and density. The density is 2.6 g/cm^3, similar to that of primitive rocks. Partly on this basis, it appears that these two S-type asteroids are probably coherent and are composed of materials similar to ordinary chondrite primitive meteorites. However, the spectral mismatch between these objects and known chondrites in our meteorite collections continued to baffle investigators after these two flybys. In addition, the presence of large families of grooves or lineaments on both asteroids suggested that they had global-scale cracks resulting from past impacts.

Mathilde was the first main-belt C-type asteroid to be examined at close range. NEAR-Shoemaker found a unique shape for this asteroid, dominated by several apparent craters whose diameters are greater than the radius of the asteroid. Such a configuration is not possible for a "normal" rocky target because the formation of the most recent of these craters would have been expected to destroy preexisting giant craters or perhaps even to disrupt the target entirely. Only a "soft" target that has a less competent interior can absorb great shocks without internal disruption. This interpretation was reinforced by the measured density of 1.3 g/cm^3, indicative of about 50% porosity. Thus, Mathilde became the first confirmed rubble-pile asteroid.

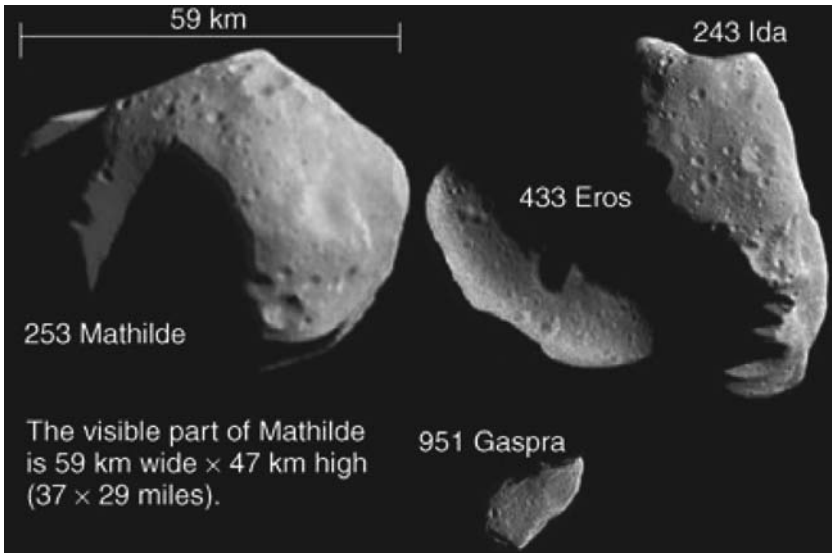

Fig. 7. Family portrait of spacecraft images of asteroids Gaspra, Ida, Mathilde, and Eros, shown to scale. Gaspra and Ida (both main-belt asteroids) were imaged by the Galileo spacecraft. Mathilda (main-belt) and Eros (near-Earth) were imaged by NEAR-Shoemaker (images courtesy of NASA, the Caltech Jet Propulsion Laboratory, and the JHU Applied Physics Laboratory)

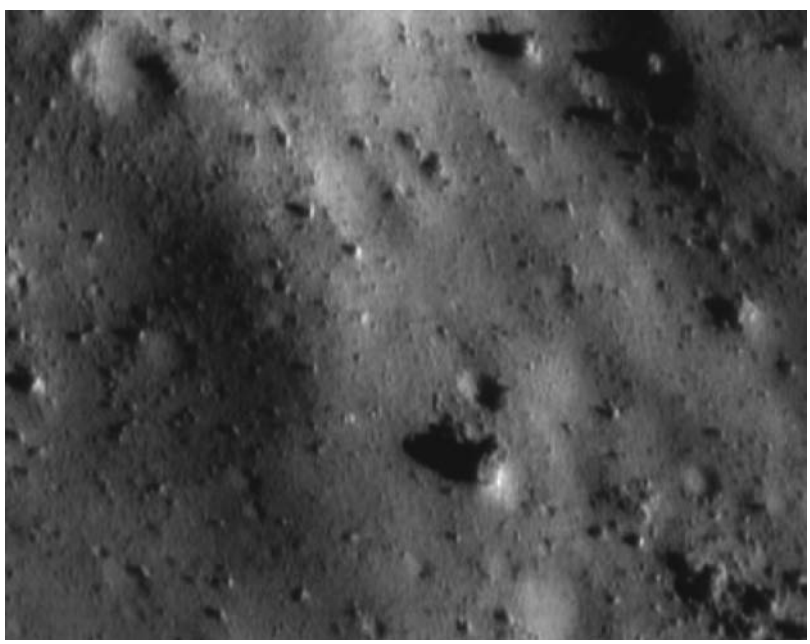

Fig. 8. Close-up of near-Earth asteroid Eros as seen from the NEAR-Shoemaker cameras at a range of just 7 km. Most of the scene (about 350 meters across) is covered by rocks of all sizes and shapes, but the floors of some craters are smooth, suggesting accumulation of fine mobile material. The smallest visible features are about 1 meter across. (image courtesy of NASA and the JHU Applied Physics Laboratory)

The NEAR-Shoemaker Mission to Eros. The most ambitious and successful spacecraft investigation of the asteroids was carried out by a small (Discovery-class) NASA spacecraft called the Near Earth Asteroid Rendezvous (NEAR) mission. It was further christened NEAR-Shoemaker in honor of Eugene Shoemaker, the father of asteroid geology. NEAR-Shoemaker missed its original rendezvous date with Eros in December 1998 due to a malfunction, but it recovered after one more trip around the Sun and finally arrived in February 2000. It achieved an initial high orbit, then gradually lowered its altitude during the next year, and studied Eros with a variety of instruments. The spacecraft obtained thousands of multispectral images and more than 10 million laser altimetry measurements, making Eros one of the best-mapped objects in the solar system.

After 1 year in orbit, NEAR-Shoemaker began a staged descent to the surface, taking pictures of ever-increasing resolution (Fig. 8). It landed on 12 February 2001 at an impact velocity of 1.6 m/s. Fortunately, the spacecraft was not damaged, even though it had not been designed for such a maneuver. Using its low-gain antenna, it continued radioing data from the surface for more than a week, providing the best measurements of elemental composition. The mission ended on 28 February when a command from Earth turned off the spacecraft.

The quantitative measurement of radioactivity from K, Th, and U, as well as gamma-ray lines of Fe, O, Si, and Mg, demonstrated that Eros has a primitive composition equivalent to the low-iron group of ordinary chondrite meteorites. Eros is a normal class-S asteroid, so this *in situ* result finally settled questions that had remained open for decades concerning the nature (primitive or differentiated) of the S asteroids. The density of Eros (2.67 g/cm^3) is also generally consistent with this meteorite identification, although it still implies a substantial bulk porosity of about 25%. Evidently asteroids, like many terrestrial sediments, are

consistently less dense than the individual rocks of which they are composed.

Long ridges seen in some of the images demonstrate that Eros is a consolidated and coherent body that has global-scale tectonics. As suspected for several other asteroids, Eros is a solid collisional fragment of a larger parent body (not a rubble pile), but it is also not a monolith because its interior has been heavily fractured. The surface is cratered, but there is a surprising deficiency of small craters, combined with an excess of boulders up to the 100-m size. There are actually more boulders than craters in the tens-of-meters sizes. Some measured slopes are greater than the angle of repose. Dark material has flowed down-slope, exposing underlying bright material. The effects of space weathering are evident in the different spectral reflectivity of exposures of differing age. Apparently Eros has a complex, mobile regolith, whose small-scale surface roughness is similar to that of lunar regolith (somewhat surprising because the gravity is so much less).

As noted in summer 2001 by MIT scientist Richard Binzel, "We're getting to know asteroids as tangible objects, on the same scale and geologic sense that we know mountains on Earth." And like terrestrial mountains, their interiors can be highly fragmented.

The Deep Space 1 Mission to Braille. Deep Space 1 was launched from Pad 17-A at the Cape Canaveral Air Station at 12:08 UT (8:08 a.m. EDT), 24 October 1998, the first launch under NASA's Med-Lite booster program, on a Delta 7326-9.5 (a Delta II Lite launch vehicle with three strap-on solid-rocket boosters and a Star 37 FM third stage). At 13:01 UT the third stage burn put DS1 into its solar orbit trajectory. DS1 separated from the Delta II about 550 km above the Indian Ocean. Telemetry was received by the NASA Deep Space Network 1 hour, 37 minutes after launch, a 13 minute delay from the expected time. The reason for the delay is not known. All critical spacecraft systems were performing well.

DS1 flew by the near-Earth asteroid 9969 Braille at 04:46 UT (12:46 a.m. EDT) on 29 July 1999 at a distance of about 26 km at approximately 15.5 km/sec relative velocity. See Fig. 9. A software problem caused the spacecraft to go into a safing mode at approximately 12:00 UT on 28 July, but the problem was solved an the spacecraft returned to normal operations at 18:00 UT. Up to six minor trajectory correction maneuvers were scheduled in the 48 hours prior to the flyby. The spacecraft made its final pre-encounter transmission about 7 hours before closest approach, after which it turned its high-gain antenna away from Earth to point the MICAS camera/spectrometer camera towards the asteroid. The spacecraft had a target-tracking problem and the MICAS instrument was not pointed towards the asteroid as it approached, so no images or spectra were obtained. MICAS turned off about 25 seconds before closest approach at a distance of about 350 km and measurements were taken with the PEPE plasma instrument. The spacecraft then turned after the encounter to obtain images and spectra of the opposite side of the asteroid as it receded from view, but due to the target-tracking problem only two black and white images and a dozen spectra were obtained. The images were taken at 915 and 932 seconds after closest approach from 14,000 km and the spectra were taken about 3 minutes later. The data were transmitted back to Earth over the next few days. The diameter of Braille is estimated at 2.2 km at its longest and 1 km at its shortest. The spectra showed it to be similar to the asteroid Vesta. See also **Deep Space 1 Mission**.

The Stardust Mission. Stardust was launched on 7 February at 21:04:15.238 (4:04 p.m. EST). The launch took place from Pad A, Launch Complex 17 at Cape Canaveral Air Station aboard a Delta 7426 (a Delta II Lite launch vehicle with four strap-on solid-rocket boosters and a Star 37 FM third stage). After one solar orbit, an Earth flyby on 15 January 2001 at 6008 km altitude was used to boost the spacecraft aphelion to 2.7 AU and the inclination to 3.6 degrees. On 2 November 2002 at 04:50 UT (1 Nov at 11:50 p.m. EST) Stardust flew within 3300 km of asteroid 5535 Annefrank. The Stardust camera resolution was sufficient to show that Annefrank was about 8 km in length, twice the predicted size from Earth-based observations. The surface reflects about 10% to 20% of the sunlight, slightly less than predicted. See also **Stardust Mission**.

The Hayabusa Mission. The primary scientific objective of the Hayabusa (formerly Muses-C) mission is to collect a surface sample of material from the small ($550\times$ 180 meter ($1,084 \times 591$ feet) asteroid 25143 Itokawa (1998 SF36) and return the sample to Earth for analysis. It is also a technology demonstration mission. Other scientific objectives of the mission include detailed studies of the asteroid's shape, spin state, topography, color, composition, density, photometric and polarimetric properties, interior and history.

The spacecraft was launched on 9 May 2003 at 04:29:25 UT (1:29 p.m. local time, 12:29 a.m. EDT) on an M-5 solid fuel booster from the Kagoshima launch center. Following launch, the name Muses-C was changed to Hayabusa (the Japanese word for falcon) and the spacecraft was put into a transfer orbit to bring it to asteroid 25143 Itokawa (1998 SF36), a 0.3×0.7 km near-Earth object. Rendezvous with the asteroid occured in September 2005 with the spacecraft coming to rest relative to the asteroid at a distance of 20 km at 1:17 UT on 12 September.

Fig. 9. Deep Space 1 encounterwith asteroid 9969 Braille (*NASA*)

Hayabusa initially surveyed the asteroid's surface from a distance of about 20 km in the "home position", a region roughly on a line connecting the Earth with the asteroid on the sunward side. This is global mapping phase 1, the phase angle during this phase was small, no greater than 20-25 degrees. Global mapping phase 2, which lasted about a week, began on 4 October when the spacecraft reached a position near the terminator at a distance of 7 km, affording high phase angle views of the asteroid. Following this the spacecraft moved back to the home position and then moved close to the surface in November for a "rehearsal" touchdown. This touchdown was attempted on 4 November but was aborted due to an anomalous signal at 700 meters above the asteroid's surface.

On 12 November a second rehearsal touchdown was attempted. The spacecraft began its descent from 1.4 km altitude at 3 cm/sec to an altitude of 55 meters. The small lander/hopper, Minerva, was deployed at 6:34 UT (3:34 p.m. JST) but unfortunately Hayabusa had already reached the 55 meter level and had begun an automatic ascent so the release was at a higher altitude than planned. Contact was lost and it is believed Minerva floated off into space without landing.

At 12:00 UT on 19 November (9:00 p.m. JST, 7:00 a.m. EST) Hayabusa began its descent towards the asteroid from an altitude of 1 km. At 19:33 UT (4:33 a.m. JST 20 November) the final approach was commanded and the descent began from an altitude of about 450 meters at 12 cm/sec. The target marker was released at 20:30 UT 19 November (5:30 a.m. JST 20 November) about 40 meters above the asteroid and Hayabusa's descent was slowed to 3 cm/sec to allow the marker to fall ahead of it. The spacecraft reduced its speed to zero and then began free-fall at an altitude of 17 meters at which point contact was lost. Later telemetry indicated that Hayabusa hit the surface at 20:40 UT 19 November (5:40 a.m. JST 20 November) at roughly 10 cm/sec and bounced. It bounced again at 21:10 and then landed at 21:30 within about 30 meters of the target marker. At 21:58 (6:58 a.m. JST 20 November) it was commanded to make an emergency ascent. The craft remained on the surface for about half an hour but did not collect a sample. This was the first ever controlled landing on an asteroid and first ascent from any other solar sytem body except the Moon.

A second touchdown and sampling run was made on 25 November, early telemetry indicates the spacecraft touched down at 10 cm/sec and two sampling bullets were fired 0.2 seconds apart at 22:07 UT 24 November (7:07 a.m. JST 25 November) but examination of later telemetry indicates it is not clear that the bullets were fired. More details will be available when further telemetry is returned and analyzed. On 9 December contact was lost with the spacecraft, presumably because of torques caused by a thruster leak which altered the pointing of the antenna. As of December 14, 2005 attempts to restore communication are ongoing, but may take several months. It has been decided to reschedule the Earth return to June of 2010.

The Rosetta Mission. Rosetta was launched at 7:17 UT on 2 March 2004 on an Ariane 5 G+ from Kourou, French Guiana. The spacecraft entered heliocentric orbit and will have an Earth flyby and gravity assist in March, 2005. A Mars flyby/gravity assist will follow in March 2007, and two more Earth gravity assists are scheduled for November 2007 and November 2009. In between these Earth flybys, on 5 September 2008, Rosetta will fly within 1700 km of asteroid 2867 Steins at a relative velocity of 9 km/s. Steins is a main belt asteroid a few km in diameter. After the second Earth flyby the spacecraft will enter the main asteroid belt for the second time and fly by asteroid 21 Lutetia at a distance of 3000 km and a speed of 15 km/s on 10 July 2010. Lutetia is a large asteroid, about 100 km in diameter. The spacecraft will enter a hibernation phase in July of 2011. In January 2014 Rosetta will come out of hibernation and begin its rendezvous manuever for Comet Churyumov-Gerasimenko in May 2014. See also **Rosetta Mission**.

Asteroids up Close: Future Missions

The Dawn Mission. Dawn is a mission designed to rendezvous and orbit the asteroids 4 Vesta and 1 Ceres. The scientific objectives of the mission are to characterize the asteroids' internal structure, density, shape, size, composition and mass and to return data on surface morphology, cratering, and magnetism. These measurements will help determine the thermal history, size of the core, role of water in asteroid evolution and what meteorites found on Earth come from these bodies, with the ultimate goal of understanding the conditions and processes present at the solar system's earliest epoch and the role of water content and size in planetary evolution. The data returned will include, for both asteroids, full surface imagery, full surface spectrometric mapping, elemental abundances, topographic profiles, gravity fields, and mapping of remnant magnetism, if any.

The Near Earth Asteroid Prospector (NEAP). The Near Earth Asteroid Prospector (NEAP) is a spacecraft being built and operated by a private company, SpaceDev. The mission could be the first deep-space mission defined and executed by a non-governmental entity. First conceived in 1997 as a 350-kg minisatellite to be launched on a Russian Eurokot launcher, this low-cost deep-space mission has evolved to a 200-kg microsatellite launched as a secondary payload on the Ariane 5 to the asteroid Nerus.

NEAP is designed to carry a mix of science, entertainment, engineering and "novelty" payloads as multiple attached and ejectable packages. NEAP could be ready to launch in as little as 3-5 years, choosing from many different potential target objects. When the mission was first conceived in early 1997, only about 300 near earth asteroid targets had been discovered. That number is now over 1,000 providing many more options than previously available.

Asteroid Collisions with Earth

To some specialists in the field, it is not a question of will an asteroid collide with the earth, but of the probability of such an event. There is growing evidence of past encounters of this nature. As shown by the map of Fig. 10, craters on earth are relatively numerous. The geographical regions of central and eastern Canada embrace nearly 50% of all known ancient impact craters although the region represents only about 1% of the earth's land surface. Evidence of craters also has been found in Europe, Asia, and other areas. However, there are no known regions with the similar concentration of that in Canada. This has not been satisfactorily explained to date except in a rather qualitative way — to the effect that the Canadian scientists have conducted a much more extensive survey for craters. There is also the likely possibility that many craters are simply undiscovered in other areas because they are covered over with the debris of millions of years in the past and may be located in regions that are not particularly active in terms of other geologic interests. In commenting on the Canadian craters, as well as craters elsewhere, one scientist has observed that, on the basis of the best available crater count, it is estimated that during the past 600 million years about 1500 Apollo objects (about 1 kilometer in diameter) or larger have struck the earth. This estimate assumes that about 70% of these bodies fell into the sea rather than on land. See also **Astrobleme**.

The relatively few craters on the earth and those many more observed on our moon and on many of the satellites of other planets are believed to have been caused by asteroid and/or comet impacts, among meteorites and other causal factors. The investigations of such impacts and their effects upon the earth not only fall within the realm of astrophysics, but of paleontology and paleogeology as well. Over the past two million years, there have been five relatively rapid environmental changes that have affected the biomass of the earth. There are hypotheses that attempt to explain periods of glaciation and intervening periods of warmer climates. That all or some of these environmental changes have occurred as the result of extraterrestrial forces has been discussed for many years. Shortly after the discovery of Ceres in 1801, there were proposals that asteroids colliding with the earth have been the principal cause of the major environmental periods, and, in particular, the most severe of these changes, which occurred at the end of the Cretaceous period and beginning of the Tertiary period, about 65 million years ago, when life epitomized by the dinosaurs became extinct. Paleontologists for several decades generally have not considered this hypothesis seriously and for understandable reasons, have opted for the more gradual causes of the Cretaceous-Tertiary extinctions, as contrasted with a single catastrophic event. The gradualists base these opinions in part upon the lack of geological and fossil evidence that would support the asteroid hypothesis. Further, no impact of an asteroid has been recorded during the time of recorded history.

As early as 1973, Urey speculated on the impact of a comet as the event that ended the Cretaceous period. The nuclei of comets are estimated within the same size range as an acceptable value for an impacting asteroid, i.e., from 1 to 10 kilometers (0.6–16 miles) in diameter. It is further observed, however, that comets, unlike asteroids, are composed of much ice and other substances that tend to reduce the comet size during swings close to the sun, which volatilize these materials and further enrich a nebulous coma. See also **Comet**. If the estimate of the size of comets is relatively reliable, authorities suggest that observable comets have not been sufficiently abundant to produce the number of large craters on the moon,

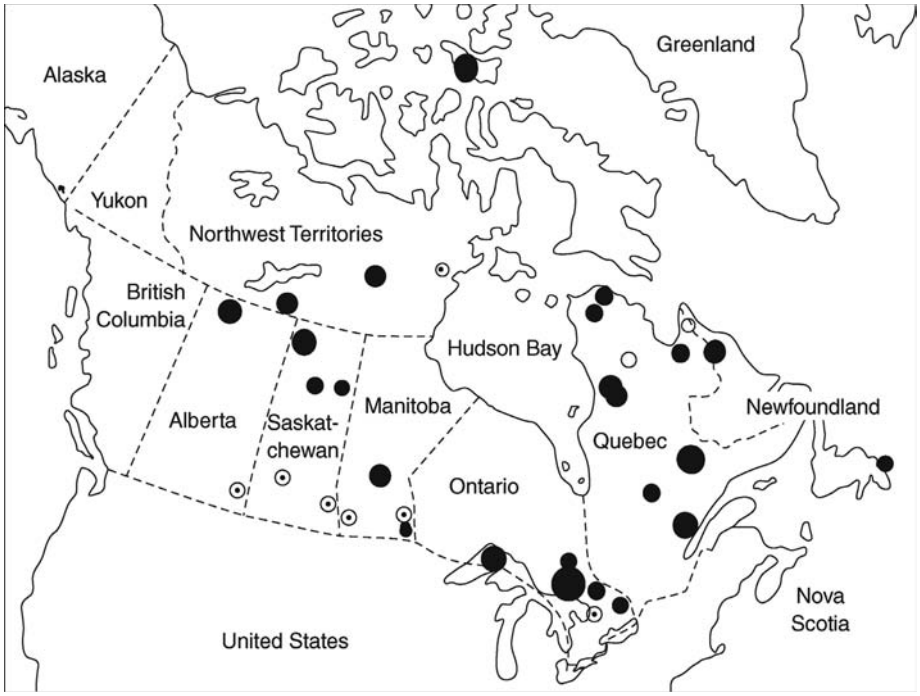

Fig. 10. Concentration of ancient (asteroid) craters in Canada, particularly in central and eastern portions. Over twenty craters (black circles) have been identified. Circles with dots identify locations of possible impact structures. These craters range in age from an estimated 1.8 billion years to less than 5 million years. The oldest crater is located near Sudbury, Ontario; the youngest crater is located in extreme northern Quebec, east of Hudson Bay. Size of circle approximates size of crater (as compared with other craters). (*Drawn from data provided by Earth Physics Branch, Department of Energy, Mines and Resources, Canada.*)

but that the abundance of Apollo objects has been sufficient to cause these craters. It has been suggested that perhaps comet impacts account for up to 35% of the larger lunar (and possibly a few earth craters), whereas the other craters have been caused by impacting asteroids and meteoroids.

The number of asteroids crossing the earth's orbit of a size sufficient to cause the five major environmental events in the earth's history (one possible example, the end of the Cretaceous period) would have required a hit about once every 100 million years. Some authorities believe that abundance of Apollo objects is sufficient to cause four collisions per every million years. Within the last few years, Alvarez and Alvarez (University of California at Berkeley) and Asaro and Michel (Lawrence Berkeley Laboratory) http://www.lbl.gov/ have located direct physical evidence (as contrasted with biological changes seen in the paleontological record) for an unusual event at exactly the time of the extinctions in the planktonic realm. A hypothesis has been developed to explain nearly all the available paleontological and physical evidence (Alvarez, et al., 1980). The Cretaceous-Tertiary boundary layer has been inspected in a number of locations, including Denmark and Italy. Deep-sea limestones exposed in New Zealand, Italy, and Denmark show iridium increases of about 20, 30, and 160 times, respectively, above the background level at precisely the time of the Cretaceous-Tertiary extinction. Field investigations indicate that this iridium is of extraterrestrial origin, but did not come from a nearby supernova. The Alvarez hypothesis accounts for the extinction and the iridium observations. Impact of a large earth-crossing asteroid would inject about 60 times the object's mass into the atmosphere as pulverized rock; a fraction of which would remain as dust in the stratosphere for several years and be distributed worldwide. The darkness resulting would suppress photosynthesis, and the expected biological consequences match quite closely the extinctions observed in the paleontological record. One prediction of this hypothesis has been verified — the chemical composition of the boundary clay (believed to have come from the stratospheric dust) is decidedly different from that of clay mixed with the Cretaceous and Tertiary limestones, which are chemically similar to each other. The research team has made four separate estimates of the diameter of the suspected asteroid, giving a value in the range of 10 ± 4 kilometers. It has been estimated that the kinetic energy of the asteroid would have been about equivalent to that of 108 megatons of TNT.

In a summary of this hypothesis (Alvarez, (1980)), the asteroid impact is compared with that of Krakatoa, an island volcano in the Sunda Strait between Java and Sumatra which erupted on August 26 and 27, 1883. See also **Volcano**. Whereas the estimated 14 cubic miles of material ejected into the atmosphere by Krakatoa required between 2 and 21/2 years to settle and to return the atmosphere to normal clarity, it is suggested that the debris from the hypothesized asteroid impact would have been greater by a factor of about 10^3 and thus would have put the earth essentially into darkness for a period of several years.

In 1963, when 10 Apollos were known, öpik (Armagh Observatory in Ireland) http://star.arm.ac.uk/home.html concluded that there must be at least 43 Apollos and possibly many more. Since that time, an additional 28 Apollos have been discovered and the current rate of discovery is about four bodies per year. There is a general opinion as of the early 1980s that the number of Apollos, at a minimum, is well over 200. At this time, none of the known Apollo objects is on a collision course with the earth. However, both the Apollo and Amor asteroids are under continuous gravitational influence of nearby planets, particularly Jupiter, which causes the asteroidal orbits to precess. Because of precession, the major axis of an elliptical orbit gradually rotates through 360° in space. Thus, those asteroids with a perihelion inside the earth's orbit and an aphelion beyond the earth's orbit are destined at some time to be in an orbit that intersects the earth's orbit. It follows that the probability of any given Apollo to intersect the earth's orbit is once in every 5000 years. It further follows that the likelihood of the earth and asteroid being in precisely the same spot in the earth's orbit is very small — with an estimated collision probability of only about 5×10^9 per year (once in 200 million years).

Near-Earth Asteroids

Asteroid populations that can impact Earth are of special interest to us. They are generally referred to as Near-Earth Asteroids (NEAs) or Earth-crossing asteroids (ECAs). Because of their unstable, planet-approaching orbits, the NEAs have impacted the surfaces of the planets in the inner solar system (including Earth) and have influenced both geologic and biological evolution. There is reason to expect further impacts in the future, so the NEAs are a topic that has profound political and societal overtones. The

impact hazard represents the intersection of asteroid science and public welfare and governmental policy.

It is highly improbable that a large (diameter >1 km) NEA will hit the Earth within our lifetimes, but such an event is entirely possible. In the absence of specific information, such a catastrophe is equally likely at any time, including next year. Recognition that Earth (and Moon) are impacted by asteroids and comets is less than a century old, and it was not even securely proven that the prominent Meteor Crater (Arizona) was of impact origin until the work of Eugene Shoemaker in 1960. The fortunate fact that the atmosphere protects us from impacting bodies smaller than a few tens of meters in diameter (except for the rare iron meteorites) has the perhaps unfortunate consequence that we have almost no direct experience with cosmic impacts.

Tunguska and Meteor Crater. On the timescale of a human lifetime, the 1908 Tunguska impact in Siberia is the most notable. It was estimated (primarily from barographic and seismic records) that it had an explosive energy of ~15 megaton (TNT equivalent) when it disintegrated about 8 km above the ground. The impactor had the force of a large contemporary nuclear weapon. The explosion affected an unusually remote part of the world, and the first expedition to study Tunguska was delayed by two decades. At the time, before the existence of an Earth-crossing asteroid population was recognized, it was naturally suggested that the culprit was a small comet. Other fringe-science explanations included the impact of a mini black hole and the crash of a UFO spacecraft. Not until the 1990s did numerical modeling of the entry physics clearly indicate that a comet (low-density, friable material) of this kinetic energy would disintegrate at very high altitudes and could not penetrate into the troposphere. Now we recognize that the event in Tunguska was simply the most recent example of an ongoing bombardment of Earth by NEAs.

A better known site of asteroidal impact is Meteor Crater (also called Barringer Crater) in northern Arizona. In this case, an iron asteroid about 40–50 meters in diameter struck about 50,000 years ago and formed a crater slightly more than 1 km in diameter. The energy of this impact was approximately the same as that of Tunguska (about 15 megaton), but because of the greater strength and density of the projectile, the explosion occurred at or below the surface, and a crater was formed.

Impacts and Extinctions. NEAs entered the scientific and popular mainstream in the 1980s when they were identified as the possible agents of biological mass extinctions. Alvarez and others proposed that the dinosaur-killing KT mass extinction was due to an impact by a comet or asteroid, inferred from the chemical signature of extraterrestrial material in the boundary layer at the end of the Cretaceous. This bold hypothesis received general acceptance after the 200-km- diameter Chicxulub crater in Mexico (still among the largest craters identified on Earth) was discovered and it was dated exactly to the age of the KT extinction. See also **Mass Extinctions**.

The most revolutionary insight of Alvarez and his colleagues was not that impacts take place on Earth (which was obvious), but that even small impacts (on a geological or astronomical scale) can severely damage the fragile terrestrial ecosystem. From the size of the Chicxulub crater, the energy of the KT impact is estimated at about 100 million megaton, and a consistent value of the size of the impactor (10–15 km in diameter) is derived from the observed extraterrestrial component in the boundary layer. Immediate effects of the impact included blast and the generation of a tsunami (because the impact occurred in a shallow sea). However, the primary agents of global stress appear to have been a short-lived firestorm from atmospheric heating of ejecta followed by a persistent (months to years) blackout due to particulates suspended in the stratosphere. Large land animals (such as the dinosaurs) were incinerated within a few minutes of the impact, and the marine ecosystem collapsed a few weeks later as a result of the global blackout. Fortunately, impacts of this size are exceedingly rare; they occur at average intervals of the order of a hundred million years. Today, there is no NEA comparable to the KT impactor that can hit Earth. However, we have no such assurance of immunity from smaller impacts.

Impacts from asteroids and comets have influenced the biological history of our planet in a variety of ways. It is widely thought that carbonaceous asteroids have been the dominant source of Earth's water and other volatiles, including many organic compounds required for originating life. At the same time, the impact environment of early Earth must have challenged the development of life and may have led to short episodes in which the oceans boiled away and the planet was sterilized. The phenomenon has been called the "impact frustration of life". After the end of the heavy bombardment of Earth about 3.8 billion years ago, impact catastrophes of this dimension were not possible. However, the Earth must have experienced dozens (or more) of impacts of the size of the KT event that punctuated biological evolution with occasional episodes of dramatic environmental stress. Impacts have been suspected in several other mass extinctions besides the KT, but in no other case is the evidence truly compelling. However, we know that these impacts have happened, and it is entirely plausible that they played a major role in biological evolution.

The Asteroid Impact Hazard

The average frequency of impacts by NEAs as a function of kinetic energy is illustrated in Fig. 11, adapted from a graph published in 1983 by Shoemaker. Comparison of this size–frequency distribution with the

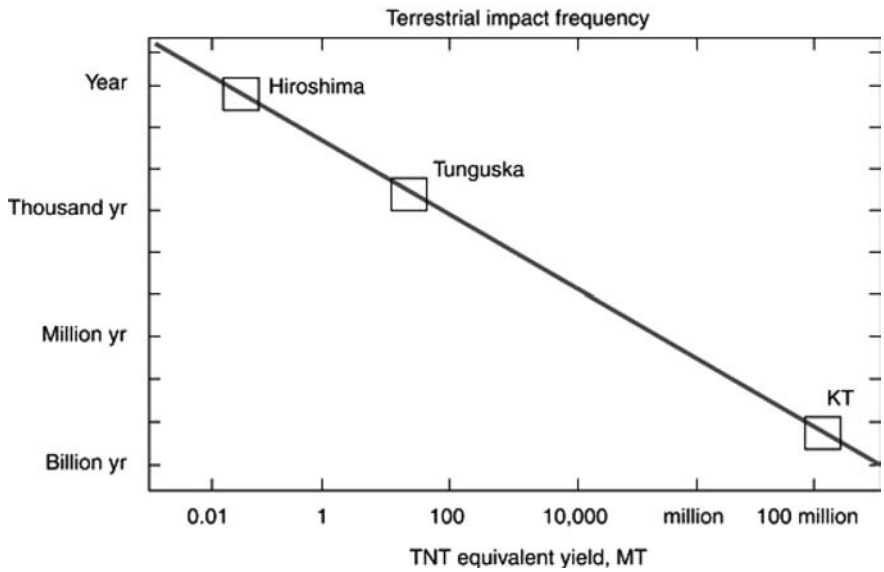

Fig. 11. Plot of frequency of impacts on Earth vs. impact energy for near-Earth asteroids (NEAs). The power law is a long-term average derived primarily from lunar cratering and the current number and distribution of known NEAs. Shown plotted at their estimated energies are the Hiroshima nuclear bomb, the Tunguska impact of a small asteroid in Siberia (1908), and the KT impact that led to the extinction of the dinosaurs (65 million years ago). (courtesy of David Morrison and NASA Ames Research Center)

expected environmental damage caused by impacts of different energy leads to the conclusion (19) that the greatest risk is from large impacts, those that create a global ecological catastrophe. The threshold for global catastrophe is in the vicinity of 1 million megatons of energy, corresponding to an NEA whose diameter is about 2 km. Below this threshold, impacts create regional or local disasters, but the population (and social stability) of the planet are not threatened.

Although impacts below this million-megaton threshold are much more frequent, the total hazard from the sum of all such smaller impacts is less. Unlike more familiar natural hazards, the impact risk is primarily from extremely rare events — literally unprecedented in human history. The impact hazard represents the extreme case of a calamity of low probability but high consequences, including the possible end of civilization as we know it. It is logical to concentrate first on mitigating the risk from global catastrophes. Later, it may be desirable to extend mitigation efforts to smaller impacts that are much more likely to happen within our lifetimes, although they do not threaten society as a whole.

The preceding discussion treats impacts as if they are random statistical events, but they are in fact clearly deterministic. There either is or is not an NEA on a trajectory to collide with the Earth within, say, the next century. Any discussion of mitigation must recognize that these events can be predicted and even eliminated by deflecting a threatening NEA. The key requirement is adequate warning time. This is the philosophy behind the international "Spaceguard Survey" being carried out by ground-based optical telescopes equipped with state-of-the-art wide-field detectors and automated search capability (20). The NEAs are found as they repeatedly fly past Earth at typical distances of tens of millions of kilometers. If one of them should be on course for a future collision, it should be discovered decades (or more) in advance. The initial goal of Spaceguard is to discover and catalog at least 90% of all NEAs larger than 1 km in diameter within 10 years (by 2008). The focus is on NEAs of this size because 1 km is near the lower bound for an impact that can cause a global catastrophe. However, the observers continue to discover more NEAs below 1 km than above it, and over time the survey will extend completeness to smaller sizes.

The threat of impacts and the requirement to survey the NEAs have been recognized by the governments of the United States, the United Kingdom, Japan, and the Council of Europe, as well as by many *ad hoc* technical panels. The current Spaceguard Survey is being carried out by half a dozen observing teams primarily supported by NASA and the USAF. More than half the discoveries are being made by the Lincoln Lab/MIT group called LINEAR. As of the end of 2001, more than 500 of the estimated 1000 NEAs larger than 1 km have been found, and their orbits have been calculated. We can say with assurance that none of the discovered NEAs poses any threat on the timescale of a human lifetime, but of course we still cannot speak for the objects not yet discovered. How far the survey will be extended, and what plans will be developed for possible planetary protection against impacts, are questions for society as a whole, not just the small number of scientists who are currently studying NEAs.

Possible Exploitation of Asteroids

Although in a very early stage of speculation, a number of scientists have been giving consideration to the possible use of satellites as permanent sites for space stations as well as sources of minerals. Gaffey and McCord (1977) worked out a rather elaborate, even if preliminary plan for an asteroid mining operation, including means for transporting materials to earth. Details are given in the references listed.

ASTHENOSPHERE. A term proposed by Barrell, in1914, for the zone beneath the relatively rigid lithosphere. The asthenosphere is considered to be the level of no strain in which there is maximum plasticity, and in which the igneous rock magmas are thought to originate. See also **Earth**.

ASTHMA. Asthma is a major chronic airway disorder that poses a serious public health problem in countries throughout the world. It affects about 10% of the world's population and is an important cause of respiratory morbidity and mortality. The term "asthma" was first used by Hippocrates (460–357 BC) to describe "episodic shortness of breath" of any cause. In 1556, Agricola defined asthma as episodic breathlessness due to bronchial disease, while Henry Hyde Salter in 1860 described narrowing of the airways due to smooth muscle contraction as the major underlying mechanism for symptoms of asthma. However, with the advent of new research tools and rapid advances in the fields of immunology and molecular biology, asthma is now recognized to involve chronic airway inflammation, which underlies disordered airway function and symptomatology. Despite substantial advances in our understanding of the pathogenesis, clinical characteristics and genetics of asthma, an all-encompassing definition remains difficult to construct. A recent international consensus document provides the following description:

> Asthma is a chronic inflammatory disorder of the airways in which many cells play a role, in particular mast cells, eosinophils and T lymphocytes. In susceptible individuals, this inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough particularly at night and/or in the early morning. These symptoms are usually associated with widespread but variable airflow limitation that is at least partly reversible either spontaneously or with treatment. The inflammation also causes an associated increase in airway hyperresponsiveness to a variety of stimuli. [In: *Global Initiative for Asthma: Global Strategy for Asthma Management and Prevention*. NHLBI/WHO Workshop, NIH Publication 95-3659. Bethesda, MD: NIH.]

Incidence and Prevalence

There is growing evidence that the incidence of asthma is increasing worldwide. Asthma affects individuals of all ages, but predominates in early life among children from westernized countries, with about one-half of all cases developing before the age of 10 years and another third occurring before age 40 years. Childhood asthma is more frequent in boys than girls (2:1), while during adolescence and adulthood the prevalence in females tends to equal or exceed that in males. The incidence of asthma in children aged under 5 years is 8.1–14 per 1000 per year for boys and 4.3–9 per 1000 per year for girls, while for all age groups the incidence of asthma has been estimated to lie between 2.65 and 4 per 1000 per year.

There is wide variation in the prevalence of asthma between populations. Higher rates have been found among children from westernized countries than in developing countries and in those from warmer climates compared to temperate regions. According to the International Survey of Asthma and Allergy in Children, the prevalence of asthma varies worldwide between 4% and 48% in 13–14 year olds and between 4.1% and 28.8% in adults. The highest figures occurred in children from New Zealand, Australia, the UK and the Republic of Ireland, while countries in eastern Europe, Asia and Africa have low rates.

Compared with other chronic lung diseases, the mortality rate for asthma is small, in part because most asthma is in young people and because asthmatic airway obstruction is usually reversible. Most recent figures indicate fewer than 5000 deaths per year out of a population of approximately 10 million patients at risk. Death rates, however, appear to be rising in some countries, whereas in others, possibly due to more effective treatment, they have stabilized or declined.

Factors Influencing the Developments of Asthma

Genetic Factors and Atopy. It is well established that asthma and allergies (atopy) have an important hereditary component, the heritability being estimated to be between 40% and 60%. Parental (especially maternal) history of asthma and atopy is thought to have a powerful influence on the development of childhood asthma. However, despite overwhelming evidence of an important genetic component, controversy still exists over the mode of inheritance of both atopy and asthma, probably because multiple genes with major and minor effects are involved. Several genes have been implicated in asthma pathophysiology. Family studies suggest that genetic and environmental components are required before asthma becomes evident (Fig. 1).

Atopy, defined as an increased predisposition to develop immunoglobulin (Ig) E antibodies to various antigens and/or one or more positive skin-prick tests to common aeroallergens, rhinitis or conjunctivitis, is the most important risk factor yet identified for the development of asthma, increasing the risk by 10–20-fold compared with those who are nonatopic. The commonest allergens identified by skin-prick tests as significant triggers

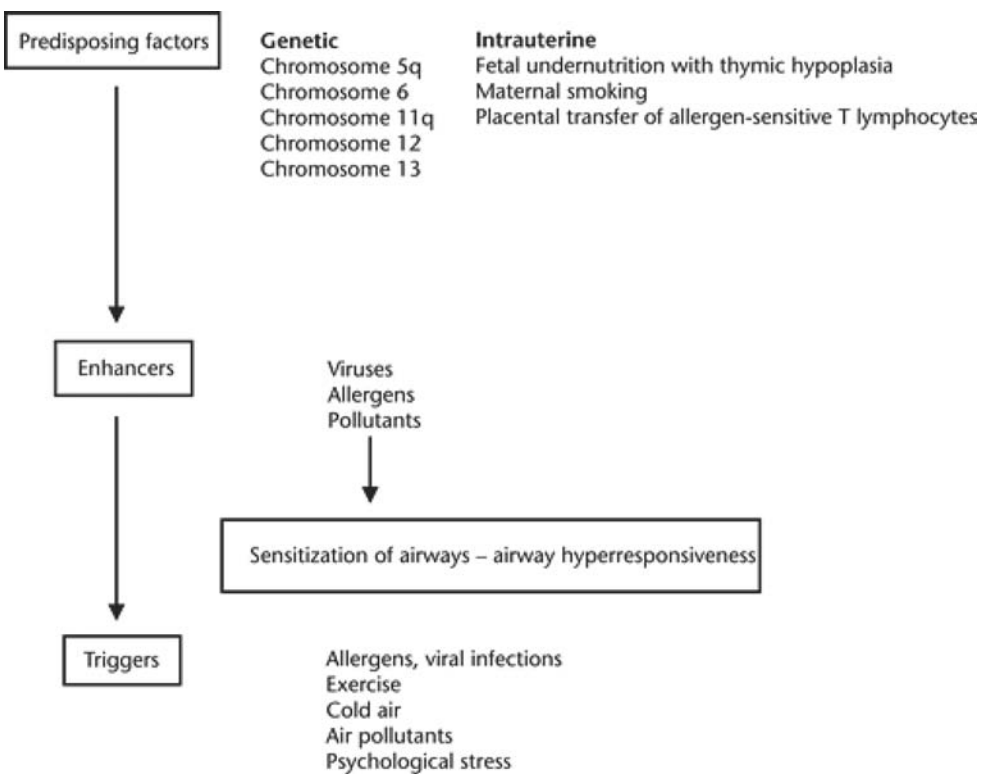

Fig. 1. Factors influencing the development of asthma.

are house-dust mites, cats, fungal spores, pollen and cockroaches. Although the majority of asthma is associated with atopy, some 30% of asthmatics are nonatopic, particularly patients with adult-onset asthma. These include aspirin-sensitive patients whose chronic severe asthma is exacerbated by exposure to aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs).

Early Life Environmental Factors. Intrauterine environmental factors may in part account for the maternal influence over the immune response of the progeny in favor of atopy. The effects of gestational allergen exposure may be modulated by adjuvant factors including maternal smoking, which raises cord blood IgE levels and impairs lung function, and by fetal nutrition. Disproportionate fetal growth (large head and small trunk), which is often linked with a birthweight of less than 2.5 kg (5.5 lbs), has been shown to be associated with an increased risk of developing asthma during childhood or adolescence. Exposure to allergens *in utero* and during the first year of life appears to be important in many children who later develop allergic disorders. Exposure to viruses and air pollutants (especially environmental tobacco smoke) has also been identified as an important early life risk factor for the development of asthma, the level of exposure determining both the age of onset and severity of symptoms.

Other Environmental Factors:

Indoor and Outdoor Allergens. The commonest allergens provoking asthma are proteins in the fecal particles of the house-dust mite *Dermatophagoides pteronyssinus* and protein components of wind-dispersed pollens from grasses (rye, couch, timothy), weeds (ragweed, mugwort) and trees (birch, alder). Mold spores (*Aspergillus*), bird feathers, and animal dander's and urine (cat, dog, rodents) also contain common allergens. Allergens sensitize atopic subjects by stimulating the development of specific T-lymphocyte clones and the production of specific IgE antibodies. Once sensitized, re-exposure to the same allergen predisposes to the development of allergic inflammation and asthma exacerbations. Pollen allergen from trees, grasses and weeds, and fungal spores are the commonest outdoor allergens that cause asthma in susceptible people.

Occupational Sensitizers. Occupational antigens include animal and plant proteins associated with farming, animal breeding, brewing and baking, bacterial enzymes used in detergents, and relatively small molecules that may sensitize only after haptenization, including oil paints, heavy metals and their salts.

Air Pollution. Asthma is more frequent in industrialized countries. Air pollutants emitted from vehicular exhausts and industrial sources, such as ozone, nitrogen oxides, acidic aerosols and particulate matter, have been shown to be significant risk factors for the development of asthma exacerbations. There is, however, little evidence that air pollution is directly responsible for the increased prevalence of asthma in these countries.

Diet. The influence of diet on asthma has not been properly examined. Conflicting data have been reported about the protective role of breast-feeding for the development of asthma. Increased salt intake and reduced fish intake have been associated with an increased prevalence of asthma. There is some evidence that food allergy in infancy is followed by asthma.

Region of Residence. Transfer from an urban to a rural environment appears substantially to increase the likelihood of developing childhood asthma. These increases are most likely due to environmental factors, in particular aeroallergens, which provoke expression of asthma symptoms in susceptible individuals in the new location.

Asthma Triggers. Triggers are risk factors that cause asthma exacerbations by inducing inflammation or provoking acute bronchoconstriction or both. Allergens, exercise, cold air, irritant gases, air pollutants, weather changes, extreme emotional expression, viral respiratory infections, food additives, NSAIDs and other drugs, rhinitis, sinusitis and nasal polyposis are important triggers for asthma.

Pathophysiology

Histopathology of the Asthmatic Airway. Recent descriptions of asthma stress the chronic underlying airway inflammation that is linked to bronchial hyperresponsiveness to nonspecific triggers, including allergens, exercise/cold air, aspirin-like drugs, air pollutants and occupational chemicals. Major advances in understanding the inflammatory causes of episodic airway obstruction in asthma have come from investigation of pathological changes in bronchial mucosal biopsies and bronchoalveolar lavage fluid obtained at fiberoptic bronchoscopy. Even in relatively mild asthma, changes include mucus hypersecretion, airway oedema, epithelial desquamation, goblet cell hyperplasia, smooth muscle hypertrophy, infiltration of the bronchial wall with eosinophils and T lymphocytes, activation of mast cells, and deposition of collagen beneath the basement membrane (Fig. 2). See also **Bronchial Asthma**.

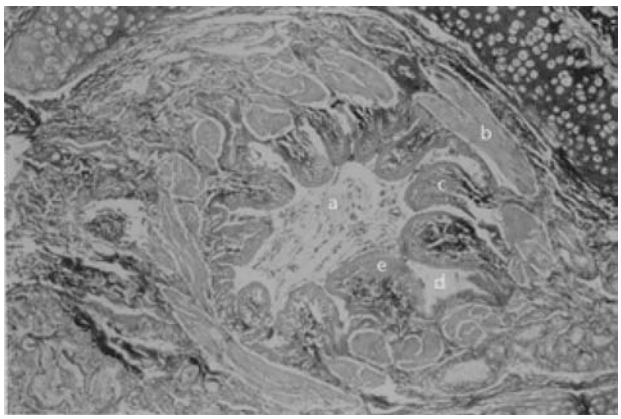

Fig. 2. Pathology of the asthmatic airway. (**a**) mucous plugging; (**b**) smooth muscle hypertrophy; (**c**) thickening of basement membrane; (**d**) loss of epithelium; (**e**) mucus gland hypertrophy.

Clinical Features and Diagnosis

Asthma is recognized by a characteristic pattern of symptoms including wheeze, cough, chest tightness and dyspnoea, and is best confirmed by evidence of variable or reversible airflow obstruction accompanying symptoms. In children, asthma usually presents only as nocturnal or postexercise cough. Wheeze, a polyphonic sound, may be present on inspiration as well as expiration and is generally thought to be the cardinal symptom of asthma. It is produced by vibrations set up in the narrowed airways, and is often detectable only on exercise and forced expiration. Some asthmatics do not experience wheeze and only report other airway symptoms.

Although these symptoms are also found in other respiratory conditions, a diagnosis of asthma is suggested by their episodic nature and by diurnal variability, with symptoms waking sufferers in the early hours of the morning (3–5 a.m.) or on waking at the normal time. A nocturnal influx of activated T cells and eosinophils into the lung periphery has been shown to be closely linked to nocturnal asthma but the mechanisms for this have yet to be defined.

Airway hyperresponsiveness is the cardinal pathophysiological feature of the asthmatic airway and often correlates with disease severity. It is defined as decreased threshold of airway narrowing in response to a variety of nonspecific stimuli that under healthy conditions do not evoke an airway obstruction. These nonspecific stimuli include pharmacological agents (histamine, methacholine, adenosine), exercise, cold air, fog, tobacco smoke, viral infections, inorganic dusts, perfumes, volatile organic compounds and chemical irritants. Airway hyperresponsiveness is absent in some patients with other clear evidence of asthma and may variably be present in some people without significant respiratory symptoms. Evidence of variable or reversible airflow obstruction, such as a 15% increase in forced expiratory volume in 1 s (FEV_1) or peak expiratory flow (PEF) occurring spontaneously or with treatment, is helpful if present. However, asthmatic patients who smoke or work in highly polluted atmospheres may develop less reversible disease, whereas some patients develop irreversible disease despite being life-long nonsmokers.

Differential Diagnosis

Upper airway obstruction by tumor, laryngeal oedema or glottic dysfunction can occasionally be confused with asthma. Persistent wheezing localized to one area of the chest in association with paroxysms of cough indicates endobronchial disease such as foreign-body aspiration, neoplasm or bronchial stenosis. The signs and symptoms of acute left ventricular failure may also mimic asthma. Recurrent episodes of bronchospasm occur with carcinoid tumors, recurrent pulmonary emboli and chronic bronchitis. In chronic obstructive pulmonary disease there are no true symptom-free periods and a history of chronic cough and sputum production can usually be obtained as a background upon which acute attacks of wheezing

are superimposed. Eosinophilic and chemical pneumonias are also often associated with symptoms of asthma.

Management

Asthma is a chronic disorder which often remits spontaneously in some individuals. With the recognition that asthma is a chronic inflammatory disorder of the airways, and that the accompanying inflammation causes recurrent episodes of symptoms, variable airflow limitation and increased airway responsiveness, treatment of the underlying inflammation and elimination of the causative agent(s) from the environment are the most successful means available for treating this condition. Numerous clinical studies have shown that persistent asthma is more effectively controlled by intervening to suppress and reverse the inflammation than by treating only the bronchoconstriction and related symptoms. Guidelines for asthma management stress a stepwise approach to the treatment of persistent asthma of varying severity (Fig. 3).

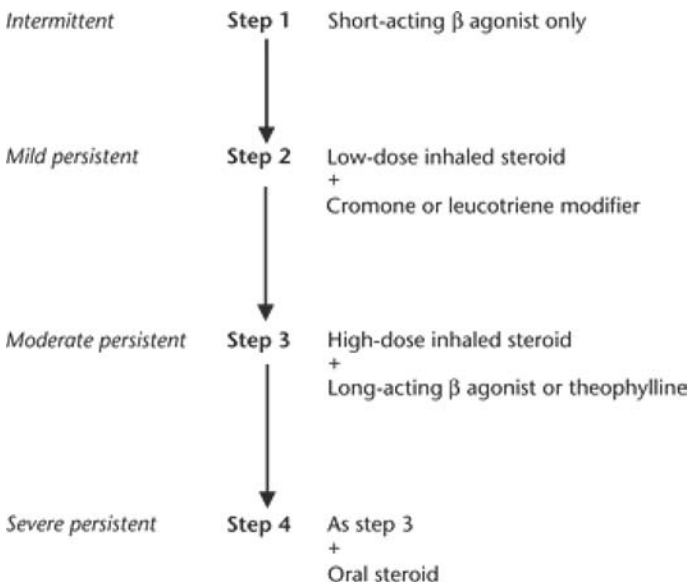

Fig. 3. Stepwise management of chronic asthma.

Pharmacological control of asthma can be achieved with anti-inflammatory "controller" medications, of which the most effective at present are the inhaled corticosteroids. Corticosteroids interact with cytosolic receptors and with nuclear transcription factors, themselves interacting with gene promoter regions, to modulate the expression of inflammatory genes, including those for cytokines, adhesion molecules and mediator-synthesizing enzymes. In the airways, inhaled corticosteroid therapy reduces the numbers and activation status of mast cells, eosinophils and T cells, and reduces the number and severity of acute asthma exacerbations. Corticosteroids have to be used daily on a long-term basis to achieve and maintain control of persistent asthma. Systemic adverse effects are rare with inhaled corticosteroids even at high doses, and oral thrush and dysphonia can be reduced by the use of spacer devices. A burst or cycle of oral corticosteroids is often used when initiating long-term therapy for a patient with uncontrolled asthma or during a period when the patient experiences a gradual decline in their condition. Although longer-term oral corticosteroid therapy is sometimes required to control severe persistent asthma, its use is limited by the risk of systemic adverse effects, which include osteoporosis, arterial hypertension, diabetes, cataracts, obesity, muscle weakness, skin thinning and easy bruisability, suppression of the hypothalamic–pituitary–adrenal axis and peptic ulceration.

Cysteinyl leucotrienes play an important role in bronchoconstriction and chronic airway inflammation in asthma. Inhibitors of leucotriene synthesis such as zileuton and cysteinyl leucotriene receptor antagonists such as montelukast and zafirlukast are significant new antiasthma drugs that have become available for oral maintenance therapy within the past 2 years. Antiallergic compounds such as ketotifen and antihistamines may be helpful in some asthmatics. Other controller medications include sustained release theophylline, long-acting β_2-Adrenergic agonists (inhaled salmeterol, formoterol, oral bambuterol and slow-release terbutaline), and the "mast cell stabilizing drugs" sodium cromoglycate and nedocromil sodium. Although these drugs improve baseline lung function and reduce the severity of asthma exacerbations, their capacity to suppress airway inflammation is unclear.

Short-acting bronchodilators (inhaled salbutamol, terbutaline) are used as rapid-onset "reliever" medications to reverse acute manifestations of asthma such as respiratory symptoms and airflow limitation. They act selectively at β_2-adrenergic receptors to raise intracellular levels of cyclic adenosine, causing relaxation of bronchial smooth muscle and reduced release of mediators from mast cells, but they do not reverse airway inflammation. Severe exacerbations of asthma are managed by close monitoring of the patient's condition and response to treatment with serial measurements of lung function. Quite often patients need to be admitted to hospital and therapy started with oral corticosteroids, oxygen and subcutaneous adrenaline (epinephrine) along with nebulized β_2 agonists.

Identification and control of triggers is an important step in the management of asthma, preventing exacerbations, reducing symptoms and the requirement for medication, and in the long term decreasing airway inflammation and hyperresponsiveness. Some triggers may be easier for susceptible patients to avoid than others. Prompt measures to avoid further exposure to chemical sensitizers as soon as occupational asthma has been recognized help to prevent the development of irreversible airflow obstruction. Desensitization or immunotherapy with extracts of the suspected allergens has enjoyed widespread favor, but controlled studies are limited and have not shown unequivocal efficacy.

A combination of increased awareness, enabling early recognition of the disorder, sensible application of effective prophylactic therapies, and education to ensure that management is optimal has succeeded in reducing much of the fear inspired by asthma and made it controllable in most sufferers. However, asthma cannot be cured. Although remissions occur, relapse is also frequent and continuous treatment over many years is a fact of life for most asthmatics.

Prognosis and Clinical Course

Evidence suggests a good prognosis for 50–80% of all patients with asthma, particularly those in whom disease is mild and develops in childhood. Spontaneous remissions occur in approximately 50% of patients who develop asthma during childhood and in 20% of those who develop asthma as adults. Even when untreated, asthmatics do not progress inexorably from mild to severe disease over time, the clinical course being characterized instead by exacerbations and remissions. Although some patients with asthma develop irreversible changes in lung function, these individuals frequently have comorbid stimuli such as cigarette smoking that could account for the findings.

ASTIGMATIC FOCUS. In an astigmatic system (see Astigmatism) some of the bundle of rays from an off-axis point meet in a line perpendicular to a plane containing the point and the optical axis. Some meet in a line (at a greater image distance) which lies in a plane containing the point and the optical axis. At all other image distances the bundle is an ellipse (or circle). The first line is called the primary or meridianal or tangential focus. The second line is called the secondary or sagittal focus.

ASTIGMATIC KERATOTOMY (AK). Astigmatic keratotomy is a variation of Radial Keratotomy (RK), which was the first truly successful refractive vision correction procedure. The RK procedure was designed to correct mild to moderate cases of myopia nearsightedness) whereas the AK procedure (was used to correct moderate astigmatism. Although major improvements were made in both the RK and AK procedures through the years, both have been largely replaced by more modern refractive surgery techniques such as laser *in-situ* keratomileusis (LASIK).

To understand how refractive surgery works, it is first necessary to understand the visual function of the eye. See also **Visual Function (Eye)**.

Astigmatism is a refractive eye disorder that exists because the shape of the cornea is less than spherical. It is more oblong, somewhat like the back side of a spoon. Thus, light rays, or visual images, are bent out of shape either horizontally or vertically before they strike the retina. Because astigmatism often exists in conjunction with nearsightedness, the RK and AK procedures were often combined and performed at the same time.

For the AK procedure, incisions are made in the surface of the cornea in a sideways manner. They are made where the corneal curve is the steepest, rounding out the cornea. The AK incisions can be made in a straight line or in an arclike form, depending on the data generated by the preoperative testing, evaluation process, and the surgeon's judgment. The incisions are made outside of the central zone, or visual axis, of the cornea.

After surgery, eyes may feel gritty, be sensitive to light, and appear red. Antibiotic eye drops help guard against infection. Although the AK procedure was done successfully for many years with good results in correcting astigmatism, newer forms of refractive eye surgery are more precise and produce more consistent results.

Vision Rx, Inc., Elmsford, NY

ASTIGMATISM. Astigmatism is a vision disorder that occurs when the cornea of the eye is uneven in shape. More rarely, it can result from the way in which the eye's natural crystalline lens refracts light. Either condition causes a distorted image to fall on the retina.

The human eye works much like a camera with two lenses: the cornea, which is a clear membrane that covers the front of the eye, and the natural crystalline lens, which is located behind the pupil. These two lenses work together to focus light on the retina, which is the membrane that covers the back two-thirds of the eye and works like the film in a camera. A normal cornea should be curved equally in all directions, allowing light to focus exactly on the surface of the retina. Most vision problems result from an irregularity in the curvature of the cornea or in the shape of the eye.

Nearsightedness, or myopia, occurs when the cornea is too steeply curved or when the eye is more elongated than normal, causing light rays to focus in front of the retina. With farsightedness, or hyperopia, the cornea itself is flatter than normal or the eye is shorter from front to rear, resulting in too short a distance from the retina. If the cornea is uneven in shape, the result is astigmatism, which causes light rays to be bent out of focus, either horizontally or vertically, resulting in distorted vision at all distances.

Astigmatism is prevalent and, in most cases, people who have it were born with it. Just as one's hands are shaped differently from other people's hands, so are one's eyes. Eyelid swelling, corneal scars, and keratoconus, a rare condition that causes the cornea to be misshapen, can also cause astigmatism.

Very mild astigmatism may cause no visual symptoms because the muscles of the eye will compensate for the uneven curvature of the cornea. If the eye has to work too hard to compensate, however, eyestrain and headaches can result. In addition, mild astigmatism can cause eye fatigue or blurry vision at certain distances. Severe astigmatism will usually cause distorted, double, or blurry vision.

An eye doctor detects astigmatism during the course of a regular eye examination.

Astigmatism can be treated surgically or nonsurgically. Prescription eyeglasses and contact lenses or laser vision correction surgery correct most cases of astigmatism. The most prevalent nonsurgical correction is a prescription for rigid gas permeable (RGP) contact lenses. Because it is rigid, an RGP lens will fill in the irregular areas of the cornea with tears, creating a smooth spherical surface and correcting astigmatism. Special soft contact lenses called torics also compensate for the astigmatic shape of the corneas. In those cases where the astigmatism arises from the eye's natural crystalline lens rather than the cornea, a special bitoric contact lens may be prescribed. It offers refracting surfaces on the front and back to correct the problem in much the same way that eyeglasses do.

If you are contact lens-intolerant or just want to be free from glasses or contacts, you may opt to have some form of vision correction procedure performed by a qualified eye surgeon. LASIK, the most popular form of laser vision correction, can provide correction for relatively high degrees of nearsightedness and astigmatism as well as some cases of farsightedness and astigmatism. See also **Hyperopia (Farsightedness)**; **Keratoconus**; **Laser In-Situ Keratomileusis (LASIK)**; **Presbyobia**; **Refractive Eye Surgery**; and **Vision and the Eye**.

ASTON, FRANCIS WILLIAM (1877–1945). Aston was an English scientist who studied chemistry at Mason College and worked there with P.F. Frankland on optical rotations. In 1910, Aston entered the Cavendish Laboratory, Cambridge, to work under J.J. Thomson, who at the time was examining the positive rays produced in discharge tubes. Aston left his research during the war but returned to Cambridge in 1919. He began using positive-ray analysis to study isotopes. One of Aston's greatest contributions is his invention of the mass spectrograph which he used to examine the isotopic conditions of over 50 (fifty) elements. Today, an improved mass spectrograph is used in the study of nuclear physics, chemistry, and organic chemistry. Aston had the honor of being Nobel Laureate in chemistry in 1922. See also **Aston Whole Number Rule**; and **Spectroscope**.

J. M. I.

ASTON WHOLE NUMBER RULE. The atomic weights of isotopes are (very nearly) whole numbers when expressed in atomic weight units, and the deviations from the whole numbers of the atomic weights of the elements are due to the presence of several isotopes with different weights.

ASTRO-1 AND ASTRO-2 MISSION. See **Space Science Missions: Universe**.

ASTROBIOLOGY. Astrobiology is a relatively new term that embraces the multidisciplinary study of the living Universe. It is the investigation of the origin, evolution, distribution, and destiny of life in the Universe. Astrobiology addresses some of the most profound questions of humankind: How did life begin? Are there other planets like Earth? What is our future as terrestrial life expands beyond the home planet? These questions are age-old. In the twenty-first century, however, advances in biological sciences, informatics, and space technology may make it possible for us to provide some answers.

Although the term had been used occasionally during previous decades as a synonym for "exobiology," astrobiology in its present incarnation was proposed by NASA Associate Administrator for Space Science Wesley Huntress in 1995. NASA encouraged this new discipline by organizing workshops and technical meetings, establishing a NASA Astrobiology Institute, providing research funds to individual investigators, ensuring that astrobiology goals are incorporated in NASA flight missions, and initiating a program of public outreach and education. NASA's role is derived from its history of studying the origin of life and searching for evidence of life on Mars or elsewhere in our solar system. Under the umbrella of astrobiology, these efforts are expanded to include the search for life within other planetary systems, as well as investigating the response of terrestrial life to global changes on Earth and to exposure to conditions in space and in other worlds. Astrobiology addresses our origins and also our aspirations to become a space-faring civilization.

Science Goals

Astrobiology addresses three basic questions, which have been asked in some form for generations. Today we have the technology to begin to answer these fundamental questions.

- How Does Life Begin and Develop?
- Does Life Exist Elsewhere in the Universe?
- What Is Life's Future on Earth and Beyond?

Pivotal questions about the origins of life and its distribution in the universe, once limited to the realm of philosophers, are, today, the

very stuff of hard science. The cross-disciplinary field of Astrobiology addresses precisely these questions, as biology, chemistry, genetics, geology, planetology, astronomy, cosmology, and other fields converge. The NASA Astrobiology Institute (NAI) provides the architecture essential to ensuring that Astrobiology's collaborative science connections are both possible and fruitful.

The diversity of life on Earth traces its ancestry to a single beginning. For insights into our past, we can examine the fossil record, where traces of life are found as early as 3.9 billion years ago, and we can study existing simple organisms. Microbial life, the single-celled organism, is and has been far more abundant than large and complex animals and plants, today and throughout Earth's history. Cyanobacteria, the "inventors" of photosynthesis, conditioned the Earth for oxygen-using life forms. They, and the inhabitants of extreme environmental niches (icy Antarctic rocks, Siberian permafrost, sulfurous thermal springs, salt beds, and deep sea hydrothermal vents) have much to teach us about life in Earth's cradle.

Work has begun on unraveling the mysteries inherent in our quest to understand our origins and the possibilities of life originating elsewhere. We know that liquid water, an essential ingredient for life on Earth, once flowed on the surface of Mars and likely exists today below the icy crust of Jupiter's moon Europa. Hints of fossil microorganisms tantalize us in a rock from the surface of ancient Mars. We find organic chemistry in interstellar clouds, we see planets circling other stars. We are discovering both the fragile and the robust aspects of life, as we investigate the history of mass extinctions on our planet, the results of subtle alterations in climate triggered by atmospheric change, and threats to our protective blanket of ozone. While we celebrate the ability of astronauts to live and achieve wonderful feats of science and engineering in space, we ponder the implications of adaptive changes experienced in the space environment. We are only beginning to probe the future of life beyond our home planet, Earth.

Searching for Habitable Planets

Is there anybody out there? Whether our imagination has been piqued by science fiction or by simply staring up into the night sky, we are fascinated by the possibility that life may exist in other worlds. Astrobiology and the technologies that accompany it suggest that someday this question may have an answer. The first step in reaching this goal is to find other planets outside our solar system that have the potential for supporting life.

The search for habitable planets begins with the search for all planets, habitable or not. With instruments such as the Keck Interferometer, large Jupiter-sized planets have been discovered, numbering more than the planets in our own solar system. Looking at the structure of the planets around our sun, it is tempting to conclude from these findings that other planets, smaller and possibly Earth-like, may hide in the shadows of these giants.

As we know it, life depends on the presence and long-term stability of liquid water. If we are to be successful in our search for life outside our solar system, we must be able to detect extrasolar planets that house this essential to life. Instruments like the Terrestrial Planet Finder (TPF) will search for hints of liquid water in the energy emitted from Earth-sized planets, perhaps giving humanity its first true hope at the possibility of life on other worlds.

Development of instruments such as the airborne Stratospheric Observatory for Infrared Astronomy (SOFIA) and the Space Infrared Telescope Facility (SIRTF) are already paving the way towards Astrobiology's goal of detecting habitable, Earth-like planets. The discovery of such worlds would undoubtedly shed new light on the nature of our universe, as well as our place within it. See also **Infrared Astronomy**; **Space Infrared Telescope Facility (SIRTF)**; and **Telescope (Astronomical-Optical)**.

Education and Public Outreach

The NASA Astrobiology Institute's outreach efforts establish it as an important medium for disseminating the unprecedented breakthroughs of Astrobiology to the American public. From K-12 curriculum development to Postdoctoral Fellows Program, from numerous workshops and conferences to its Internet site (**http://nai.arc.nasa.gov**), the Institute distributes key information to students, the media, and world at large. More importantly, the Institute serves as an initial entry point for these audiences as they enter into the adventure of Astrobiology. If you've ever wondered what a Polycyclic Aromatic Hydrocarbon is, log on to the website and Ask an Astrobiologist or interact with others in online forums.

Lead Institutions such as UCLA are already offering courses on both the graduate and undergraduate level. At UCLA, graduate students in the Microbiology program can join a course where original research papers relevant to Astrobiology are analyzed and evaluated in oral presentations.

For three years, The Marine Biology Laboratory has offered "Living in the Microbial World", a one-week intensive, hands-on teacher enhancement workshop for middle and high school teachers (grades 6–12), which focuses on the diversity and importance of microbes in the biosphere.

As the world of Astrobiology expands, the Institute, along with the Lead Institutions and Co-institutions are reaching out to their communities, bringing the world of stars and galaxies home . . . to Earth.

Astrobiology Roadmap: Goals and Objectives

The NASA Astrobiology Roadmap is the product of efforts by more than 150 scientists and technologists, spanning a broad range of disciplines. More than 100 of these participated in a three-day Roadmap Workshop held in July 1998 at NASA Ames Research Center, while others attended previous topical workshops and are participating by email. The co-chairs of the Roadmap team are David Morrison, Director of Space at NASA Ames Research Center, and Michael Meyer, Astrobiology Discipline Scientist at NASA Headquarters and Program Scientist for Mars Sample Return. The Roadmap participants include NASA employees, academic scientists whose research is partially funded by NASA grants, and many members of the still wider community who have no formal association with NASA.

The NASA Astrobiology Roadmap will provide guidance for research and technology development across several NASA Enterprises: Space Science, Earth Science, and the Human Exploration and Development of Space. The Roadmap is formulated in terms of ten Science Goals, and 17 more specific Science Objectives, which will be translated into specific programs and integrated with NASA strategic planning. In addition, the NASA Roadmap emphasizes four Principles that are integral to the operation of the Astrobiology Program.

In order to answer the fundamental questions of Astrobiology, the NASA Astrobiology Program purses the following ten science goals.

How Does Life Begin and Develop?

Goal 1: Understand How Life Arose on Earth. Terrestrial life is the only form of life that we know, and it appears to have arisen from a common ancestor. How and where did this remarkable event occur? We can now perform historical, observational, and experimental investigations to understand the origin of life on our planet. We should determine the source of the raw materials of life, either produced on this planet or arriving from space. We should seek to understand in what environments the components may have assembled and what forces led to the development of systems capable of deriving energy from their surroundings and manufacturing copies of themselves. We should also investigate the exchange of biological materials between planets to assess the possibility that life formed elsewhere and subsequently migrated to Earth.

Background. For the prebiotic Earth, we seek to understand the origin and chemical nature of organic and inorganic compounds, and the energy sources and micro-environments that created the context for the origin of life. Given a plausible primary source of organic components, alternative pathways by which such prebiotic compounds formed the ancient counterparts of proteins, nucleic acids, and lipid-like molecules can be investigated within plausible constraints. One major objective is to construct laboratory models of assemblies of biopolymers recognizable as protocells. These will then be used to create models for the first microorganisms able to replicate and evolve on the early Earth, thereby leading to a common ancestry that is consistent with the later development of biological diversity. Another approach is to use the phylogenetic and geologic record to point to characteristics of our earliest ancestor. We should also consider the possibility that life formed elsewhere and was seeded onto the developing Earth; if so, we can ask under what conditions elsewhere life might have arisen and been transported to our planet. Understanding the interplanetary transportation and survivability of organisms is also relevant to issues surrounding possible contemporary exchange of biological material with Mars and hence the importance of quarantine of Mars samples returned to Earth. Theoretical calculation of mass transport rates, life on Earth in extreme environments (See Goal 5), and further study of meteorites and collections of interstellar materials

should allow significant progress in understanding whether these natural processes provide a mechanism for spreading life through the universe. This research is closely related to the issue of planetary habitability (See Goal 6) and the general issue of the life principle (See Goal 2).

Goal 2: Determine the General Principles Governing the Organization of Matter into Living Systems. To understand the full potential of life in the universe we must establish the general physical and chemical principles that lead to the emergence of systems capable of converting molecules for energy and growth (catalysis), generating offspring (reproduction), and changing as conditions warrant (evolution). Terrestrial life is based on the chemistry of carbon moderated by liquid water. Such organic chemistry is common throughout the cosmos. But are terrestrial biochemistry and molecular biology the only such phenomena that can support life? Having only one example, we do not know which properties of life are general and necessary, and which are the result of specific circumstances or historical accident. We seek these answers by pursuing laboratory experimental approaches and computational theoretical approaches.

Background. The molecular machinery leading to the origin of life on other planets might well be substantially different from the one that formed on the early Earth because the remarkable versatility of organic chemistry offers multiple solutions for the basic requirements of life. Life on Earth represents only one example of living systems. One genetic code, one set of amino acids of specific chirality, and one energy currency have survived from primitive Earth. To understand the full potential of life in the universe it is necessary to go beyond our specific example and establish the general physical and chemical principles that lead to the emergence of the primary attributes of the living state: auto-catalysis, self-organization, spatial containment of functions, reproduction and evolution. This can be done by combining experimental and theoretical (computational) approaches, in which the fundamental principles governing biological organization of matter can be tested by constructing new biomimetic systems that possess the main attributes of a living state. This research is in effect a generalization of the origin of terrestrial life (See Goal 1) and is related directly to the question of life on other worlds (See Goal 6, 7, and 8).

Goal 3: Explore How Life Evolves on the Molecular, Organism, and Ecosystem Levels. Life is a dynamic process of changes in energy and composition that occurs at all levels of assemblage, from the molecular level to ecosystem interactions. Much of traditional research on evolution has focused on organisms and their lineages as preserved in the fossil record. However, processes such as the exchange of genetic information between organisms and changes within DNA and RNA are key drivers of evolutionary innovation. Modern genetic analysis, using novel laboratory and computational methods, allows new insights into the diversity of life and evolution at all levels. Complementary to such studies are investigations of the evolution of ecosystems consisting of many interdependent species, especially microbial communities.

Background. The powerful techniques of molecular biology and molecular phylogenetics are revolutionizing our understanding of the diversity of life and relationships between organisms. Studies of RNA and other conserved gene sequences have revealed previously unknown kingdoms of organisms in unlikely habitats, and have led to new hypotheses about environmental conditions for the origins of life. However, an understanding of the evolution of primary lineages requires more detailed studies at the genome level. Indeed, initial studies indicate that, early in evolution, transfers of genes between organisms may have been common. Coupled with mechanisms such as gene duplication and gene rearrangement, these processes indicate that simple mutation and selection are not the only evolutionary drivers. Studies of individual gene families must be extended to previously undescribed microbial species. New research teams and methodologies are needed to develop and process genome data from key taxa. If gene transfer is indeed an ancient process, it will be important to determine when and how key functions arose and spread in genomic consortia. This effort will allow reconstruction of the development of genomic complexity. Coordinated studies of microbial diversity and of changes in microbial communities are required in order to identify genetic and environmental factors that influenced the spread of biological diversity and its influence upon biospheric change. For example, we must understand how organisms affect each other, and how ecosystems alter the environment through modulation of chemistry and the composition of the oceans and atmosphere. The study of Earth's global ecology is being transformed by new technology (remote sensing and geographic information systems), process-oriented and interactive system modeling, as well as new paradigms for thinking about the global ecosystem. Our understanding of evolution will also be altered by considering catastrophic environmental changes of external origin, including asteroid and comet impacts and the consequences of nearby stellar explosions. This research is linked to studies of the co-evolution of life and the planet (See Goal 4), the ability of life to survive in extreme environments (See Goal 5), and the search for biomarkers on distant planets (See Goal 7). See also **Molecular Biology**.

Goal 4: Determine How the Terrestrial Biosphere has Co-Evolved with the Earth. Just as life evolves in response to changing environments, changing ecosystems alter the environment of Earth. Scientists can trace the co-evolution of life and the planet by integrating evidence acquired from studies of current and historical molecular biology (genomics) with studies of present and historical environments and organismal biology. We seek to understand the diversity and distribution of our ancient ancestors by developing increasingly sensitive technology to read the record of life as captured in biomolecules and in rocks (fossils), to identify specific chemical interactions between the living components of the Earth (its biosphere) and other planetary subsystems, and to trace the history of Earth's changing environment in response to external driving forces and to biological modifications.

Background. We need to use the geologic record to attach dates and environmental context to evolutionary events, leading to a robust history of the biosphere, based on biomolecular, paleoenvironmental, and paleobiological evidence. Further, by examining the history of life in an environmental context and by studying the evolution of biochemical pathways that yield preservable records (biominerals, accumulations of trace elements, organic molecules, characteristic fractionations of stable isotopes, etc.), we can begin to reconstruct the mechanisms that link environmental and biological changes. Research on these biochemical pathways will also create an inventory of bio-indicators that may be sought in ancient rocks on Earth and on other planets. Specific chemical interactions between the biosphere and its host planet, and their role as evolutionary drivers, will be illuminated by studies of biogeochemical cycles and significant biological byproducts, such as molecular oxygen. The development of Earth's atmosphere will thus be understood in much greater detail, with a new and more fundamental view of factors controlling its levels of oxygen and carbon dioxide. Another outcome will be a better understanding of the evolution of Earth's biosphere. Paleontological evidence for the first appearances of novel kinds of organisms will be integrated with molecular phylogenies using quantitative approaches to the fossil record and precise geochronology. Understanding the full diversity of our evolving biosphere requires that the fossil records of extreme environments be explored and documented, an exercise that also has relevance for the search for life on other worlds. All of this research requires a deeper understanding of evolutionary mechanisms at the levels of molecules, organisms, and ecosystems, as discussed under Goal 3. The results contribute directly to the identification of biomarkers (See Goal 7).

Does Life Exist Elsewhere in the Universe?

Goal 5: Establish Limits for Life in Environments That Provide Analogues for Conditions on Other Worlds. Life is found on the Earth anywhere liquid water is present, including such extreme environments as the interior of nuclear reactors, ice-covered Antarctic lakes, suboceanic hydrothermal vents, and deep subsurface rocks. To understand the possible environments for life on other worlds, we must investigate the full range of habitable environments on our own planet, both today and in the past. We will investigate these extreme environments not only for what they can tell us about the adaptability of life on this planet, but also as analogues for conditions on other bodies in our solar system, such as Mars or Europa.

Background. To understand the potential for life on other worlds, we should begin by investigating the limits to life on our own planet. The tolerance for extreme conditions shown by terrestrial life is much broader than previously thought. Recent research on some of the Earth's smallest inhabitants has shown them to be remarkably versatile in their choice of lifestyles, with communities of microorganisms thriving in such extreme environments as nuclear reactors, perennially ice-covered Antarctic lakes, the interiors of rocks, hydrothermal springs and deep subsurface aquifers. Some extreme environments, such as those near marine hydrothermal vents, have actually been suggested as possible sites for the origin of life on

Earth. Investigation of extremophile organisms and their habitats provide first-order scientific return in their own right (e.g., adaptive mechanisms, origin and evolution of life) as well as analogue environments for Mars and Europa exploration (See Goal 8). It is also of interest to identify terrestrial environments that do not support life, such as glacial ice fields, and to ask why life has not adapted to fill all environmental niches that are energetically possible. Such studies can also assist in identifying the chemical or morphological signatures of life in environments that differ significantly from that of the bulk of the Earth's surface (See Goal 7). See also **Mars**.

Goal 6: Determine What Makes a Planet Habitable and How Common These Worlds Are in the Universe. Where should we look for extraterrestrial life? Based on our only example (life on Earth), liquid water is a requirement. We must therefore determine what sort of planets are likely to have liquid water and how common they might be. Understanding the origin of water on our own planet and other member of the solar system will yield insights on the ways in which water might be distributed within an emerging planetary system, and research on climate changes in response to solar variability will investigate the long-term stability of habitability on a planet. Studying the processes of planet formation and surveying a representative sample of planetary systems will determine what planets are present and how they are distributed, essential knowledge for judging the frequency of habitable planets.

Background. The abundance of planets with habitable environments is critical for understanding the role of life in the universe. The formation of planets, and the resulting configuration of planetary systems, can be approached both empirically and theoretically. In order to understand fully the process of planet formation, especially as it relates to planetary habitability, our current observational data base must be expanded to include higher spatial and spectral resolution studies of protoplanetary disks, detection and study of extra-solar planetary systems (down to and including Earth-sized planets), and distribution and properties of small bodies and dust in the solar system. From our only known example of life, we conclude that habitability depends on the existence and long term stability of liquid water in which nutrient and waste transport can occur and catalytic function and exchange of genetic material are possible. There must also be a source of energy that maintains the system away from the equilibrium state. Since all life with which we are familiar requires liquid water during at least some stage of its life cycle, the criteria for habitability should begin with the need for liquid water. Even with this limitation, there are many questions to be answered in order to understand where life might originate and thrive. Was Earth's water included in the original planetesimals from which Earth formed, or added later by impacts of asteroids or comets? Given the changes in the Sun's brightness over the past 4.5 billion years, how was water maintained as a liquid throughout most of Earth's history? As a starting point, the habitable zone in any planetary system is most simply defined as the region where liquid water is stable on a planet's surface, which depends on the type of star and the planet's orbit (and may even be possible on a satellite around another planet). The frequency of occurrence of planets in habitable regions around other stars be answered empirically, by surveying a representative sample of planetary systems (including Earth-mass planets) and determining their configuration. Understanding the stability of climate is related to Goal 4, while establishing the limits of habitability relates directly to Goal 5 and Goal 8.

Goal 7: Determine How to Recognize the Signature of Life on Other Worlds. We are poised on the brink of searching for life, past or present, on a variety of worlds. This search requires that we be able to recognize extraterrestrial biospheres and to detect the signatures of extraterrestrial life. Within our own solar system, and based on our experiences here on Earth, we must learn to recognize structural fossils or chemical traces of extinct life that may be found in extraterrestrial rocks or other samples. To understand remotely sensed information from planets circling other stars, we should develop a catalog of possible signatures of life.

Background. Today, with recent discoveries of extrasolar planets and of possible evidence for past life on Mars, the age-old question "Are we alone?" is once again in the forefront of scientific inquiry. Our search for life beyond Earth requires an ability to recognize the potential for extraterrestrial biospheres and a capacity to detect the signatures of extraterrestrial life. Within our own solar system, we must learn to recognize the fossils or other biomarkers of extinct life that may be found in returned samples. It is also essential to learn to identify the chemical signatures of life on a distant world through remote sensing of its atmosphere or surface. On Earth, life has produced easily detectable atmospheric and surface changes. These changes include high concentrations of O_2 and O_3 in the atmosphere and the presence of a distinctive spectral feature (due to chlorophyll) on the surface. However, these effects have been most pronounced only for the last billion years of Earth history. For the previous several billion years during which Earth had life, the atmospheric and surface signatures are not fully understood. In exploring other worlds, it is critical that we generalize the process of coevolution of planet and life (See Goal 3 and Goal 4). A long-term consideration is to develop alternative methods of searching for life, such as detecting radio signals or other artifacts from an advanced civilization. See also **Planets and the Solar System**; and **Mars**.

Goal 8: Determine whether There Is (or Once Was) Life Elsewhere in Our Solar System, Particularly on Mars and Europa. Exciting data have presented us with the possibility that at least two other worlds in our solar system have (or have had) liquid water present. On Mars, there is evidence for stable flowing water early in that planet's history. Both in situ investigations and the analysis of returned samples will be necessary to understand Mars' historical climates and its potential for life. Extensive exploration of the martian surface will be required to evaluate the total potential for life on that planet, both past and present. Furthermore, exploration of the subsurface probably offers the only credible opportunity to find extant life on either Mars or Europa. Other planetary missions may identify additional sites of biological potential in our solar system.

Background. Beyond the Earth, the two worlds in our solar system that the are most likely to have, or have had, liquid water are Mars and Europa. The presence of liquid water, together with suitable energy sources, appears to be a requirement for life as we know it. On Mars there is evidence for stable flowing water early in that planet's history. Sedimentary deposits from possible paleolakes could hold fossil evidence of life that might have existed during this early wet period. Subsurface hydrothermal systems may persist on Mars today and are a possible target for a search for extant life. Both in situ investigations and the analysis of returned samples will be necessary to understand the past climate of Mars and its potential for life. In both cases, the selection of promising landing sites and identification of samples of biological significance are key. Europa is another planetary body, which probably has liquid water. If the presence of liquid water is confirmed, we will still need to address the history of these global oceans, to know whether they have persisted over geological time. Access to suitably selected europan surface samples may provide information on the contents of the water. On longer time-scales, deep penetration of the ice layer could provide a direct sample of the europan ocean and lead to remote submersible vehicles instrumented to search for evidence of marine life. Access to the deep subsurface of both Mars and Europa will required autonomous drilling technologies to provide the primary potential for discovery of extant alien life in our solar system. Understanding where to search and how to identify evidence for life are directly related to Goal 5, 6, and 7.

What is Life's Future on Earth and Beyond?

Goal 9: Determine How Ecosystems Respond to Environmental Change on Time-Scales Relevant to Human Life on Earth. Human-induced changes on Earth-including contamination of oceans, freshwater and soil; deforestation and desertification; exotic species invasion; ozone depletion in the stratosphere; changes in atmospheric CO_2 levels, and the potential for sea level rise, are altering the adaptation and evolution of our biosphere. Research at the level of the whole biosphere is needed to examine the habitability of our planet over time in the face of both natural and human-induced environmental changes. To help assure the continuing health of this planet and to understand the potential long-term habitability for other planets we need to assess the role of rapid changes in the environment and develop our knowledgebase to enable predictive models of environment-ecosystem interaction.

Background. Astrobiology will seek to understand and to predict how changes on Earth have and will alter the adaptation and evolution of our biosphere on time scales measured in units of one million years to less than one year. Rapid environmental changes on Earth associated with recent human activities include toxic contamination of oceans, freshwater and soil, deforestation and desertification, exotic species invasion, decline in ozone in the stratosphere, and large changes in atmospheric CO_2. To help assure the habitability of a planet for humans,

we will need to develop experimental methods to detect critical biophysical and geochemical components and their interactions during the formation of new ecosystems. It will be necessary also to integrate experimental results by development of models and theory that can address indirect effects and nonlinear environmental interactions that could produce unexpected and counter-intuitive impacts on the human biosphere. This integrated research approach will seek ultimately to identify the consequences for habitability of Earth if environmental changes outpace the capacity for adaptation and evolution of natural ecosystem components. Ultimately we desire to understand a range of conditions that applies to other planets as well as the Earth, including planets that are both young and old, biologically more simple or more complex than present-day Earth. We should attempt to broaden our perspective of the planet over time to investigate the spectrum of biosphere development. Biosphere-level research is needed to define the general habitability a planet and mechanisms of bioprotection, mainly through study of the interactions of Earth's ecosystems with its atmospheric chemistry and radiation balance. This research is a natural extension of Goal 3 and 4 into current times, moving from historical studies into direct observation and experiment dealing with rapid rates of change. See also **Ocean**.

Goal 10: Understand the Response of Terrestrial Life to Conditions in Space or on Other Planets. All life that we know (that is, terrestrial life) has developed in a one-gravity field, protected by the Earth's atmosphere and magnetic fields. What happens when terrestrial life is moved off its home planet and into space or to the Moon or Mars, where the environment is very different from that of Earth? Can organisms and ecosystems adapt to a completely novel environment and live successfully over multiple generations? Are alternative strategies practical, such as bioengineering organisms for specific environments? The results from attempting to answer such questions will determine whether life is strictly a planetary phenomenon or can expand its evolutionary trajectory beyond its place of origin.

Background. All life that we know evolved on Earth. Now, for the first time in human history, we have the capability to intentionally move life beyond our home planet. Organisms have been carried to other surfaces in our solar system and have survived; yet they have not proliferated there. Environmental conditions on other planets provide potentially insurmountable challenges for evolution of terrestrial organisms. Delineating the mechanisms that organisms use to adapt to environmental extremes on Earth or simulated environments for other planets will provide insights into the environmental envelope that allows life to exist. The critical near-term questions to be answered are whether (and what kinds of) organisms live reproductively successful lives over multiple generations beyond Earth, and what genotypic changes (changes in the genes or DNA sequence) and phenotypic changes (changes appearance or physiology) result. The International Space Station will provide a testbed for studying evolution and ecological interactions of organisms. These studies will determine if simple organisms and their ecosystems evolve.

How Does Life Begin and Develop?

Sources of Organics on Earth; Objective 1. Determine whether the atmosphere of the early Earth, hydrothermal systems, or exogenous matter were significant sources of organic matter.

Determining the primary sources and nature of organic matter from which living systems emerged on the prebiotic Earth is still a controversial endeavor. The key proposed sources include synthesis in the atmosphere of the early Earth; synthesis in warm hydrothermal systems or in geothermal subsurface environments; delivery to the early Earth by comets, meteorites and microscopic, interplanetary dust particles; or some combination of these possibilities. Each hypothesis leads to different predictions about the composition and availability of organic starting material and the nature of the earliest pre-metabolic processes leading to the origin of life. We must, therefore, determine the relative contributions of each of these sources of organic material to life's origins on the primitive Earth, and define and characterize those mechanisms that allowed adequate concentrations of these chemicals for the necessary interactions and reactions to occur.

Near- to Mid-Term. Using space missions and infrared telescopes, explore how organics, initially synthesized in the interstellar dust cloud from which the Solar System was formed, are chemically altered before they are delivered to earth. This research will help to determine the chemical structure and composition of exogenous organic compounds and the extent to which they contributed to the inventory of prebiotic organics on earth. This task will benefit from missions to analyze organic material in both interplanetary dust particles as well as meteor showers. In addition, ground, air (SOFIA) and space-based (SIRTF) observatories will provide key data. See also **Infrared Astronomy**.

Conduct realistic laboratory simulations of chemical reactions under the conditions existing on planetary bodies, on the surface of the primitive earth and in hydrothermal vents. Investigate the potential of the synthesized compounds to contribute to the formation of biological structures.

Perform computer modeling of prebiotic chemical synthesis in different environments taking into account appropriate external constraints, such as energetics, temperature, pressure, and surface catalysis potential.

Examine the geological record for evidence of environmental conditions on the early Earth. Examine ancient rock formations for the signature of early life in the form of microfossils, isotope ratios, and mineral assemblages, and obtain evidence for the redox state of the earth mantle near the time of the origin of life. A reducing mantle was essential to maintain a reducing atmosphere on the prebiotic Earth.

Study natural environments (e.g., hydrothermal vents) as models for primordial chemistry.

Future Extensions. Perform space missions to characterize more precisely quantities and compositions of exogenous and subsurface organic material.

Construct integrated models of the chemistry on the prebiotic earth that include contributions from different sources of organic matter and environmental constraints.

Perform planetary subsurface missions to obtain virgin endogenous material.

Perform planetary missions to understand possibilities for prebiotic evolution.

Origin of Life's Cellular Components; Objective 2. Develop and test plausible pathways by which ancient counterparts of membrane systems, proteins and nucleic acids were synthesized from simpler precursors and assembled into protocells.

For living systems to emerge from abiotic matter, organic constituents on the prebiotic Earth must have self-organized and acquired the capabilities needed to survive and reproduce, thus forming the earliest precursors of life. Eventually, the biomolecules of life became enclosed within a lipid membrane, forming rudimentary assemblages that resembled cells as we know them, or protocells. Among the essential protocellular functions were the acquisition and transduction of energy from the environment, and catalysis to support the synthesis of cellular components (metabolism) and information transfer to succeeding generations (genetics). To explain the origin of life on Earth, it is necessary to demonstrate that essential functions can be accomplished utilizing only the molecules that may have been available in the protobiological milieu. In contemporary life, all these functions are performed by complex systems of proteins, nucleic acids, and membrane-forming material. The early systems must have been much simpler.

Near- to Mid-Term. Conduct ground-based laboratory research on chemical pathways leading to the emergence of the macromolecules of life. These pathways should be consistent with the thermodynamic and environmental constraints on the early Earth. Develop models of primitive bioenergetics, replication, and catalysis of the reactions in metabolic pathways which can be linked via plausible, continuous paths to the same functions in modern organisms on Earth.

Future Extensions. Combined with studies on the chemistry and environmental conditions on the prebiotic Earth and with the analysis of metabolic evolution of microorganisms, this work will ultimately lead to the reconstruction of protobiological evolution from a collection of organic molecules to the earliest, unicellular organisms.

Models for Life; Objective 3. Establish replicating, catalytic systems capable of evolution and construct laboratory models of metabolism in primitive living systems.

To the best of our knowledge, the principal attributes of living systems anywhere in the Universe are their capabilities to replicate, to catalyze the chemical reactions of life, to integrate their diverse components to act in concert to support these activities, and to evolve. Building models that exhibit these properties from nucleic acids, proteins, membrane-forming molecules, other organic molecules, and possibly minerals, and establishing the range of conditions under which these systems can operate, will provide essential clues about hypothetical, different life forms that may have arisen

beyond the Earth. Such new models for the formation of chemical systems with the attributes of life can be predicted by computer simulations and constructed in laboratory experiments.

Near- to Mid-Term. Through laboratory experiments, develop and characterize self-replicating systems based on diverse molecules and recognition mechanisms. Based on *in vitro* evolution and rational design, construct simple structures capable of catalyzing biochemical reactions, driving bioenergetics, and performing other functions of a living system. Demonstrate coupling between these functions. Develop a computational research program to describe and understand auto-catalytic reaction networks, self-organization and self-reproduction phenomena, and collective behavior of simple biological systems with and without central (genomic) control.

Future Extensions. Construct models of self-replicating, evolving systems, capable of performing the basic functions of a living system. Relate these models to the environmental conditions in habitable zones in which they may arise. Of special interest are conditions that may have existed on Mars and Europa. This could provide clues about extinct or extant life forms, and generic recognizable features, that may be found in missions to these bodies. Establish the general, physical and chemical principles that drive the emergence of catalytic networks of chemical reactions, self-replication and the formation of cell-like compartments. General models of living systems offer considerable promise for biotechnology.

Genomic Clues to Evolution; Objective 4. Expand and interpret the genomic database of a select group of key microorganisms in order to reveal the history and dynamics of evolution.

Modern computational techniques in genomics and bioinformatics give exciting new insights into biological structure and function at all levels. Using these increasingly sophisticated techniques, detailed studies of evolutionary dynamics at the genome level should be conducted, ultimately to allow the reconstruction of the development of genetic complexity through evolutionary relationships. Recognizing that simple mutation and selection are not the sole drivers for evolutionary change, we must define the roles of mechanisms such as gene transfers between organisms, and gene duplication and gene rearrangement within an organism. Using the large array of databases now available, we must extend studies of individual gene families to previously uncharacterized microbial species. These studies, along with phylogenetic studies of evolutionary orthologues for key metabolic and information-processing systems in living cells, comparisons of sequences from discrete evolutionary lineages, and evolutionary studies of complex gene families within a single genome, will help determine when and how key biological functions arose and spread.

Near- and Mid-Term. Exploit the genomic databases that are already available, studying them in order to infer sequences of evolutionary steps and thus to estimate mechanisms (for example, duplication vs. transfer of genes). Notable progress for eukaryotic organisms can be expected using this approach.

Expand the databases by instituting a program of genomics focused on organisms representative of the metabolic diversity found among the prokaryotes. Full closure, with complete coverage of an organism's genome, is not required. Instead, information highly useful for the goals of the Astrobiology program can be obtained from the techniques of so-called "random genomics," in which accessible fragments resulting from diverse cleavages are sequenced.

Develop new information systems to organize and interpret molecular sequence data in order to determine the mechanisms, frequency, and impact of key molecular drivers of evolution.

Future Extensions. This effort will contribute to a model for the evolutionary dynamics of microbial genomes, with potential applications that range from a reconciliation of biomolecular records of early life with geologic records, and also to enabling revolutionary new vistas in bioengineering.

Linking Planetary and Biological Evolution; Objective 5. Describe the sequences of causes and effects associated with the development of Earth's early biosphere and the global environment.

It has already been established in specific instances that the environment has influenced the evolution of certain biota. For example, respiring animals have developed as atmospheric levels of oxygen increased. But the events that have triggered such linked trends and the forces that have sustained them are either unknown or poorly characterized. We can ask, did the geologically controlled availability of a particular trace element suddenly allow the synthesis of a key enzyme? Or, were biological developments themselves the initiators? To answer such questions, we must more accurately determine the times at which biological and geological events occurred, the sequences of the steps involved, and the budgets and distributions of geochemical reactants and products in the Earth's crust, oceans and atmosphere. In this way, we can attach dates and environmental contexts to evolutionary events, and thereby develop a robust, integrated history of the biosphere that incorporates biomolecular, paleoenvironmental, and paleobiological evidence.

Near- to Mid-Term. Conduct intensive sampling of ancient sediments to reconstruct, at high temporal resolution, their settings at the times of their deposition.

Examine such comprehensive collections using geochemical and paleontological techniques at levels of detail that allow the dissection of the record of key events in earth history and the definition and testing of plausible relationships between causes and effects.

Elaborate the phylogenies and mechanisms of evolution of key enzymes and of metabolic pathways that had profound impacts on the environment (e. g., production of biomass, oxygenic photosynthesis, sulfate reduction, nitrogen fixation, and methanogenesis).

Define those features within the record (morphological fossils or rock textures, biogeochemical signals) that are related to those significant evolutionary transitions.

Reconstruct the development of the biogeochemical cycles of carbon and of its redox partners.

Because of their clear relevance to planetary exploration, search specifically for strata that provide information about possible forms of life and chemical reactions in hydrothermal systems, aquifers, and evaporitic basins.

Future Extensions. Determine the first appearances of novel organisms and integrate them with molecular phylogenies using quantitative approaches to the fossil record and precise geochronology. A better understanding of the fossil records of extreme environments will greatly improve the effectiveness of the search for life on other worlds. These studies will lead to a better understanding of the evolution of Earth's biosphere and environment.

Develop chronologies on less than 10,000 year timescales to broaden our understanding of ecosystem responses to rapid changes, relevant to human-related timescales.

Microbial Ecology; Objective 6. Define how ecophysiological processes structure microbial communities, influence their adaptation and evolution, and affect their detection on other planets.

We must expand studies of microbial ecosystems because the diversification, evolution, and survival of the early biosphere depended upon the efficient coordination of resources and processes by diverse microbial populations. Interdisciplinary studies of microbial communities are required to identify the genetic and environmental factors that influenced the spread of biological diversity and its impact on biospheric change. For example, we must define and quantify the relationship between environmental heterogeneity and microbial diversity and its bearing on evolution. We must understand how organisms affect each other, and how ecosystems modulate the environment through the processes of chemistry and the changing composition of the oceans and atmosphere due to natural geophysical processes and biology.

Near- and Mid-Term. Establish how mutualistic and competitive interactions within communities influence the development of biological diversity.

Document the role of ecological processes in the exchange of genetic information between microorganisms.

Document how microbial communities produce biological marker compounds, structures, minerals, and isotopic compositions that might serve as ecological signatures preserved in rocks and detectable in remotely sensed atmospheres.

Relate microbial communities to their fossil equivalents by understanding the processes of diagenesis, mineralization and burial of these communities.

Future Extensions. Microbial ecological studies will substantially improve our understanding of early life's adaptation and evolution. These studies will guide the development of both laboratory and theoretical models for the structure and function of ecosystems. These models will contribute ultimately to a better understanding of life's potential to adapt to future changes on Earth and beyond.

Does Life Exist Elsewhere in the Universe?

The Extremes of Life; Objective 7. Identify the environmental limits for life by examining biological adaptations to extremes in environmental conditions.

The habitable zone is defined ultimately by life's capacity to adapt to extremes in key environmental parameters. For example, Mars' habitability is severely constrained by low temperatures, low water potential, and damaging photochemical reactions. The hazards of extreme conditions can be mitigated by biochemical and structural countermeasures within cells, and by processes at the ecosystem level. An effective research program will combine studies of natural ecosystems, physiology, and genetics with the development of new research technologies and missions for the exploration of extreme environments-first in our own Solar System and later, beyond.

Near- to Mid-Term. Identify and characterize the biota in those extreme environments on Earth that are most relevant for a search for life on Mars and Europa.

Define more completely the range of strategies for obtaining biochemically-useful energy.

Define the mechanisms that cells and ecosystems have evolved to survive the extremes in environmental conditions.

Define the potential for fossilization and preservation of biota in extreme environments.

Determine whether the life forms from extreme environments on Earth could exist in other planetary environments.

Future Extensions. This research will help to define more completely the full range of life's capacities for survival. It will lead to more effective strategies to search for life beyond Earth, because it will aid in the selection of sites for exploration, and it will optimize our ability to recognize evidence of life and its fossils.

Past and Present Life on Mars; Objective 8. Search for evidence of ancient climates, extinct life, and potential habitats for extant life on Mars.

The requirements for life on Earth imply that liquid water is the critical requirement for life on other worlds of the Solar System. Operationally, the search for past or present life is therefore a search for past or present environments where liquid water may be (or may have been) found. There is direct evidence that Mars once had liquid water on its surface, and indirect evidence that even today there may be subsurface Martian aquifers and/or hydrothermal systems. The search for fossils, either biochemical or structural, would focus on aquatic depositional environments, such as sedimentary deposits from former lakes or hydrothermal systems. Chemical, analyses of samples formed under habitable conditions can offer insights into biologically relevant chemistry that may have occurred in these environments. Both the selection of sites bearing evidence of habitable environments (past and present) and the in-situ analysis of surface materials will enable a sample return program that effectively addresses astrobiology goals.

Near- to Mid-Term. Continue to collect martian meteorites and conduct comprehensive analyses of them. Improve methodologies for identifying biomarkers.

Conduct global visual and spectral reconnaissance of Mars to identify paleolakes and sites of past hydrothermal activity by determining the presence of fluvial features, shorelines, and precipitates such as carbonates, phosphates, silica and evaporites.

Locate, sample, and characterize geologic deposits that record evidence of the early Mars climate and potential biosphere.

Develop geophysical methods to remotely characterize the potential for subsurface liquid water on Mars. Working with external agencies and industry, develop technologies capable of accessing and retrieving samples from deep (>5 km) below the Martian surface.

Develop technologies for accessing broad areas of the Martian surface.

Future Extensions. On Mars access to sediments deposited in lakes as well as potential subsurface hydrospheres requires sampling capabilities beyond the current state-of-the-art. To reach paleolake sediments it would be necessary to get through the aeolian dust which may extend to depths of 10 meters (32.8 feet), and access to depths of 5 or more kilometers (over 3 miles), may be required for hydrospheres. The long-term goals in the search for extant and extinct life on Mars thus rely in large extent upon broadening the sphere of Martian exploration through advanced mobility and drilling technologies. Even in the short term, greater access will allow sample returns with greater relevance to life. These returned samples will help us look more effectively for life elsewhere. In the long term, increasing the sphere of exploration will set the stage for the human assisted search for past or present life on Mars. See also **Mars**.

Life's Precursors and Habitats in the Outer Solar System; Objective 9. Determine the presence of life's chemical precursors and potential habitats for life in the outer solar system.

Recent tantalizing evidence for the possible presence of subsurface liquid water on Europa and other Solar System bodies has extended the search space for life to the outer Solar System. A first step in this search, as with Mars exploration, is to determine the spatial and temporal distribution of liquid water in our Solar System. The discovery of organic or other prebiotic substances on these bodies may shed light on both the origin of these materials and the chemical processes that determine(d) their composition. For example, we might establish whether prebiotic substances came from the infall of primitive exogenous debris, or from aqueous chemical transformations within Europa itself. This knowledge will help us understand the relevance of such chemistry to prebiotic processes and/or life itself, either Earth-based or extraterrestrial. Finally, observations of Titan — and lesser bodies such as comets and asteroids — will shed light on the complexity and prebiotic relevance of organic chemical reactions that occurred in those bodies.

Near- to Mid-Term. Determine the organic and biogenic element composition of the gas, ice particles, dust, and smaller bodies (eg. comets and asteroids).

Develop orbital flight experiments to determine the inventory of organic compounds and biogenic elements on Europa's surface.

Map the thickness of the surface ice and search for evidence of liquid water on Europa.

Initiate technology development for in-situ and/or sample return analysis of surface material on Europa associated with dark (linear, etc.) surface features.

Future Extensions. Explore further for evidence of habitable conditions and/or life on Europa and other outer planet satellites. Analyze, in situ and on returned samples, organic material from the youngest units on Europa for biogenic origin. Initiate technology development for exploration of the purported subsurface ocean on Europa, searching for signs of life. Develop technology for performing chemical analyses of comets, asteroids and other small objects to determine their prebiotic relevance.

Natural Migration of Life; Objective 10. Understand the natural processes by which life can migrate from one world to another.

The observational data that demonstrates the availability of organic molecules and water throughout the cosmos raises the possibility that living systems can exist beyond Earth. Other data allow us to argue that life could be transported between planetary bodies and could, possibly, become established on another world. Current models indicate that there are natural means to propel organisms into interplanetary space. For example, meteorites that originated on Mars have been found on Earth; these samples verify that such an exchange of planetary material has occurred. In addition, experimental evidence from the orbiting Long Duration Exposure Facility and from at least one Surveyor lunar lander indicates that some common terrestrial microorganisms can survive in excess of five years. Finding life in extreme environments on Earth suggests that life might survive in liquid water niches on other planetary surfaces, and that certain life forms may be common throughout our Solar System. For several reasons pertinent to Astrobiology, we must determine if life from one world can establish an evolutionary trajectory on another.

Near- to Mid-Term. Establish models to determine probabilities for life's transport to, and survival on another planet.

Search for evidence of an external origin for terrestrial life, or of exchanges between the biosphere of Earth and of that Mars or other planets. Search for this evidence in meteorites, in geologic samples and in the biochemistry of life.

Sample and analyze cometary material to search for evidence of extraterrestrial life or its precursors. Examine meteor storms, comet coronae and tails, and cometary debris collected by orbiting satellites.

Future Extensions. The potential seeding of Earth life on other planetary surfaces, both intentionally and unintentionally, is possible.

Understand the interplanetary transportation and survivability of organisms and use this information as a basis for quarantine of samples returned to Earth.

Origin of Habitable Planets; Objective 11. Determine (theoretically and empirically) the ultimate outcome of the planet-forming process around other stars, especially the habitable ones.

Because of our working assumption that life is a planetary phenomenon, we must understand the planet formation process. Astronomers must determine, in a statistically valid manner, the distribution of planets and planetary orbits and masses — around a range of star types having a range of ages. Specifically, astrobiology is most concerned with habitable planets, defined as those where liquid water can exist on the surface. Other types of bodies, for example Saturn's moon, Europa, might have subsurface liquid water and perhaps subsurface life as well, but the life zones on such bodies cannot be examined remotely in the way that surface biospheres can. The size and location of this zone varies with the type of star and its age. A multi-pronged program should be mounted to detect habitable planets in sufficient numbers so as to understand their distribution, and help guide the development of future large spaceborne interferometers — the technique of choice for finding (and, perhaps, characterizing) distant planetary bodies. Astrobiologists must also create theoretical models of the processes that lead to the origins of habitable planets, to understand the provenance of the water, minerals, and organics that permit the origin and early evolution of life. Analyses of meteorites will continue to help us constrain these models.

Near- to Mid-Term. Conduct theoretical modeling of the planetary formation process, and catalog the conditions that lead to habitable planets. Incorporate meteoritical studies of aqueous alteration of primitive bodies as in-situ boundary conditions on these models.

Conduct ground based studies to search for the smallest planets that can be detected around a variety of stellar types. Utilize a variety of techniques, including astrometry (Keck and Large Binocular Telescope interferometers, plus others), radial velocity searches, and eclipse photometry, to carry out sustained searches for habitable planets. This will lead to solutions for key technological, and data analysis problems facing larger spaceborne systems. See also **Telescope (Astronomical-Optical)**.

Carry out eclipse photometry or alternative techniques that will characterize the distribution, sizes, and orbits, of planets surrounding a wide variety of star types, with adequate statistics to establish the properties of the planet forming process, down to and including terrestrial size planets in the habitable zones of their stars.

Coordinate efforts with existing and planned facilities to study the process of planetary system formation: SIRTF and SOFIA to inventory the number and composition of small bodies in the Solar System, and to study protoplanetary disks in the Galaxy; SIM to accurately characterize the dynamics of planetary systems identified by the survey mission. Simulate in the laboratory the formation, growth, and evolution of interplanetary grains and organics that contribute directly to planet formation. Develop the criteria for, and a catalog of potentially habitable systems.

Future Extensions. Construct coupled cosmochemical/astrophysical evolution models of growing planetesimals and early planets that can serve as boundary conditions for the origin of life. This will lead to understanding aspects such as the influence of early core formation and metal segregation, and giant impacts (as perhaps controlled by different configurations of giant planets) on thermal, oxidation, and atmospheric state.

Contribute these research findings to the development and flight of TPF to image nearby planetary systems and take global spectra of planets in the habitable zones.

Effects of Climate and Geology on Habitability; Objective 12. Define climatological and geological effects upon the limits of habitable zones around the Sun and other stars to help define the frequency of habitable planets in the universe.

The limits of a star system's habitable zone are determined in part by the stability of liquid water on the surface of planetary bodies, both instantaneously and over long time periods, as the parent star luminosity changes. Planetary habitability also depends on the stability of the planetary system, including the gravitational effects of large (Jovian-sized) planets or nearby stars on the distribution and dynamics of potential large impactors. Detection of habitable planets outside of our own Solar System will rely on spectroscopic observation of key atmospheric constituents-including water, carbon dioxide, ozone, and possibly others. Among the factors which affect liquid water's stability are the mass, composition, and dynamics (including effects of clouds) of a planet's atmosphere. The development of multidimensional general atmospheric circulation models-including the effects of clouds-for other planets will be critical in defining the distribution of liquid water in the universe.

Near- to Mid-Term. Conduct a theoretical research program to model the role of clouds (both CO_2 and H_2O) on early Mars, to explore could formation, radiative effects, and effects on atmospheric dynamics, all of which affect the location of the outer edge of the liquid water region, or habitable zone.

Study the radiative effect of water clouds in a dense, runaway greenhouse atmosphere such as may have existed on Venus, and determine how this influences the location of the inner edge of the habitable zone.

Extend these models to include a broader range of planetary sizes and orbital radii, in order to explore more fully the role of climate in determining the extent of habitable zones in other putative solar systems.

Search for direct, in situ evidence for liquid water on Mars, along with other surface minerals (e.g., carbonates and sulfates) that may provide information about long-term climate evolution.

Develop better models of how hydrogen escapes from H_2-rich, primitive atmospheres and how this would have affected atmospheric evolution on the early Earth and on other, Earth-like planets.

Determine whether the primitive Earth (and, by extension, other planets) could have developed an organic-rich, atmospheric haze layer such as that found on Titan, and explore the consequences of such haze layers for atmospheric and biological evolution.

Future Extensions. These models ultimately will generate a paradigm for planetary habitability to help guide, as well as be tested by, astronomical observations of extrasolar habitable planets. The interplay between these climate models and the Mars sample return analysis program will allow us to determine whether Mars is inhabited now or whether it may have been inhabited in the past.

Extrasolar Biomarkers; Objective 13. Define an array of astronomically detectable spectroscopic features that indicate habitable conditions and/or the presence of life on an extrasolar planet.

Perhaps within the next decade or so, we will be able to obtain infrared spectra of extrasolar planets that are situated within the habitable zones of stars within approximately 15 parsecs (approximately 50 light years) of our own Solar System. Accordingly, we must develop the database for interpreting those spectra, both for evidence of habitable conditions (e.g., the presence of liquid water) and for evidence of life. Aspects of the strategy include developing appropriate observational approaches that optimize sensitivity and spectral and spatial resolution, creating models of atmospheric chemistry and its evolution, and achieving an understanding of the factors that control the composition of biological gas emissions to the atmosphere. We must develop the ability to discriminate between those environmental conditions and gas compositions that indicate a geologically active but "lifeless" planet, versus those conditions and compositions that compel a biological interpretation.

Near- to Mid-Term. Determine the atmospheric compositions that are maintained during the lifetimes of habitable planets that lack biospheres.

Define the biological and environmental controls upon the emission of biogenic gases, including oxygen, to the atmosphere.

Develop global models for the composition of Earth's early atmosphere, with particular emphasis upon the fate of reduced biogenic gases. Calculate synthetic spectra of Earth-like planetary atmospheres, both with and without free O_2, to aid in designing future space-based interferometry missions, such as TPF.

Identify a menu of biologically produced volatile atmospheric species that could be detected using an interferometric telescope having a resolving power (I/DI) of 100.

Define the spectral signatures of the Earth's surface that might be detected remotely and provide evidence of life.

Future Extensions. The requirements for detecting extrasolar biospheres in association with a range of atmospheric compositions will be key drivers behind the designs of interferometric telescopes that will obtain spectra of extrasolar planets. The Astrobiology research program therefore must contribute substantially to the optimization of those designs. The program must lead the continuing search for novel methods to detect remote biospheres spectroscopically.

What is Life's Future on Earth and Beyond?

Ecosystem Response to Rapid Environmental Change; Objective 14. Determine the resilience of local and global ecosystems through their response to natural and human-induced disturbances.

The ability of a planet to support the long-term existence of life depends upon life's ability to withstand changes in its environment from a variety of causes. Throughout its history, life on Earth has experienced such changes with events ranging from impacts of asteroids and comets — and their resultant global manifestations — to ice ages of varying duration. Throughout each of these changes, life generally has responded initially with reductions in genetic diversity, followed by recoveries and continued increases in biodiversity. The current possibilities for major impact of human activities on the terrestrial biosphere (such as the depletion of stratospheric ozone) constitute an excellent observational laboratory to test the vulnerability of ecosystems, both large and small, to environmental changes with timescales commensurate with those of human culture. Studies of such ecosystem response to rapid environmental changes will help extend ecosystem models on the Earth and to other worlds, allow predictions of responses to major, planet-wide changes, and identify limits to these changes beyond which life may not be able to recover.

Near- to Mid-Term. Determine the critical biophysical and geochemical components and process interactions during the reformation of terrestrial ecosystems, by conducting field campaigns to sites where recent near-sterilizing events have destroyed most of a natural ecosystem (e.g., areas near volcanic eruptions, burn scars from major wildfires, oil spill sites, etc.). Couple species recovery patterns with selected measurements of radiation balance, microclimate, toxicity, and biogeochemistry.

Determine key spectral indicators of life's response to major environmental changes such as air and water temperature changes, volcanic eruptions, pollution, deforestation, desertification, etc.

Create local and global models of increasing complexity, of ecosystems and their response to changes in the environment.

Support technology development of advanced spectroscopic sensors (particularly hyperspectral), automation, and information processing suited for obtaining key data on entire ecosystems and their environments.

Future Extensions. Extend ecosystem perturbation models to increasingly large sizes, eventually aiming for global predictive models. Include remotely-sensed data, coupled with ground truth measurements, to refine these models.

Apply models obtained through research on ecosystem response to the development of biomarkers for remote detection of life.

Develop models of ecosystem change that ultimately could assist our understanding of change in the geologic past.

Earth's Future Habitability; Objective 15. Model the future habitability of Earth by examining the interactions between the biosphere and the chemistry and radiation balance of the atmosphere.

Life on Earth has been so successful that the very environmental conditions needed to support present-day life forms are strongly coupled to — and modified by — ecological processes. The chemistry of Earth's atmosphere is strongly influenced by life. For example, the evolution of oxygenic photosynthesis ultimately led to an oxygen-rich atmosphere and to the development of the protective ozone layer to block lethal fluxes of ultraviolet radiation. The production and consumption of radiatively-active trace gases — which influence global temperatures-are mediated by microbial and plant ecosystems. In the near-future, human-induced changes in levels of carbon dioxide and trace gases will alter the radiation balance of the atmosphere. In the more distant future, long-terms trends in biogeochemical cycling and solar luminosity will drive environmental changes that will compel the biosphere to adapt. Therefore, the environmental conditions of a habitable planet are influenced, not only by external and geological factors, but also by the biosphere, including humanity, and how it has evolved.

Near- to Mid-Term. Define, through both remote sensing analysis using the Earth Observing System and aircraft, as well as new laboratory and field ecology experiments, aspects of the chemistry of Earth's atmosphere that are strongly dependent on ecological processes and biogenic trace gas fluxes.

Develop new observations of the oceans and terrestrial surface that can be incorporated into coupled models of global atmospheric chemistry, and to the extent possible, used to hindcast into the past for calibration and to predict into the future.

Develop models of Earth's historical biogeochemistry, and combine these with retrospective experimental studies to understand the geochemical relations of ecosystems and organism-level studies of physiological capacity.

Future Extensions. Use computer modeling and remote sensing data analysis to develop new theories of the potential nonlinear responses that can be expected in coupled biosphere–atmosphere systems. Support the coupling of Atmospheric General Circulation Models (AGCMs) with paleo-ecological observations and modern satellite perspectives of the Earth's changing biosphere.

Bringing Life with Us beyond Earth; Objective 16. Understand the human-directed processes by which life can migrate from one world to another.

For the first time in human history, we can intentionally move life beyond our home planet. As a result, humanity is entering a new evolutionary territory — space — in a manner analogous to the first sea creature crawling out onto the land, with the attendant requirement for supporting technology. This time, however, we are able to document this evolutionary trajectory with the tools of modern molecular biology and to engineer artificial ecologies that may be necessary for evolutionary success in this new environment. Two factors must converge to enable the successful evolution of terrestrial life beyond Earth. First, we must understand and provide the physiological requirements for reproduction in space for a wide range of organisms. Second, we must engineer the artificial ecosystems that would promote survival and evolutionary success beyond Earth. The results derived from addressing this objective will answer a fundamental question about life in the universe generally and the nature of life on Earth specifically. Is life purely a planetary phenomenon or is life able to expand its evolutionary trajectory beyond its home planet?

Near- to Mid-Term. Use low earth orbit opportunities as a testbed for studying evolution and ecological interactions in the space environment (microgravity and/or high radiation) of organisms from simple to complex, including "wild" biota indigenous to the spacecraft, and determine how to promote evolutionary success. Extend these investigations to other planetary bodies in concert with human exploration of the solar system.

Identify adaptive mechanisms for responses to changes in gravity, radiation, pressure, temperature, and atmospheric components on a variety of organisms and ecosystems; identify the biological responses of these organisms and ecosystems to the space station environment or the environment on other planets.

Establish environmental limits for terrestrial life, especially those that have the potential to survive without protection or with minimal protection on other worlds.

Elucidate the characteristics of environments necessary to sustain life in space and beyond including higher plants and animals as part of a sustained regenerative ecology and indigenous resources in extraterrestrial environments.

Conduct multiple generation studies of multicellular organisms on the Space Station to determine if complex life can evolve beyond Earth.

Engineer closed and open environments as prototypes for human exploration of other planets. Test such system in analog environments on Earth and in space.

Future Extensions. Place candidate ecosystems on extraterrestrial surfaces and document their evolution.

Establish permanent colonies of humans and other organisms in space and on another planetary surface.

Engineer life for survival, adaptation, and evolution beyond Earth.

Planetary Protection; Objective 17. Refine planetary protection guidelines and develop protection technology for human and robotic missions.

Within the coming decade, significant advances in Astrobiology are likely to come from many sources — remote sensing, in situ experiments, sample return missions, and Earth-based research. We can anticipate that this new information about physical, chemical and geological environments on planets, planetary satellites, and other Solar System bodies will provide important details related to the origin, evolution, nature, and evolutionary potential for living entities on Earth and elsewhere. During this period of intense exploration and research, there will be a continuing need to apply planetary protection principles to avoid scientifically and biospherically harmful cross contamination of the planets and celestial bodies. Such planetary protection controls must meet NASA and COSPAR policies, satisfy technical and scientific concerns, and reassure the public that appropriate safeguards will be taken at every step of exploration.

Near- to Mid-Term. Conduct an international conference to discuss the ethical issues associated with planetary protection.

Assess the risk and potential impact of importation of alien life to a planet.

Develop the knowledge base and recommendations for implementation plans and policies for human exploration.

Review and recommend refinements to planetary protection policies and guidelines for robotic solar system exploration that incorporate the latest scientific information and technological advances.

Enlist the aid of a broad contingent of international experts to explore ethical and theological questions related to the existence of extraterrestrial life, the potential for harmful cross contamination, and the implications of long-term, large-scale space and planetary exploration, habitation and engineering.

Develop methodologies, taking advantage of the latest technologies, to aid in the implementation of planetary protection for robotic missions. These will include containment and isolation on Earth, life detection, cleaning, and sterilization.

Future Extensions. Understand the risk for cross-contamination of life throughout the solar system.

Develop new or refined technologies necessary to avoid harmful cross contamination during human exploration.

Develop and deploy new technologies to sense life and its diversity, to guide our exploration of the universe.

Principles

In addition to goals and objectives, the NASA Roadmap emphasizes four operating principles that are integral to the Astrobiology Program.

Principle 1 Astrobiology is multidisciplinary, and achieving our goals will require the cooperation of different scientific disciplines and programs.

Principle 2 Astrobiology encourages planetary stewardship, through an emphasis on protection against biological contamination and recognition of the ethical issues surrounding the export of terrestrial life beyond Earth.

Principle 3 Astrobiology recognizes a broad societal interest in our subject, especially in areas such as the search for extraterrestrial life and the potential to engineer new life forms adapted to live on other worlds.

Principle 4 In view of the intrinsic excitement and wide public interest in our subject, Astrobiology includes a strong element of education and public outreach.

Note: The foregoing information on Astrobiology Roadmap was furnished by DAVID MORRISON and GREGORY K. SCHMIDT, NASA, Ames Research Center, Moffett Field, CA.

NASA's Astrobiology Institute (NAI)

The Astrobiology Institute, established in July 1998, employs a multidisciplinary focus to bring together astronomers, biologists, chemists, exobiologists, geologists, and physicists. A key goal is to search for the origins of life — on Earth, elsewhere in our solar system, and beyond.

NASA selected Dr. Baruch Blumberg, distinguished professor, researcher, biochemist, and winner of the 1976 Nobel Prize for Physiology or Medicine, as Director of NASA's Astrobiology Institute (NAI) 1999-2002. On September 6, 2002 NASA announced that it has selected Dr. Bruce Runnegar of the University of California, Los Angeles, as the next director of NASA's Astrobiology Institute (NAI).

As director of the Institute, Runnegar will lead the consortium in its efforts to answer the three big questions central to astrobiology: How does life begin and evolve? Does life exist elsewhere? What is life's future on Earth and beyond? "The answers to these questions will not come quickly," said Runnegar. "That's why NASA needs to attract bright young people to the field of astrobiology." Part of his role, Runnegar said, will be to develop educational opportunities in parallel with new astrobiology science objectives.

NASA's Astrobiology Institute (NAI), with eleven Lead Institutions and numerous affiliated organizations, will coordinate and integrate the cross-disciplinary investigations fundamental to the field of Astrobiology. NAI is a "Virtual Collaboratory", distributed across the United States and bound together through advanced telecommunications and electronic networking. The Institute represents a partnership between NASA, universities, and research organizations to promote, conduct, and lead integrated multidisciplinary research, to train young scientists, and to provide public access to the adventure of studying the living universe.

Lead Member Institutions. NASA Ames Research Center initially will integrate research related to the contribution of organic matter to planets; the formation and evolution of habitable planets; the origins of key metabolic pathways in primitive cells; the structure, function, and biological markers of microbial ecosystems and the effects of rapid environmental changes on ecosystem properties. http://astrobiology.arc.nasa.gov/

The Ames Research Center is currently working on six areas of study, within the field of Astrobiology.

- Chemical Building Blocks of Life. Some of the complex organic molecular building blocks of life might be produced in interstellar space in the small (0.1 μm), cold (20 K) precometary ice particles. Brought in by comets and cometary debris, some of these molecules could have survived the accretion process that produced the hydrosphere and atmosphere on the Earth. Some of these complex molecules are formed in the interstellar/precometary ices by harsh ultraviolet radiation and some are formed in red giant atmospheres and subsequently frozen into these ices. Thus, interstellar ices are a rich source of organic feedstock material to planetary systems, carrying the potential to seed habitable planets throughout the galaxy. Recent work has shown that the ices in comets are remarkably similar to those in the protostellar regions of dense clouds. Thus, the time is ripe for in-depth studies of realistic interstellar/cometary ice analogs, both through spectroscopic observations and with realistic extraterrestrial ice simulation experiments in the laboratory.
- Habitable Planets. This research addresses the type of habitable planet in the "classical" sense, meaning a planet with an atmosphere having liquid water on the surface. Planets that fit this definition may eventually be observable spectroscopically in searches beyond our own solar system. We will study the processes that determine the water and volatile inventory of an evolving planet, emphasizing the solar system because of the existence of meteoritic and other data but also extending the analysis to other possible solar systems. We will also consider key processes that affect the evolution of water once it has been delivered to a planet. Climatological research completes the chain of studies needed to determine the existence of liquid water on a planet's surface.
- Laboratory Models of Protocellular Processes. We will create simple biomolecular systems that are capable of performing essential cellular functions, and we will determine conditions under which they can work together in a cellular environment. Our hypothesis is that the emergence of genomically controlled protocells was preceded by a period in which communities of membrane-bound, cell-like structures were evolving to gain complexity in the absence of nucleic acids. Thus, we propose a conceptually new view of protocells as structures built of evolving components related to those present in contemporary cells but functioning without genomic control. The hypothesis will be tested by building both mathematical and laboratory models of protocellular life.
- Early Microbial Ecosystems: Modern Analogs. We propose to examine the roles played by ecological processes in the early evolution of our biosphere, as recorded in geologic fossils and in the macromolecules of living cells. (1) We will better define the microbial mat microenvironment, which was an important milieu for early evolution. (2) We will compare mats in contrasting environments to discern strategies of adaptation and diversification, traits that were key for long-term survival on early Earth. (3) We will select sites that mimic key environmental attributes of early Earth and thereby focus upon evolutionary adaptations to long-term changes in the global environment. (4) Our studies of gas exchange will contribute to better estimates of biogenic gases in Earth's early atmosphere.
- Rapid Rates of Ecological Change. Regarding rapid rates of change on Earth, we will explore the hypothesis that the spatial variability and magnitude of large climate events (El Niño Southern Oscillation [ENSO] and Younger Dryas climate changes during a glacial to interglacial period, and that these events interact with fire to destabilize extant terrestrial ecosystems and produce sustained ecosystem alterations. This will contribute to efforts to define a role for the NASA's Earth Sciences program in astrobiology, by focussing on the role of rapid environmental change on ecosystems at a regional scale.
- Cold-Adapted Cyanobacteria and Potential for Life on Mars. We will take steps to preserve a culture collection that is a unique and irreplaceable resource for genetic, phylogenetic, and physiological studies in Astrobiology. The Culture Collection of Microorganisms from Extreme Environments, a member of the U.S. Federation of Culture Collections, will be transferred to the Astrobiology Institute as a research

resource and will be housed at the University of Oregon. Also, the preservation and use of a culture collection of extremophiles adapted to dryness and low temperatures will better define life's potential limits, thus helping to direct the search by the Mars Surveyor Program for evidence of a martian biosphere.

Consortium Members conducting research: Australian Geological Survey Organization, Caelum Research Corporation, California State University, Monterey Bay, Desert Research Institute, Florida State University, Harvard Medical School, Illinois State Geological Survey, Los Alamos National Laboratory, Montana State University, NASA Johnson Space Center, NASA Kennedy Space Center, National Science Teachers Association, Odense Universitet, Ohio State University, Penn State University, SETI Institute, Stanford University, University of Alabama, Birmingham, University of California, Berkeley, Irvine, Los Angeles, San Francisco, Santa Cruz, San Diego, University of Colorado, Boulder, University of Connecticut, University of Oregon, and the Technical Education Research Center.

Arizona State University will conduct research into the cosmochemistry of meteorites and organosynthesis within hydrothermal systems, the origin of early photosynthetic systems, microbial fossilization processes, complex ecosystems of extreme environments, and exploring for habitable environments elsewhere in the Solar System. (http://astrobiology.asu.edu/).

Carnegie Institution of Washington (http://www.ciw.edu/DTM-projects.html) will investigate aspects of hydrothermal systems and their potential roles as habitats for life on Earth and other solar system and extrasolar bodies. The premise of our project is that hydrothermal systems have been shown to be habitats for a diverse variety of life forms on Earth and that hydrothermal activity has either been documented or can be expected to have occurred on solar system objects ranging from meteorite parent bodies to planets and large satellites. The core of our effort will be a suite of laboratory investigations of organic chemical synthesis in water-rock systems under conditions of temperature, pressure, and chemical constituents likely to be encountered in terrestrial and extraterrestrial settings. Critical corollary efforts will involve establishing an understanding of the distribution of volatiles, notably H_2O, throughout the solar system and other planetary systems; developing predictive models for the nature and timing of hydrothermal systems on solar system objects; establishing a theoretical understanding of the organic chemical reactions observed under laboratory conditions; and exploring links between the laboratory findings and the chemical and biological characteristics of submarine and terrestrial hydrothermal systems.

Harvard University (http://www.harvard.edu/) will conduct research on the co-evolution of the Earth and its biota through time, integrating the stratigraphy, geochemistry, paleontology, microbiology, and geochronology of major evolutionary and environmental transitions in our planets' history.

A team of microbiologists, paleontologists, stratigraphers and sedimentary geologists, geochemists, and tectonic geologists has been assembled with the common goal of understanding the coevolution of life and environments in Earth history. Earth's planetary development has profoundly influenced the course of evolution, and, just as surely, evolutionary innovations have changed the planetary surface. The focus of the Harvard Astrobiology team is on integrated field and specimen-based investigations interpreted in light of insights drawn from comparative biology and research on contemporary geological and biogeochemical processes. The team is conducting research on three critical intervals of environmental change whose evolutionary consequences are in large part responsible for the current state of Earths' biosphere:

1. the Archean/Proterozoic transition (2.5 to 2 billion years ago), when large cratons stabilized, ice sheets waxed and waned, the oxidizing potential of the atmosphere and oceans increased markedly, bacteria with the capacity for aerobic metabolism radiated, and mitochondria-bearing eukaryotic microorganisms appear to have evolved.
2. the Proterozoic/Cambrian transition (800–509 million years ago) when supercontinents formed, broke apart, and reamalgamated, ice sheets repeatedly spread across the continents, global oxygen levels increased again, and large multicellular life emerged.
3. the Permian-Triassic boundary (251 million years ago) when rapid and pronounced environmental changes nearly eliminated multicellular organisms from the planet, triggering the most comprehensive reorganization of animal life since the Cambrian explosion.

What is striking about these events is that they share a number of common features, despite being separated by large spans of time, and despite the vast differences in the environmental conditions and in the ecosystems prevalent at these times. This suggests that there may be general features governing the relationship between environmental change and major episodes of ecosystem evolution. By examining, these general features of the Earth's past, we hope to provide data and insights of direct relevance to understanding the development of planetary-scale ecosystems. Further, the new techniques and approaches that we are developing for probing the terrestrial rock record will be directly applicable to and necessary for the paleobiological and paleobiogeochemical investigation of ancient sedimentary rocks on other planets.

Over the next five years, our field emphases will range from Archean rocks in Africa to Permo-Triassic boundary sections in China. Yet, in each case, we will ask comparable questions and employ comparable tools. Sequence stratigraphy will provide a framework for detailed investigations of paleontology, biogeochemistry, the geochemistry of redoxsensitive elements, and geochronology. As we proceed, therefore, we will generate not only critical data on specific time intervals, but also time series data that will provide a sense of biological and environmental evolution through Earth history. These data will allow us to test specific predictions about the relationships between environmental change and life, but perhaps most significantly, we will be equipped to answer questions seldom addressed by Earth scientists, questions of comparative Earth history.

The goal of our research team, in conjunction with other members of the NASA Astrobiology Institute, is to begin the processes of separating these general features of life from the idiosyncracies of life on this planet, and in so doing, to understand life as a planetary phenomenon.

Jet Propulsion Laboratory has developed a Consortium comprising four institutions and additional distinguished investigators, led by the Jet Propulsion Laboratory, which they propose as a member of the NASA Astrobiology Institute. The goals of the Consortium are to promote understanding in three related areas central to the mission of the NABI and the search for life in the universe: (http://www.jpl.nasa.gov/about/)

- understand the environmental contexts conducive to the maintenance of life on Earth or extraterrestrial planets
- determine the existence and nature of these environments outside the Earth
- identify approaches to confirm the existence of life, extant or extinct, in these contexts

The research plan of the Consortium is built on these corresponding themes:

- The study of Earth as a laboratory for understanding life and its relationship to its host planet. Given that Earth is where we know that life exists, the Earth and its biosphere will be used as the laboratory for understanding the contexts for life.
- The study of Mars as an analog. Mars is the best Earth-like site where we can hope to understand extraterrestrial contexts, how planets evolve and what the possible effects of the resident biota might be on the evolution.
- The identification of biosignatures that can be used to detect and identify life. We presently lack a suitable array of unambiguous indicators of life (biosignatures) that can be used to interrogate environments or samples where life is suspected to reside, as evidence by the recent report of presumptive evidence by martian life in the meteorite ALH84001.

NASA Johnson Space Center (http://www.jsc.nasa.gov/) along with U.S. and foreign Co-Investigators, will concentrate on biomarkers — specific properties in a rock which indicate that biological activity is occurring or has occurred. The research includes analysis of meteorites from Mars and some of the oldest rocks on Earth.

Finding undeniable evidence for current and past biologic activity in rock, soil, or water samples may be as simple as seeing living bugs moving about or finding obvious fossils. Indeed, for many terrestrial samples, this is the only evidence required. However, for other terrestrial samples more is needed. Some Archean rocks are an example in which it is seldom obvious whether or not they once contained life; a very detailed study is generally needed.

Using published literature and new analytical and experimental data, the Johnson Space Center proposes to make a detailed study of selected biomarkers, document their properties, and construct a database for each. For each biomarker studied in detail, they also will study similar features

made by nonbiologic processes, document these features and processes, and compare them to the true biomarkers.

A key objective of the proposed work is to identify and develop innovative new biomarkers (also termed "biological markers" or "biological signatures") not previously used on terrestrial rocks. Such new biomarkers will be documented, tried out on both modern and ancient rocks, and brought to a high state of readiness by the time Mars samples are returned. The Johnson Space Center proposes to look for new biomarkers in each of four major categories: biominerals; elemental and isotopic fractionation; morphologic features as seen at the micrometer and nanometer scale; and specific organic molecules. The goal is to develop a set of absolutely unequivocal biomarkers, along with methods to analyze for them, and to search for these biomarkers in astromaterials, including returned Mars samples. Along the way, they propose to learn much more about how organisms generate biomarkers and what such signatures tell us about the life cycle, evolution, ecology, and nature of the organisms an their interactions with the environment.

Johnson Space Center also proposes to learn how totally nonbiologic processes can generate signatures that mimic biomarkers, producing biomarker imposters. A current example is the controversy over whether carbonate globules in ALH84001 were generated by biologic or nonbiologic processes, and under what conditions. Ideally, the researchers will learn to tell them apart, or, if this is not possible, they will use such information to advise extreme caution in applying these particular biomarkers. The researchers will then narrow the list of true biomarkers to an absolutely unequivocal set, and, along the way, will learn much of how natural systems produce a variety of complex features by nonbiologic means. This knowledge will help to interpret the geologic history of the astromaterials and their parent bodies.

Marine Biological Laboratory. (http://hermes.mbl.edu./) Astrobiology at the Marine Biological Laboratory in Woods Hole seeks an understanding about the genotypic and phenotypic evolution of early life forms and how changing environments contributed to the development of complex systems in simple organisms. There are five interdisciplinary research themes united by strengths in molecular evolution and microbiology.

The first objective is to explore Eukaryote origins and the evolution of cellular complexity. Today we know little about how the eukaryotic cell was first assembled. Furthermore, our knowledge of eukaryotic diversity is biased by studies restricted to medically important parasites; even earlier diverging eukaryotes will likely be discovered in rarely-studied habitats. By combining our expertise in molecular phylogenetics and access to anoxic extreme environments we expect to identify earlier diverging eukaryotes that can be used to calibrate introduction of essential ultrastructure innovations for modern cells.

The second project will study diversity and physiology of prokaryotes in thermophilic and mesophilic environments that might resemble early Earth's biosphere. The deepest prokaryotic branches are extreme thermophiles. This suggests life either arose in a thermal environment or biological diversity has been constrained by hot refuges (or "evolutionary bottlenecks") during catastrophic events including massive bombardments or global temperature fluctuations. Sine we know little about the actual diversity and physiology of anoxic thermophillic and mesophilic marine sediments we will search for early branching prokaryote and eukaryotes from hot and anaerobic habitats. We will also determine whether there is a specific link between phenotypes, genotypes, and extreme habitats.

The third project will study genes that regulate photosymbiotic relationships. Photosymbiotic associations found in marine organisms may represent an early stage in the evolution of secondary endosymbionts. We will explore how photosymbioses are genetically regulated by cellular "talk" and determine what mechanisms control host/symbiont specificity.

The fourth objective is to study the relationship of genetic changes to phenotypic changes. Using Rhodopsins as a model, we will identify biochemical characteristics of amino acids that affect light absorbing properties of opsins and explore whether tree-based statistical methods are useful in quantifying the relationship of genotype to phenotype.

Finally, we will explore the ancestry of the earliest proteins through studies of paralogous genes and proteins from a single organism. Paralogous coding regions from ancient gene duplications will share certain structural and functional properties. If common features are mapped on gene trees that include all members of a class of proteins from a single organism, we can trace the molecular innovations for modern biochemistry back to the last common ancestral sequence. Using *E. coli* as a reference, we will determine over what evolutionary distances organisms can have related protein sets and we will infer common evolutionary pathways for the smaller families of related proteins. We will correlate the kinds of proteins that make up gene families with the different organisms that occupy different environments. In this latter context we will ask how does evolution at extreme temperature, pH, or salinity effect duplication and divergence of sets of proteins from common ancestors.

We have collected samples from several extreme anoxic environments and have established required technology for extracting and sequencing rRNAs from sediment samples. We have also cloned and sequence tubulins and ribosomal RNAs from several novel amitochondriate protists and the jakobid *Reclinomonas americanis*. Phylogenetic analysis of *R. americanis* reveals it to be a relatively late diverging lineage in the eukaryote line of descent. This is very surprising because the complexity of its mitochondrial genome predicted it would be related to basal eukaryotic branches like *Giardia lamblia* and Trichomonas. We interpret this late branching as evidence of multiple acquisition of alpha proteobacteria that were ancestral to mitochondria.

We are making progress in identifying the most ancient of protein ancestors that over time have evolved into the most common proteins in all present-day organisms. We find that enzymes have differentiated the furthest from ancestral forebears, whereas regulator and transporter proteins have not changed as much. Derivatives of some of these ancient sequences could conceivably be present in life elsewhere in the universe.

The comparison of genetic sequences makes possible the measurement of genetic differences among genes within a single organism, members of populations, species, and even among kingdoms of organisms. Molecular data provide a practical metric for assessing biodiversity and for making evolutionary comparisons among organisms. Stated differently, these elementary genetic sequences can serve as living fossils from the dawn of life. As a recent *New York Times* article stated: "Just as astronomers with powerful telescopes can see very distant events that happened close to the birth of the universe, so biologists who analyze genomes can hope to infer events that date from the earliest moments in the evolution of life." From Astrobiology studies at the Marine Biological laboratory, we will be better prepared for future discoveries about extraterrestrial life that might come from sample return missions or exploration of other planets. Furthermore we will gain important insights about the diversity and structure of microbial communities in extreme environments on planet Earth.

Pennsylvania State University. (http://psarc.geosc.psu.edu/) The major goal of research at Penn State Astrobiology Research Center is to increase our understanding of the connection between the changes in the environment and the changes in the biota on Earth, especially during the period between 4.5 billion to 500 million years ago. Here we are mainly concerned with the origin of life and the evolution and extinction of important organisms, including archaea, oxygen-producing cyanobacteria, eukaryotes, and early animals. The term "environment" refers specifically to the chemistry of the atmosphere (especially the concentrations of oxygen, carbon dioxide, carbon monoxide and methane), the chemical and thermal structure of the ocean (especially its redox state), and climate. The above research goal will be pursued by multidisciplinary research, including theoretical modeling of pre-biotic atmospheric chemistry, laboratory experiments to synthesize organic compounds, analyses of the structures and roles of metallo enzymes in archaea, molecular genetic analyses of major organisms, and geochemical and paleontological investigations of a variety of Precambrian rocks. The results of our research will greatly enhance our ability to predict the future of life on Earth and to identify the possibility of life elsewhere in the universe.

Scripps Research Institute (http://www.scripps.edu/research/) will combine efforts with the University of California-Riverside, University of Florida, and University of Texas-Austin to study the emergence of self-replicating systems and Darwinian chemistry.

Benner's laboratory at the University of Florida and Switzer's laboratory at the University of California at Riverside investigate single biopolymer origin of life theory based on modified nucleic acid structures. Centered on the RNA world origin of life hypothesis, their studies seek to investigate the properties of modified nucleic acids as both information carriers and catalysts. They have shown that replacing one of the four standard nucleobases with a functionalized nucleotide increases dramatically the potential of such biopolymers for catalysis. In addition, a variety of

alternative nucleic acid backbone structures have been investigated, thus expanding the repertoire and functional understanding of nucleic acid based systems. Their studies will continue to chart what is necessary and sufficient for nucleic acid-based self-reproducing systems and Darwinian chemistry.

Ghadiri's (http://www.scripps.edu/pub/ghadiri/) laboratory at the Scripps Research Institute investigates protein-based origin of life model. The central goal of this research program is to understand the molecular mechanisms that transform inanimate chemical reactions into the animate chemistry of living systems. The approach has been to rationally design and recreate various basic forms of autocatalytic studies will establish the structural and functional underpinnings necessary for the expression of informational self-reproducing systems. chemical networks in the laboratory and study how the interplay of molecular information and nonlinear catalysis can lead to self-organization and expression of emergent properties. Ghadiri and coworkers have shown that short helical peptides can self-replicate, in a template-dependant fashion, by catalyzing their own synthesis from appropriately functionalized shorter peptide fragments and how such species can be employed to construct self-organized (auto) catalytic networks that can display some of the basic properties often associated with living systems such as selection, reciprocation, symbiosis, and error correction. Their current efforts are focused on the design of molecular ecosystems.

Ellington's laboratory seeks to uncover experimental evidence in support of theories that have been put forth to explain the emergence of self-sustained nucleic acid replicators in the RNA world. Their studies are based on the notion that the prebiotic world most likely comprised of short (dimer to dodecamer) oligonucleotides of which the longer chains were lineal descendents. Ellington focuses on RNA sequences, which reproduce through Watson-Crick base pair-mediated and template-directed assembly. Initial experiments determined whether known sequences could be accurately copied from random sequence pools. They have found that efficiency of ligation and the degree of fidelity depend highly on the temperature of the reaction and the length of the oligonucleotide substrates present in the reaction mixture. Their data seem to disfavor a hydrothermal origin of nucleic acid-based life. Their current studies are focused on the selection of RNA sequences capable of exponential replication.

Rebek's (http://www.scripps.edu/skaggs/rebek/laboratory) laboratory at the Scripps Research Institute studies the structural and functional properties necessary for molecular self-replication. His laboratory has developed self-replicating structures based on synthetic molecules. Rebek's research suggests that a molecule's potential for self-replication lies primarily in its shape, reactive functionalities, and the principles of self-complementarity. The building blocks in the Rebek scheme are self-assembling capsules derived from calixerenes which associate through directed hydrogen bonding interactions and guest-induced molecular recognition events. Their studies will establish the structural and functional underpinnings necessary for the expression of informational self-reproducing systems.

University of California, Los Angeles (http://www.ess.ucla.edu/) will undertake multidisciplinary research on the paleomicrobiology of Earth's early life, the metabolic evolution of early ecosystems, and the development of instruments aimed at detecting life in the galaxy and the solar system.

Astrobiologists at UCLA propose to investigate five broad frontiers of knowledge using techniques and instruments that have not been widely applied before.

- Prediction, detection, and characterization of extrasolar planetary systems that may be abodes for life. Investigation of the prevalence and properties of comets and small objects observationally and also theoretically, the latter in the context of modeling planetesimal accretion in the presence of one or more giant planets.
- Geobiology and biogeochemistry of the oldest record of life on Earth and Mars. Exploration of the undiscovered Hadean history of Earth and Mars as cradles for life using Earth's oldest geological terranes (Australia, Canada, Greenland) plus Martian meteorites and returned samples.
- Paleomicrobiology and the evolution of metabolic pathways in the Archean environment. Definition of the morphological attributes plus trace element and isotopic signatures of microbial biosynthetic pathways in living cells, and the application of this knowledge to interpret the microbial fossil record of the early Earth as a prelude to Mars.
- Genomic evolution, the tree of life, and the early fossil record of life on Earth. Reconstruction of the genomes, and hence the biochemistries, of crucial nodes in the tree of life and integration of that knowledge with the fossil record using key fossils, biogeochemical signatures, radioisotopic ages, and molecular clocks. Experimental and theoretical studies of evolutionary processes.
- Detection of life in the Solar System. Small spacecraft-mounted searches for evidence of biology and prebiology on Mars, Europa, and Titan based on laboratory and field experiences on Earth. The characterization of the early Solar System environment as a habitat for life using naturally delivered and recovered extraterrestrial materials.

University of Colorado (http://argyre.colorado.edu/life/index.html) will address the origin of stars and planets, the development of habitable planets, the "RNA world" and the origins of life, biological evolution on Earth, the energetics of life on other planets, and the philosophical aspects of astrobiology and the search for life elsewhere.

Specific research topics include:

- Formation of stars and planets. Conduct an observing and analysis program using a variety of ground- and space-based platforms to understand the degree to which protoplanetary disks will evolve into debris disks that can accrete to form planets before they are destroyed by radiation fields, stellar winds, and explosions of nearby stars.
- Habitability of planets. Investigate the global effects of clouds and hazes in planetary climate and habitability, in particular the behavior of clouds created by impacts onto the Earth and other planets.
- Origin of life and the RNA world. Develop an alternative means of searching for chemical activity in nucleic acid sequences (as in primitive RNA environment) using sensitive direct chemical assays rather than biochemical selection; as this is a new approach, it is expected that new activities might be discovered and that this should lead to new ideas about the appearance and rise to prevalence of rare RNA activities in a primitive RNA world.
- Evolution of life on Earth. Study a suite of structural characteristics associated with the transition of photosynthetic organisms from water to terrestrial environment as a means of studying the paleobiological and evolutionary roles of photosynthetic organisms and the pattern of life and the general features of key habitat transitions that have characterized life on Earth throughout its history.
- Energetics of life on other planets. Explore the availability and accessibility of geochemical energy from geological environments on Mars, the early Earth, and possible Earth-like planets elsewhere, with specific attention to hydrothermal systems and to weathering of rocks as a means of obtaining energy to sustain life prior to the onset of photosynthesis.
- Philosophical implications of the search of life elsewhere and in the interactions between scientific results and society. Explore the questions of what constitutes life and what would constitute "good" evidence that life existed in an extraterrestrial system, in the broader context of the history and philosophy of science.

ASTROBLEME. A scar on the surface of the earth made by the impact of a cosmic body. The term usually connotes a so-called fossil crater of ancient origin. There are 14 large and certified meteorite craters known and undoubtedly many more that are masked by vegetation or that have been subject to subsequent alteration as the result of tectonic processes, sedimentation, and erosion. Most likely the readily visible remaining craters were created during the last million years. Over the long history of the earth, some investigators believe that many thousands of giant meteorites have impacted the surface of the planet. The moon provides strong evidence that such activity in the vicinity of the earth has been strong in the past. The moon, of course, with no atmosphere and apparent minimal tectonic activity has provided a rather ideal means for permanently recording such impacts.

Particularly since the early 1980s, there has been serious and growing support for the probable impacts on earth by asteroids as well as by meteorites. Among others, the asteroid-impact hypothesis has been pioneered by Alvarez and associates (University of California, Berkeley). See **Asteroid**; and **Mass Extinctions**.

Probably the most spectacular example is the Vredefort Ring in the Transvaal of South Africa. Very little of the original crater remains, but shatter cones give evidence that this probably was the greatest terrestrial explosion in relatively recent times (within last 250 million years). At one time, geologists ascribed the structure to a series of tectonic events. A shatter cone is a distinctively striated conical fragment of rock along which fracturing has occurred, ranging in length from less than a centimeter to several meters, generally found in nested or composite groups in the rocks of cryptoexplosion structures, and generally believed to have been formed by shock waves generated by meteorite impact. Shatter cones superficially resemble cone-in-cone structure in sedimentary rocks; they are most common in fine-grained homogeneous rocks, such as carbonate rocks (limestones, dolomites), but are also known from shales, sandstones, quartzites, and granites. The striated surfaces radiate outward from the apex in horsetail fashion; the apical angle varies but is close to 90 degrees. Geologists have studied the shatter cones in the area of the Vredefort Ring and confirm that, if the rocks were returned to their original positions, the shatter cones would all point inward toward the center of the ring. It is postulated that an asteroid about a mile (1.6 kilometer) or more in diameter struck the earth from the southwest, drilling into the earth and releasing enormous shock forces. Strata some 9 miles (∼14.5 kilometers) in thickness peeled back in the fashion of a flower, opening a crater some 30 miles (∼48 kilometers) in diameter and 10 miles (∼16 kilometers) deep. The energy released is compared with the extent of energy required to produce the Tycho and Copernicus craters on the moon. It is further estimated that the Vredefort blast was about a million times larger than the 1883 Krakatoa volcanic explosion and probably exceeded by several thousand times the largest possible earthquake. In terms of the force of nuclear explosions, it is believed that the Vredefort blast would have been classified as a 1.5-million-megaton event.

The meteorite crater (Barringer Crater) located in Arizona is much more recent (estimated 25,000 years old) and much smaller than the Vredefort event. On a nuclear scale, as mentioned in the prior paragraph, the Barringer event would have been only a 5-megaton explosion. This crater is $\frac{3}{4}$ mile (1.2 kilometers) across and 600 feet (180 meters) deep. While not in evidence at Vredefort, coesite is found at Barringer. Coesite is a monoclinic mineral, SiO_2. It is a very dense (2.93 grams/cubic centimeter) polymorph of quartz and is stable at room temperature only at pressures above 20,000 bars. The silicon has a coordination number of 4. Coesite is found naturally only in structures that are presently best explained as impact craters, or in rocks, such as suevite, associated with such structures. Coesite is believed to be a second shock-wave product and its presence has been helpful in confirming at least five astrobleme sites. Coesite was created artificially by Loring Coes, Jr. (Norton Company, Worcester, Massachusetts) in 1953 in apparatus that produced pressures exceeding 20,000 atmospheres. See also **Meteoroids and Meteorites**.

Coesite and suevite have been found at Ries Kessel (Giant Kettle), an ancient basin formation some 17 miles (27.4 kilometers) across and located 26 miles (41.8 kilometers) from the Steinheim Basin in southern Germany. Based upon studies within the last twenty years, Ries Kessel is now considered an astrobleme. Coesite also has been found in rather large amounts of silica glass in connection with the Wabar craters in the Empty Quarter of Arabia. Similar findings have been made at the Ashanti Crater in Ghana and at the Teapot Ess Crater in Nevada (the latter created by an atomic blast at the Nevada Proving Grounds). By seeking the presence of coesite, it is believed that additional astrobleme sites will be identified.

Several fossil craters have been identified in Canada, including Carswell Lake, Keely Lake, Deep Bay, Westhawk Lake, Lac Couture, Nastapoka Arc (Hudson Bay), Clearwater Lake, Menihek Lake, Ungava Bay, Sault-Aux-Cochons, Brent, Franktown, Lake Michikamau, Manicouagan Lake, St. Lawrence Arc (New Brunswick), Mt. Canina Crater, and Holleford. The Holleford Crater is now a slight depression about 11/2 miles (2.4 kilometers) in diameter, eroded and filled with sediments. It is located in Ontario farmland and is believed to be the result of an impact some 500 million years ago. It was discovered by means of aerial photography. Interesting shatter cone sites in the United States, in addition to the Barringer Crater, include Kentland, Indiana (in a large limestone quarry), Sierra Madera, Texas, Serpent Mound, Ohio, Flynn Creek and Wells Creek in Tennessee, and Crooked Creek in Missouri. Craters over one million years old are located at Boxhole, Dalgaranga, Henbury, and Wolf Creek in Australia.

Much pioneering work in recent years in connection with seeking shatter cones, coesite, and location of astroblemes has been done by Robert S. Dietz, whose writings on the subject are listed in the references.

Dietz suggests that the creation of coesite and of minute diamonds by meteorite impact opens up the new field of impact metamorphism, explaining that meteorite impacts are natural "experiments" in ultrahigh pressures on a scale that most likely will never be equaled in the laboratory.

In the twentieth century, two great impacts have been known to occur, both in Siberia. The event at Tunguska probably was caused by the fall of a comet head. At Sikhote-Alin in 1947, a very large meteorite fell that was disintegrated in mid-air, leaving more than 100 craters on the ground. All known meteorite impacts have occurred on land, but it is highly probable that many more have fallen into the sea and thus leaving evidence very difficult for geologists to uncover with present technology.

One of the most recent impact phenomena to be reevaluated is Lonar Crater, in the Buldana District of Maharashtra, India (19°58′N, 76°31′E). This is an almost circular depression in the basalt flows of the Deccan Traps. The crater is 1830 meters across and nearly 150 meters deep. Most of the floor is covered by a shallow saline lake (Lonar Lake). Around most of the circumference, the rim is raised about 20 meters above the surrounding plain. A second crater appears to lie about 700 meters north of the large crater. Early investigators ascribed the formation to a volcanic explosion of subsidence. However, in 1896, Gilbert emphasized the similarity of Lonar Crater with Barringer Crater in Arizona. Studies of the crater are detailed by Fredriksson, Dube, Milton, and Balasundaram in *Science*, **180**, 4088, 862–864, May 25, 1973.

ASTROCHEMISTRY. Application of radioastronomy (microwave spectroscopy) to determination of the existence of chemical entities in the gas clouds of interstellar space and of elements and compounds in celestial bodies, including their atmospheres. Such data are obtained from spectrographic study of the light from the sun and stars, from analysis of meteorites, and from actual samples from the moon. Hydrogen is by far the most abundant element in interstellar space, with helium a distant second. Over 25% of the elements, including carbon, have been identified, as well as molecules of water, carbon monoxide, carbon dioxide, ammonia, ethane, methane, acetylene, formaldehyde, formic acid, methyl alcohol, hydrogen cyanide, and acetonitrile. When applied to the planets only, the science is called chemical planetology.

ASTROGRAPHIC TELESCOPE. A refracting telescope designed to give a field of 10° or more. The objective is a designed compromise between the various optical aberrations at a specified wavelength. See also **Telescope (Astronomical-Optical)**.

ASTROLABE. An ancient form of portable astronomical instrument invented during the second or third century B.C., probably either by Hipparchus or Apollonius. In its most common form, the astrolabe consists of a circular disk suspended by a ring so that it will hang in the plane of a vertical circle. A pointer, or alidade, is pivoted at the center of the disk, and angular graduations are marked about the edge. For purposes of measuring altitude, the ring is suspended by the thumb of one hand, and the other fingers of the same hand are employed to steady the disk as the alidade is moved, by the other hand, until it points directly at the object under observation. The altitude can then be read directly on the disk.

The astrolabe was used by navigators for the determination of latitude, from the 15th Century until the invention of the sextant. Since that time, it has been used as a teaching instrument in elementary classes. The astrolabe, in its modern version, is essentially the only impersonal instrument for the measurement of time and latitude that does not rely on secondary standards. The zenith telescope will do the same observational tasks as the astrolabe, but it is necessary to introduce nonfundamental stars. The modern astrolabe is free of personal errors, and gives stellar positions with an accuracy on the order of one-tenth of a second of arc.

ASTROMETRY. Astrometry plays a very particular part in the realm of astronomy. On the one hand, it is essentially an ensemble of techniques that provides some essential data to astronomers and astrophysicists about celestial objects. On the other hand, until the second half of the nineteenth century, what is now called astrometric observations were the only astronomical activity that existed. Actually, astronomy has a tradition that goes back to Egyptian, Assyrian, and Greek astronomy. Astrometry is the oldest of all sciences and still is a scientific domain of its own, encompassed by theoretical developments such as stellar dynamics and celestial mechanics now supported by the theory of general relativity.

One can define astrometry as the part of astronomy that measures the apparent positions of celestial bodies on the sky. And, because these positions vary with time, the objective is to describe and study these motions that, for stars, provide two essential parameters: the proper motion and the parallax from which the distance is derived. As an extension, one ascribes also to astrometry the measurement of apparent dimensions and shapes of celestial bodies. However, in this article, we shall consider the determination of star positions, the primary goal of space astrometry. See also **Astrometry**.

The physical quantities that are measured by astrometry are angles that are often very small. Radians are not used in astrometry; the basic units are degrees and seconds of arc (denoted′). Smaller units are necessary, and astrometrists are currently using milliseconds of arc (denoted mas, that is, a milliarcsecond) and now are starting to use one millionth part of a second of arc (μ as). Their respective values are close to 5×10^{-9} and 5×10^{-12} radians.

Essentials of Astrometry

Before discussing how astrometric measurements are performed, it is appropriate to present some basics that have to be known for further understanding.

Reference Systems and Frames. The position of a point in the sky is defined by its two spherical coordinates. The most frequently used are the equatorial system. The principal plane is the celestial equator coplanar with Earth's equator. Starting from the vernal equinox at the intersection of the equator and the ecliptic, the right ascensions (denoted α) are reckoned counterclockwise. The second angular coordinate is the declination (δ), counted from the equator, positive to the North, negative to the South (Fig. 1). We shall also use the ecliptic system. The principal plane is the ecliptic, and the celestial longitudes (λ) are reckoned counterclockwise from the vernal equinox. The second coordinate is the celestial latitude (β), also shown in Fig. 1. Because both the physical equator and ecliptic are moving, the principal planes have a conventional fixed position (sometimes called mean equator or ecliptic).

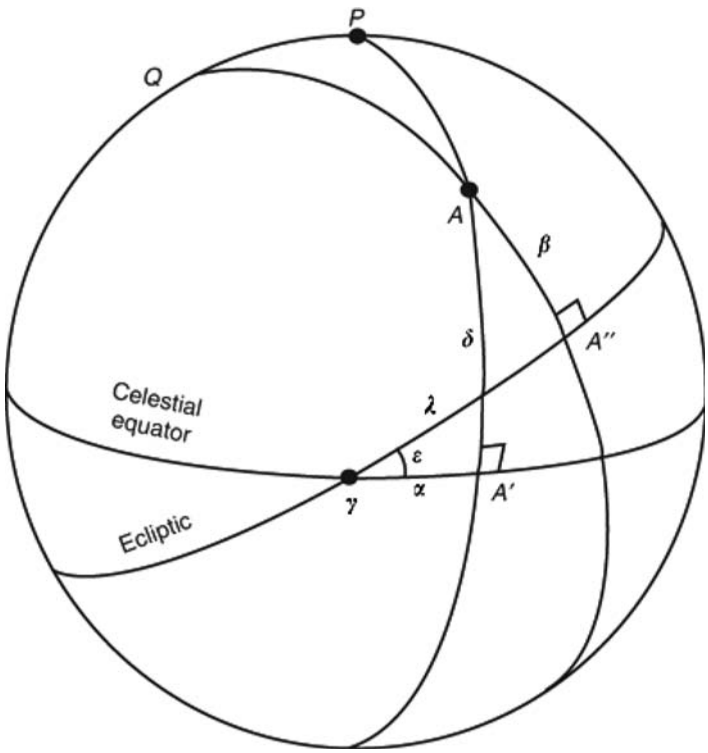

Fig. 1. Equatorial (α, δ, pole P) and ecliptic (b, l, pole Q) coordinate systems.

These coordinate or reference systems are virtual and are obviously not actually located in the sky. A reference system is actually determined by assigning a consistent set of coordinates to a number of objects (fiducial points). Such a catalog of positions is said to be a reference frame. The position of any object is deduced from relative measurements with respect to fiducial points. Another important condition is that the coordinate systems must be fixed in time, so that the apparent motions of celestial bodies are not falsified by spurious rotation. This is realized now by choosing as fiducial points very distant objects (quasars or galaxies) whose motions are slower than the speed of light and so appear negligible as seen from Earth. The system so defined is the International Celestial Reference System (ICRS) http://aa.usno.navy.mil/faq/docs/ICRS_doc.html, and the catalog of fiducial extragalactic objects is the International Celestial Reference Frame (ICRF) http://rorf.usno.navy.mil/ICRF/, a radio-source catalog extended to optical wavelengths by the Hipparcos catalog, http://tdc-www.harvard.edu/catalogs/hipparcos.html.

Apparent and True Positions. The direction from which the light arrives at the instrument has undergone a series of deviations. For this reason, it arrives from an apparent position of the star, not the true one. There are three causes for this deviation.

Atmospheric Refraction. Light from outer space is bent progressively as it enters the atmosphere which is composed of layers of different refractive indexes. The integrated effect depends upon the pressure, temperature, and humidity of the atmosphere and the wavelength of the light. The lower the object in the sky, the larger and the more uncertain the correction to be applied. In practice, ground-based astrometric observations are not performed below 60° zenith distance.

Aberration. The apparent direction of a source is a combination of the direction from which the light arrives and the the velocity of the observer. In ground-based observations, one distinguishes the diurnal aberration due to the motion of the observer as a consequence of Earth's rotation and stellar aberration due to the motion of Earth around the Sun. In astrometry from space, the diurnal aberration is replaced by the orbital aberration due to the motion of the satellite in its orbit.

In the Newtonian approach, the apparent direction **r** of a star is linked to the undeviated direction $\mathbf{r}'$ by

$$r = r' - rV/c, \tag{1}$$

where **V** is the velocity of the observer and c is the speed of light. For very precise astrometry, one must use a more complex formulation based on the theory of general relativity.

Relativistic Light Deflection. Following the theory of general relativity, a massive body produces a curvature of space, and the geodesic followed by the light ray is not a straight line: it deviates by a small amount toward the massive body. For the Sun, the deviation is

$$\gamma = 0.00407'' \operatorname{cotan} \theta/2, \tag{2}$$

where θ is the angle between the directions of the star and of the Sun.

Parallactic Displacements. The true position obtained after applying the corrections described above refers to a moving observing site. For positional comparisons, this is not convenient, and it is necessary to refer to a more stable origin of the coordinate system. The correction to be applied to get the direction viewed from another point is the parallactic displacement or correction. Two cases are useful.

Geocentric Coordinates. The parallactic correction necessary to shift from ground-based or satellite-based observations to the center of Earth is totally negligible for a star. This is not the case for observations of objects in the solar system.

Barycentric Coordinates. This coordinate system is centered at the barycenter of the solar system. It is the only point whose motion in space is linear with very high accuracy, because it corresponds to an orbit around the center of the Galaxy described in 280 million years. For all practical applications, it can indeed be considered linear without any dynamic effect on the members of the solar system. The construction of the parallactic correction is sketched in Fig. 2. Let B be the barycenter of the solar system, E the center of Earth in its orbit C around B. Let S be the actual position of a star and r its distance; $\mathbf{r} = \mathbf{BS}$. From Earth, S is seen along the vector $\mathbf{r}' = \mathbf{ES}$. The apparent direction **ES** differs from the barycentric direction **BS** by the angle

$$p = (r, r') = (ES, BS). \tag{3}$$

If we call θ the angle **(EB, BS)**,

$$\sin p = R/r \sin \theta,$$

where R is the length BE. So the variation of the paralllactic displacement p with time is a function of the motion of Earth on C, usually taken as an ellipse but may be made more precise using ephemerides.

Stellar Parallax. The angle p is of the order of or smaller than R/r. The convention is to express R/r not in radians, but in seconds of arc and define a quantity called stellar parallax, or simply parallax, which is equal to the angle p when R is equal to the mean Earth–Sun distance, that is one astronomical unit (149,597,870 km). Because $1'$ is equal to $2\pi/(360\times3600)$ radians, the distance for which the parallax is equal to $1'$ is 206, 265 AU or 3.2616 light-years. This distance is called the *parsec* (parallax-second, abbreviated as ps) and is the commonly used distance unit outside the solar system. With this unit, the distance r is simply

$$r = 1/\overline{\omega} \tag{5}$$

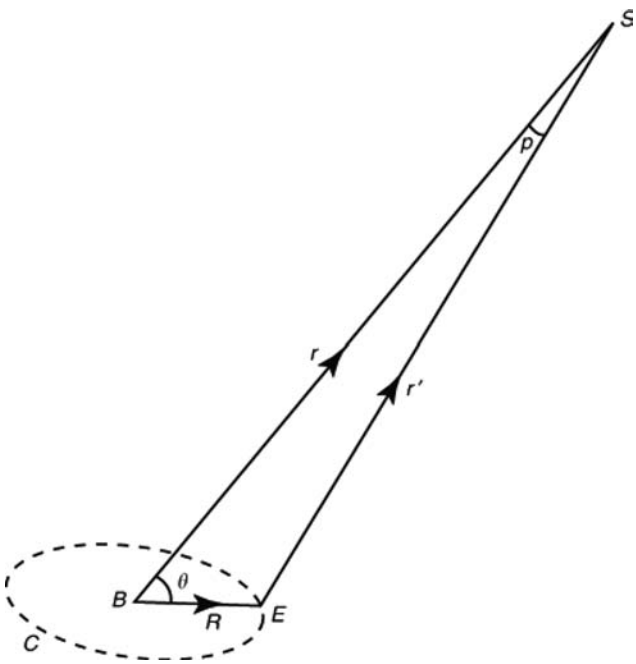

Fig. 2. Stellar parallactic correction.

where $\overline{\omega}$ is the parallax p expressed in seconds of arc. Note that the nearest star, Proxima Centauri, has a parallax of 0.762^2. Very few stars are at distances smaller than 10 ps and most of the stars of astrophysical interest have parallaxes of the order of a few hundredths or even thousandths of an arc second. This implies that to be significant, their parallaxes should be determined at least at an accuracy of 1 mas, and even much more. This is the major challenge to astrometry nowadays, and this is the main driver for very accurate astrometrical measurements, possible only from space.

Motion of Stars. Stars move in space, and observing their apparent motion in the sky allows us to access dynamic properties of groups of stars (double and multiple stars, star clusters and the Galaxy itself). Two types of motion can be distinguished.

Proper Motions. The position of a star with respect to a fixed celestial reference frame varies with time. Very often, the motion is linear and is expressed as yearly variations of the coordinates, called proper motion:

$$\mu_\delta = d\delta/dt; \tag{6}$$

$$\mu_\alpha = d\alpha/dt. \tag{7}$$

In local coordinates centered at the star, the components of proper motion are $\mu_\alpha \cos\delta$ and μ_δ. It is often useful to express the tangential velocity in kilometers per second. This is possible only if the distance is known and, after some transformations of units, for any component μ of the proper motion,

$$V = \mu/4.74\overline{\omega} \text{ km } s^{-1}. \tag{8}$$

This is the projection of the actual velocity of the star on the plane perpendicular to the direction of the star. The third component of space velocity is radial velocity, which is measured by spectroscopic techniques. It is obtained by measuring the Doppler shift $\Delta\lambda$ of spectral lines at a wavelength λ_0:

$$V_R = c\Delta\lambda/\lambda_0, \tag{9}$$

where c is the speed of light.

Sometimes, the path of a star is not linear. This means that it is attracted by some invisible body, generally a companion of the star such as another faint star, a brown dwarf, or a planet. The star is then called an astrometric double star.

Relative Motions. One star moves with respect to another one, close to it. The observation of such motions is of particular importance in the case of double stars, when one of them revolves around the other following Newton's law of universal gravitation. If M_1 and M_2 are the masses of

the components, the force that attracts M_2 by M_1 is

$$F = \frac{kM_1M_2}{|\rho|^3}\rho \tag{10}$$

where k is the gravitational constant and ρ is the radius vector between the components. Observing double stars is one of the main activities in astrometry. If the distance to the star is known, the sum of their masses can be determined by modeling the apparent path as the projection of a Keplerian orbit. In addition, simultaneous knowledge of the radial velocities or the actual absolute path of both components, as shown in Fig. 3, taken from Van de Kamp, also allows us to determine M_1/M_2 and hence obtain the values of both masses.

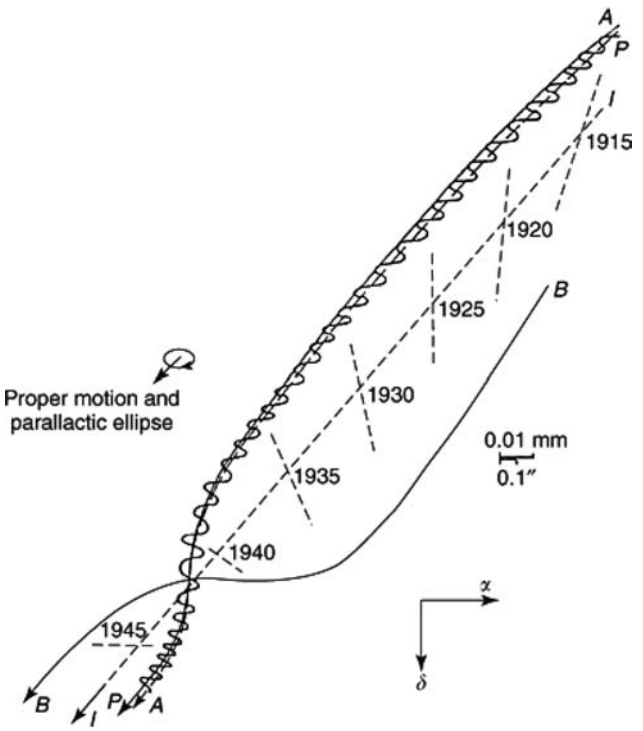

Fig. 3. Geocentric path of the components of a double start (99 Herculis).

The determination of relative motions in a star cluster is the material from which one can study the kinematic and dynamic properties of the cluster and compare the results to models. An example of what can be achieved with the best presently available astrometric data and radial velocities is found in Perryman, Brown, et. al.

Ground-Based Astrometry

Before describing what space has brought to astrometry and what it is expected to bring in the future, it is necessary, for comparison, to present the achievements of ground-based astrometric observations. One must distinguish two classes of instruments that differ by the area of the sky measured. Detailed descriptions of the instruments mentioned in this section can be found in Kovalevsky.

Small-Field Astrometry. The positions of the celestial bodies are in this case measured with respect to neighboring stars instrument's in the field of view. The typical small-field instrument is the telescope that has either a photographic plate or — more generally now — charge-coupled device (CCD) arrays at its focal plane. The field of view of an array is a fraction of a square degree, but there is way to increase it by the scan mode. In this observing method, the telescope is fixed, and the charge transfer in the CCD is continuous at the rate of the diurnal motion. By this technique, it is possible to scan a narrow but long band along a declination circle.

The field of view of photographic plates, depends on the focal distance of the telescope. In Schmidt telescopes, it is as large as $5^\circ \times 5^\circ$, and the precision of position measurements is limited to $0.2'$. In long-focus telescopes (10 to 20 meters (33.8 to 65.6 ft), the field is reduced to a fraction of a square degree, but the relative position of a star with respect to another is as close as a few hundredths of a second of arc. By combining several tens of long-focus observations, one obtains the best ground-based parallaxes to a few mas precision. Michelson interferometry that has a coherent field of a few seconds of arc is used to measure star dimensions and very close double stars at accuracies of the order of one mas. Speckle interferometry which allows a larger field, is perfect for double star observations, and reaches precision of a few mas.

Semiglobal Astrometry. Instruments in this category are designed to determine relative positions of widely separated celestial bodies, much farther apart than their fields of view. However, because one cannot see the whole sky from any place on Earth, one is constrained to some regions; the corresponding astrometry is called semiglobal, rather than global.

The oldest, and still the most used, instrument of this kind is the transit. It consists of a refractor telescope that can rotate around an east–west axis. The optical axis can be set to any direction on the local meridian. A micrometer registers the path of the star image on the focal plane and, by interpolation, one gets the time t of the transit of the star through the meridian. Then t is transformed into T, the Greenwich sidereal time and one obtains the right ascension of the star by

$$\alpha = L + T, \tag{11}$$

where L is the longitude of the observatory. Simultaneously, the inclination θ of the axis of the tube is measured using a divided circle, and one gets the declination δ by a formula such as

$$\delta = \rho + \theta \cdot 90 \tag{12}$$

for a southern transit in the northern hemisphere, or similar formulas in other configurations, where ϕ is the latitude of the observatory. After determining all of the instrumental parameters, one obtains precisions of the order of $0.1'$ or slightly better for stars that can be as much as 120° apart in observations that last the whole night.

Astrolabes have been also used for semiglobal astrometry. They observe star transits through a horizontal celestial small circle a little more accurately, but they are much less efficient. Recently, Michelson interferometry has been tested to determine relative star positions in various directions. Although there are hopes that this technique can give much more accurate results, the only existing instrument (the Navy Prototype Optical Interferometer in Arizona) is too new to permit definite statements on its performance. In any case, the number of observations per night remains quite limited in comparison with a transit instrument which may observe several stars during a single night. See also **Astrolabe**.

Limitations of Ground-Based Astrometry. Except for limited instances in long-focus or interferometric small-field astrometry, the actual uncertainties in observations are of the order of $0.1'$. Even if the same stars are reobserved many times, the resulting precision is hardly improved by more than a factor of 3 due to the presence of systematic errors. Compared with the milliseconds of arc required for astrophysically significant results, at least one order of magnitude is to be gained. Several reasons exist for this fundamental limitation.

Atmospheric Refraction. As already mentioned, refraction is not fully predictable. It varies with time and position in the sky, and the correction applied is not perfectly modeled. The result is that, in semiglobal astrometry, the remaining refractive error is generally of the order of a few hundredths of a second of arc and has some systematic component. The use of multicolor observations, which is practical only in interferometric techniques, improves the situation, but not to the level of milliseconds of arc.

Atmospheric Turbulence. The atmosphere is not a smooth medium. Atmospheric stratifications move, and unstable vortices develop and evolve with time. They produce variations in refractive indexes and in the inclination of equally dense layers. The largest affect the angle of refraction. The dimension of the smallest turbulent cells are in the range of 5–30 cm (2–12 in) and are produced by the temperature difference between the ground and the air and by the irregularities of the surface. They move with the wind so that the light is randomly deviated and seems to originate from different points in the sky. In addition, rays interfere, and the resulting instantaneous image of a star, called speckle, is deformed and moves rapidly around some central position on timescales of a few hundredths of a second. The resulting accumulated image is a disk whose

size is at best 0.5′ and is generally of the order of one second of arc on good nights, 2 – 3′ on others. These numbers characterize the visibility and indicate that, however small the theoretical resolving power of a telescope may be, the images are always larger than 0.5′. So, whatever is the care with which the photocenter of such an image is determined, the pointing precision is necessarily limited to a few hundredths of a second of arc.

Mechanical Properties of the Instrument. The structure of a telescope, in particular of the transit, is subject to torques that depend on its inclination. In practice, it is impossible to model it so that its effects introduce biases in determining refraction. In addition, again in the case of a transit, declination is determined by using a divided circle. The accuracy and the precision of the readout of the marks are limited, not to mention the deformations of the circle due to temperature. These effects bias the observations as a function of the time of observation during the night. These causes of errors, together with other perturbations specific to individual instruments, constitute an ensemble of limitations to the accuracy of astrometric observations that are of the same order of magnitude as those due to the atmosphere.

Sky Coverage. It is important for all global studies (kinematics and dynamics of the Galaxy, for instance) that positions and proper motions be referred to a single frame, independently of their situation on the sky. To achieve a global astrometric catalog, it is necessary to compile it from regional catalogs produced by many semiglobal instruments. Despite all of the efforts that are made to reduce the systematic differences among them, inevitably not all are corrected, especially if there are undiscovered correlations or similar systematic effects. The last — and best — global catalog is the FK5, produced in 1988, that contains 1535 stars. The accuracies are about 1 mas in proper motions per year and 0.08′ in position at the date of the catalog. The latter figure is an enhanced marker of the uncertainties of the proper motions used to update the positions from the mean epoch of observations (1950) to the present. The systematic differences with accurate space observations by Hipparcos, shown in Fig. 4, illustrate the complex structure of the biases due to the various causes described before. The figure also shows the actual intrinsic limitations of ground-based astrometry. Only astrometry from space can improve the situation significantly.

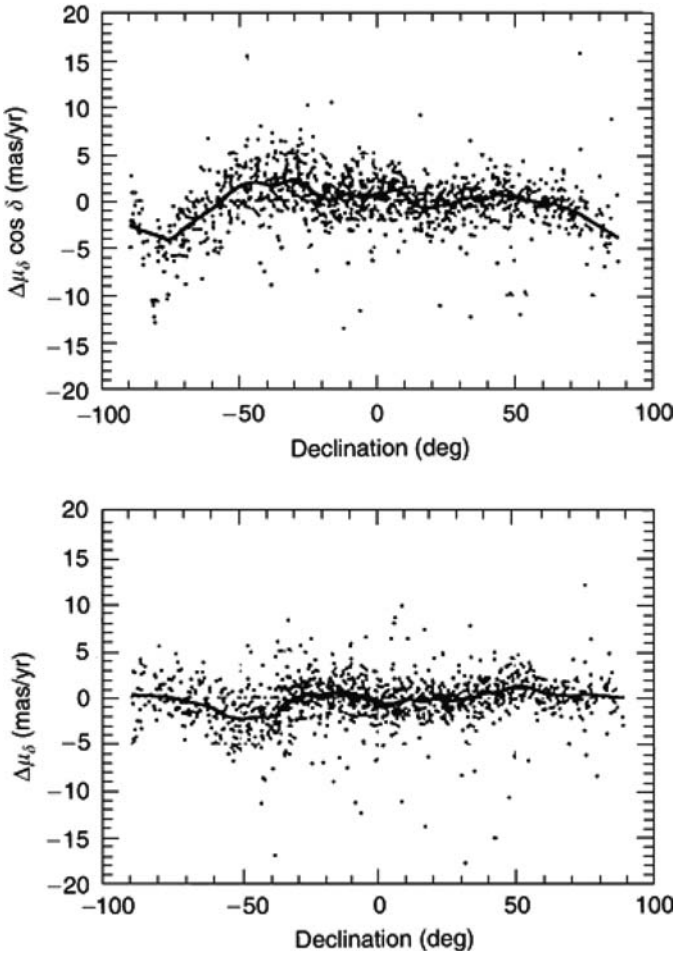

Fig. 4. Differences in proper motions in right ascension and declination between the FK5 and *Hipparcos Catalogue* as functions of declination. The solid line is a robust smoothing of the data.

Space Astrometry

Going to space to perform astrometric observations has long been a dream of astrometrists. A principle that could be used was first published in 1966 by P. Lacroute. The method proposed was actually retained for Hipparcos and is now adopted for several future projects. However, at that time, space technology could not meet the accuracy challenges. Reproposed in 1973 to the European Space Agency (ESA), a feasibility study of such a mission was approved in 1976, and the project was included in the ESA mandatory science program in 1980. The project was delayed because of the priority given to the Halley comet space mission Giotto, so that the detailed design study was completed only in December 1983, and the hardware development started immediately after. Another delay was caused by a failure of the Ariane launcher, so that the actual launch of the satellite occurred in only August 1989.

What was required from space astrometry was first to eliminate the limitations described earlier. Clearly, the absence of atmosphere was the first objective, but at the same time, the possibility of homogeneously scanning the whole sky and giving rise for the first time to true global astrometry was achieved. In addition, the very small gravitational and radiative pressure torques that exist in space do not affect the shape of the instrument. Finally, in the absence of atmospheric turbulence, the shape of the star image is entirely defined by optics and can be modeled with extreme accuracy.

However, a new very serious difficulty appeared: how to monitor the orientation of the satellite. In ground-based astrometry, the orientation of the instrument in space is a function of the parameters of Earth's rotation which are determined independently and very accurately by a specialized service, the International Earth Rotation Service (IERS). They include Universal Time from which sidereal time is computed, polar motion and, in space, precession and nutation. All are known with superabundant accuracy. In space, there is no such external reference and, at least for global astrometry, the orientation (or attitude) of the satellite must be determined simultaneously as accurately as the expected accuracy of star observations.

Two space astrometry missions were launched successfully. The Hipparcos mission was a global astrometric mission. The other comprises the astrometric facilities on board the Hubble Space Telescope (HST) all directed toward small-field astrometry. Both are described in the following sections. In addition, there are several space astrometric projects expected to be launched, if approved, during the first decade of the twenty-first century. Their principles are mentioned in the preceding section. See also **Hipparcos Mission**; and **Hubble Space Telescope (HST)**.

Projects for the Future

The successful entry of astrometry among space astronomical techniques is a powerful incentive to devise and propose to space agencies new more powerful, more effective space astrometric missions with a better science return to cost ratio. Many projects have been presented during the last decade. Some have already been thoroughly studied, and engineered descriptions of a possible realization exist. Other are in a more dormant state. The two most ambitious projects are described.

The Space Interferometry Mission (SIM). In the early 1990s, a group of scientists and engineers at NASA's Jet Propulsion Laboratory made an extraordinary claim: They could develop a space telescope powerful enough to detect Earthlike planets around nearby stars.

SIM PlanetQuest has successfully completed the last of eight seemingly impossible technology milestones required to prove that the mission can accomplish its ambitious science goals. NASA specified that the rigorous tests of the ultra-precise technologies must be finished by the end of 2005 in order for the mission to move forward.

Scheduled to launch in 2011, SIM PlanetQuest will determine the orbits and masses of planets around other stars and detect nearby Earth-size planets. The mission will also determine the distances to stars throughout the galaxy with unprecedented accuracy and perform many other fundamental astrophysics investigations. See **SIM PlanetQuest**:

http://planetquest.jpl.nasa.gov/SIM/sim_breakthrough.cfm, and http://eis.jpl.nasa.gov/planetquest/documents/WhitePaper05ver18_final.pdf

Description of the Instrument. The principle is that of a Michelson phase interferometer already in use on the ground and in a configuration now tested in actual size at Mount Palomar Observatory. The Palomar Testbed Interferometer is now operational and regularly observes some 100 stars per night by remote control from the JPL. Two options of the spacecraft have been studied. The first involved seven siderostats arranged linearly on a 10-meter (32.8 ft) boom. A second one, the so-called *RainBird* configuration will probably be the one chosen for flight. It consists of two collector pads placed symmetrically on a 7-meter (23 ft), high-precision rail with respect to the combiner pad (Fig. 5). An ensemble of solar arrays and sun shades is placed on the end of a boom to protect the instrument continually from direct sunshine.

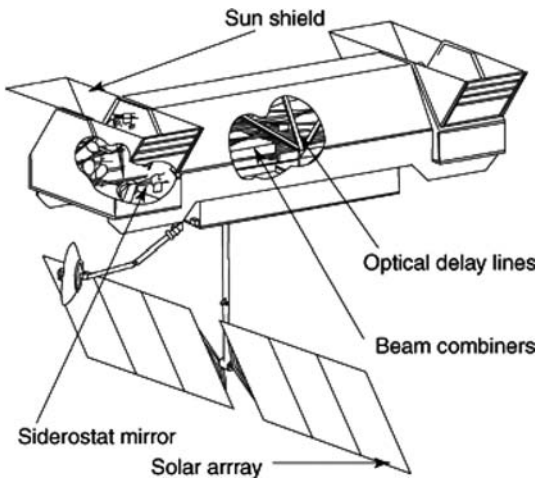

Fig. 5. Oblique deployed view of the Space Interferometry Misson.

Principle of Measurements. A sketch of the instrument is given in Fig. 6. The two collectors receive light from a star and send it to a beam combiner. One of the beams is directed into a controlled delay line so that the external path delay is equal to the internal one. Thus, interferometric fringes are obtained at the detector. The delay line is activated so that the central fringe remains on the central line of the detector. The reading of the delay line added to the calibrated other internal paths gives the path delay x which is recorded. If D is the baseline, also calibrated internally,

$$x = B\cos\theta \tag{13}$$

where θ is the angle between the baseline and the direction of the star. Two more interferometers between articulated light collectors on the same baseline measure similarly, the direction of two bright stars with known positions, part of the global rigid grid. From the results, one deduces the space orientation of the baseline at an accuracy of 30 mas. Associated with the main observation, θ defines a portion of a celestial small circle around the baseline on which the star is located. Observations at different orientations of the baseline provide the position of the star at the intersection of the loci.

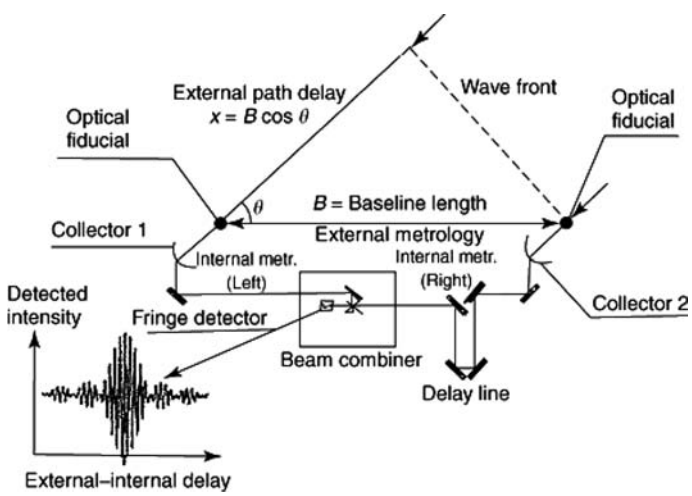

Fig. 6. Principle of the SIM interferometer. The peak of the interference pattern occurs when the internal path equals the external path delay.

Calibrations and Expected Results. The objective is to achieve microsecond of arc (μ as) astrometry at the end of the 5-year mission. During this time, the spacecraft, which is not on a geocentric orbit, progressively moves away from Earth and reaches finally a distance of 95 million kilometers. This choice minimizes the speed of variation of the aberration which is quite important for an Earth satellite. To perform this correction with a superabundant accuracy of 0.7 μ as, it will be necessary to know the velocity of the spacecraft to an accuracy of 4 mm s^{-1}. The velocity will be determined from tracking by the NASA Deep Space Network observing two hours a day.

But the major technical challenges are the onboard measurements of distances between various fiducial corner cubes needed to determine internal delays. There are two types of measurements. First, absolute determinations of distance up to 12 meters are to be made with an accuracy of 10 μm. This condition is not so stringent, but it requires a very rigorous stability of the lasers. On the other hand, relative metrology concerned with the variations of the baselines must be accurate to 1 or 2 picometers to achieve the astrometric objectives, that is, 10 million times better than the absolute length measurements. To achieve this, several different methods have been proposed and tested in the laboratory. The conclusion is that such measurements are possible on the ground and also in space. In all cases, the corresponding calibration cycles will be performed every hour for the relative internal measurement needs and every few days for the external delay. In the error budget, one has to take into account, in addition, thermal effects, even if they are reduced by severe thermal control, fringe measurement errors, and beam walk error produced by mispointing the compressed beams, warping of the pads, shear of the metrology beams, etc.

When these calibrations are performed, it is expected that a 7.5 μ as precision measurement of one locus of the star position may be obtained in 0.2 s for stars of magnitude 8, 10 s at magnitude 12, 7 minutes at magnitude 16, and four and a half hours at magnitude 20. The uncertainty also decreases as the inverse of the square root of the exposure time, so that brighter stars may be observed longer without scheduling consequences, because it is essentially the slow (0.25° per second) pointing motion and acquisition time that will limit the scheduling. Finally, an accuracy of 1 μ as will be achievable for a majority of the 10,000 stars expected to be on the program, and 4 μ as for the global grid of 4000 stars.

GAIA Mission. The Global Astrometry Instrument for Astrophysics (GAIA) is a spacecraft proposed to the European Space Agency (ESA) as a successor to Hipparcos, Gaia, was approved in 2000 as an ESA Cornerstone mission to be launched around 2001.

Gaia is a mission that will conduct a census of one thousand million stars in our Galaxy. It will monitor each of its target stars about 100 times over a five-year period, precisely charting their distances, movements, and changes in brightness. It is expected to discover hundreds of thousands of new celestial objects, such as extrasolar planets and failed stars called brown dwarfs. Within our own Solar System, Gaia should also identify tens of thousands of asteroids. Additional scientific benefits include detection and characterisation of tens of thousands of extrasolar planetary systems, a comprehensive survey of objects ranging from huge numbers of minor bodies in our Solar System, through galaxies in the nearby Universe, to about 10 million galaxies and 500 000 distant quasars. It will also provide stringent new tests of general relativity. See ESA GAIA Mission: http://www.esa.int/esaSC/120377_index_0_m.html#subhead7

Description of the Payload. The principle of GAIA is identical to Hipparcos in the sense that two fields of view separated by a basic angle (here, $\gamma = 106°$) are simultaneously observed. However, rather than directing the two fields of view on the same focal surface, there are two separate identical telescopes; each has its own receiving subsystem. The invariance of the basic angle is monitored by laser interferometers. The layout of the two full-reflective, three-mirror telescopes, thermally controlled at a temperature below 200 K (−73.15°C) (−99.7°F), is shown in Fig. 7. The space left between the two telescopes is filled by a third

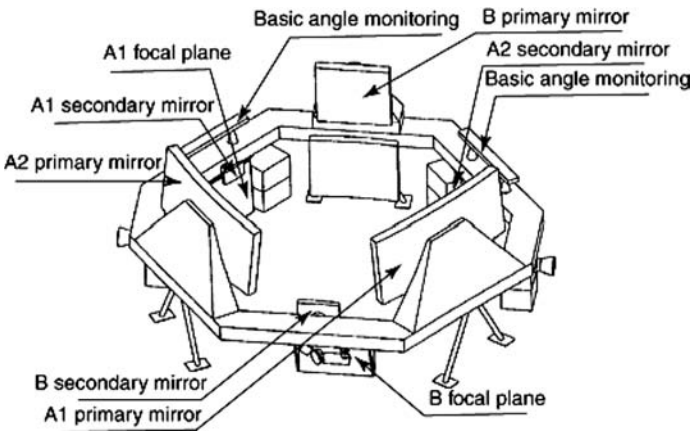

Fig. 7. Layout of the three telescopes of the GAIA project. A1 and A2 are the astrometric telescopes; B is the radial velocity/photometry telescope.

telescope adapted for radial velocity measurements and spectrophotometry. The primary mirror of the astrometric telescopes is a rectangle of 1.4×0.5 meters (4.6×1.6 ft). The optics give an equivalent 50-meter (164-ft) focal length so that the useful field of view of $0.66^\circ \times 0.66^\circ$ is projected on a detector whose dimensions are 575×700 mm (23×27.6 in). The satellite rotates around an axis perpendicular to the telescope layout and scans the sky following a law analogous to that of Hipparcos. As in the case of SIM, it was recognized that the observations should be made far from Earth. For GAIA, the choice is a Lissajous type of orbit around the Laplace L2 point of the Sun–Earth system.

The Detector System. The detector (Fig. 8), placed on the focal surface of the telescope, includes 250 CCD arrays of 2100×2660 pixels organized in 10 along-scan (horizontal) strips. Each array is 24 mm (0.9 in) wide along scan and 57 mm (2.5 in) long in the vertical direction. The pixel size along scan is 9 μ m (36 μ as in the sky) $\times$27 μm (108 μ as), compatible with the shape of the point-spread function. The observing strategy is the scan mode already mentioned earlier. The transfer of charges is done continuously, and the speed corresponds to the rate of rotation of the instrument. The collection of charges is done in the 4-mm dead zones between the arrays.

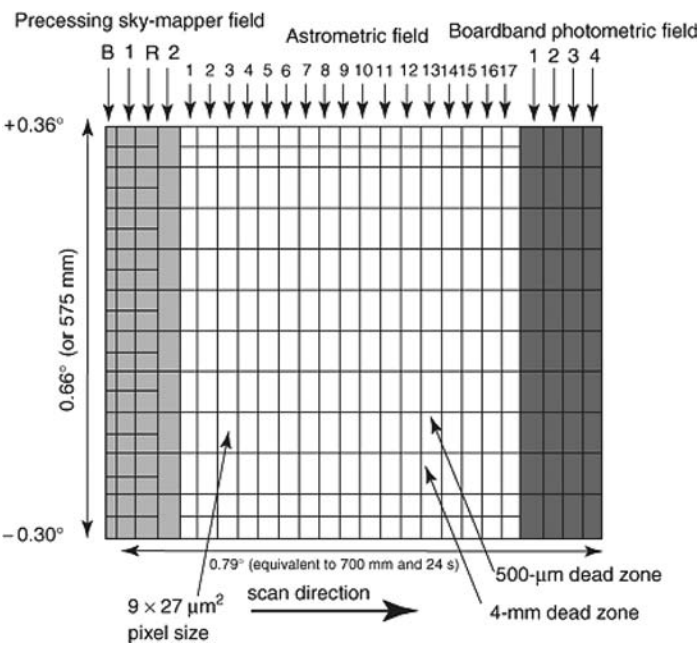

Fig. 8. Arrangement of the CCDs on the GAIA focal surface.

The vertical columns of CCDs do not have all the same functions. The first four in the scan direction form the star-mapper. All signals are processed. Those corresponding to an input catalog are used to control the attitude, but all are analyzed, and the position of those that are sufficiently bright to be measured are used to sort the useful signals in the astrometric CCDs. The latter occupy the next 17 columns in which the astrometric data are acquired. The last four columns are used for broadband photometry in different colors.

Because of the curvature of the focal surface, the arrays will be slightly tilted and individually sequenced to compensate for optical distortion. Each individual CCD features a special operating mode, which may or may not be activated, that allows reducing the integration time and acquiring bright stars with no saturation which occurs for magnitudes brighter than 12.

Expected Results. The astrometric performance depends on magnitude and also on color. Many more photoelectrons will be received from red stars than from blue ones. For intermediate stars (solar type), the accuracy floor up to magnitude 12 is 3 μ as. It degrades for fainter stars and is 10 μ as for magnitude 15. In other terms, for some 35 million stars, the astrometric accuracy in position, parallaxes, and yearly proper motions will be better than 10 μ as. For magnitude 16, the numbers will be, respectively, 60 millon stars and 18 μ as; for magnitude 18; 300 million stars and 55 μ as; and for magnitude 20, more than a billion stars and 0.2 mas. So even at the limiting magnitude of 20, it is expected that GAIA will be five times more precise than Hipparcos for its bright stars.

For the first time, radial velocities will be systematically measured all over the sky. The wavelength interval provisionally set is 847–879 nm. The expected precision is a few km s^{-1} for stars up to magnitude 17 that have spectral lines in this interval. This means that more than one hundred million radial velocities would complete the proper motion and parallax measurements for space velocities.

ASTRONAUTICS. Astronautics is the branch of engineering that deals with machines designed to work outside of Earth's atmosphere, whether manned or unmanned. In other words, it is the science and technology of travel in outer space.

Astronautics was coined by analogy with aeronautics. As with aeronautics, the restrictions of weight, heat and external forces require that applications in space survive extreme conditions, whether the heat of reentry, the radiation bombardment of interplanetary space, or the magnetic belts of orbit, space vessels must be designed to withstand forces almost unknown on Earth. Moreover, because of the extreme constraints on weight, astronautic engineering is constantly faced with the need to reduce the mission payload, in order to save propellant that powers the impulse engine.

Branches of astronautics are space mathematics, astrodynamics, space environment, spacecraft design, rocketry, attitude dynamics and control, navigation. See also **Rocketry**; **Spacecraft Design for Planetary Exploration**; and **Spacecraft Guidance**, **Navigation and Control Systems**.

Weight and Weightlessness

In Newtonian mechanics, weight is understood to mean the force that an object exerts upon its support. This would depend on two factors: the strength of gravity at the object's location (things weigh less on the moon) and, as Newton called it, the quantity of matter in a body (its "mass"). At any given location, where gravity is fixed, mass can be measured relative to a standard by noting the extension of a spring to which it and the standard are successively attached. Alternatively, the unknown and standard may be hung at opposite ends of a rod and the balance point noted. However, by an entirely separate experiment, mass can also be measured by noting the resistance of the object to a fixed force applied horizontally on a frictionless table. The measured acceleration provides the required basis of comparison with the standard. Needless to say, all objects measure identical accelerations when freely falling in the vertical force of gravity. This merely means that, unlike the arbitrary force we apply horizontally in the experiment above, gravity has the property of adjusting itself in just the right amount, raising or lowering its applied force, to maintain the acceleration constant.

It was well known that objects appear to increase or decrease their weight (alter the extension of the spring) if the reference frame in which the measurement takes place accelerates up or down. As gravity did not really change, however, most people were inclined to draw a distinction between *weight* defined as *mg*, where m is the mass and $\mathbf{g}$ is the local gravity field, and the *appearance of weight*, the force of an object on its support as measured by the spring's extension. One way to avoid the difficulty has been to speak of an *effective* $\mathbf{g}$, which takes into consideration the frame's acceleration. For example, at the equator of the earth, we measure, say by timing the oscillation of a pendulum, the effective g, some 0.34% less than the $\mathbf{g}$ produced by the mass of earth beneath our feet. If the earth were rotating with a period of an hour and a half instead of 24 hours, our centripetal acceleration at the equator would cause the effective g to vanish completely, our scales would not register, objects would be unsupported, and for all practical purposes we would be weightless.

Formally, we could state that any accelerating frame produces a local gravitational field $\mathbf{g}_{acc}$ that is equal and opposite to the acceleration. Thus, a rotating frame generates a centrifugal g_{acc} opposing the centripetal acceleration. We have at any point

$$\mathbf{g}_{\text{eff}} = \mathbf{g} + \mathbf{g}_{\text{acc}} \tag{1}$$

where g is the field produced by matter along (e.g., the earth). By identical reasoning, an object in orbit, whether falling freely in a curved or in a straight path, will carry a reference frame in which $\mathbf{g}_{\text{eff}}$ is zero, for its acceleration will always exactly equal the local $\mathbf{g}$ by the definition of the phrase, "freely falling."

This concept was placed on a firm footing by Einstein who maintained that Eq. (1) is reasonable not only in mechanics but in all areas of physics including electromagnetic phenomena. We arrive at the inevitable conclusion that we cannot distinguish by any physical experiment between an apparent $\mathbf{g}$ accountable to an accelerating frame and a "real" $\mathbf{g}$ derived from a local accumulation of mass. This central postulate of the General Theory of Relativity also unified the two separate conceptions of mass. An object resting on a platform that is accelerating toward it will resist the acceleration in an amount depending on its inertia. It presses against the platform with a force equal to that it would have if placed at rest on the surface of a planet with local field equal and opposite to the acceleration of the frame. See also **Weightlessness**.

General Principles of Central Force Motion

The gravitational force between point masses is inverse square, written

$$mg = \frac{\gamma m' m}{r^2} \tag{2}$$

where the center of coordinates from which the unit vector $\hat{\mathbf{r}}$ is described lies in m', one of the masses. Thus, the force on m is directed $-\hat{\mathbf{r}}$, toward m' and is proportional to $1/r^2$ with γ the constant of proportionality. The quantity $\mathbf{g}$ is the force on *m divided by m*, (or normalized force) for which the name "gravitational field of m'" is reserved. Of course, if m were in the field of a collection of mass points, or even in a continuous distribution of mass, the summated or integrated $\mathbf{g}$ at the location of m would no longer be an inverse square function with respect to any coordinate center. However, in one special case, the inverse square functional form would be preserved: if the source mass were symmetrically distributed about the coordinate center. This would be the case if the source were a spherical shell or solid sphere, of density constant or a function only of r. The sun and earth can be regarded, at least to a first approximation, as sources of inverse square gravitational fields.

There are some important general statements we can make about the motion of an object placed with arbitrary position and velocity in a centrally directed force field, i.e., a field such as the one described, which depends only on distance from a central point (regardless of whether or not the dependence is inverse square). As the force has only a radial and no angular components, it cannot exert a torque about an axis through the center. This means that the initial angular momentum is conserved. Now angular momentum is a vector quantity and therefore is conserved both in direction and magnitude. It is defined by $\mathbf{r} \times \mathbf{p}$, where $\mathbf{r}$ is the position vector to the mass of momentum $\mathbf{p}$. The direction of the angular momentum vector is thus perpendicular to the plane containing $\mathbf{r}$ and $\mathbf{p}$. As this direction is permanent, so also must be the plane. The planar motion of the object can be expressed in polar coordinates, so that, by writing $\mathbf{r} = r\hat{\mathbf{r}}$ and $\mathbf{p} = m(r^{\circ}\hat{\mathbf{r}} + r \cdot \dot{\phi}\hat{\phi})$, we find the specific angular momentum (angular momentum per unit mass) called h, to be

$$h = r^2\dot{\phi} \tag{3}$$

This too then must be a constant of the motion.

Consider now the rate at which area is swept out by the radius vector, dS/dt. We recall from analytic geometry that $dS = \frac{1}{2}r^2 d\phi$. Thus

$$\frac{dS}{dt} = \frac{h}{2} \tag{4}$$

so that this is a constant of the motion as well. On integration, we conclude that the size of a sector that is swept out is proportional to the time required to sweep it out. In the case of a closed orbit, the total area S would then be related to the specific angular momentum as

$$S = \frac{hT}{2}$$

This sector area-time relationship is Kepler's second law of planetary motion which was induced from Tycho Brahe's observation of Mars without prior knowledge of gravity and its central character.

The Laws of Kepler

Kepler stated two other laws of planetary motion: The orbits of all the planets about the sun are ellipses (a radical departure from the circles of Copernicus): and the squares of their period are proportional to the cubes of their mean distance from the sun, this mean being the semimajor axis of their ellipses. See Fig. 1. The third law pertained to the one object common to all the planets, the sun. Taken together, the three laws led Newton to the concept of gravitational force and its inverse-square form.

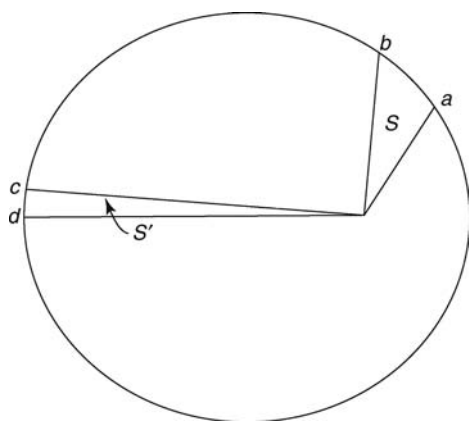

Fig. 1. Kepler's second law. The sector area S swept out is proportional to the time required for the planet to move from a to b. Thus, if $t_{cd} = t_{ab}$, then $S' = S$.

By applying Newton's law of motion $\mathbf{F} = m\mathbf{a}$, a relationship between $\mathbf{a}$, the second derivative of the position vector, expressed in polar form,

and $\mathbf{F}/m$ or $\mathbf{g}$, as given by Eq. (2), leads to the familiar conic solution for the trajectory of an object in an inverse square field,

$$\frac{1}{r} = \frac{\gamma m'}{h^2} + A\cos(\phi - \phi_0) \tag{6}$$

where A and ϕ_0 are constants. A rotation of axis will eliminate ϕ_0, thereby aligning the coordinate axis with the conic's major axis. Also, by expressing the general conic, an ellipse or hyperbola, in terms of the usual parameters of semimajor axis a and eccentricity $\in$, we can relate the geometric parameters to the gravitational-dynamical constants, viz:

$$h = [\gamma m' a(1 - \varepsilon^2)]^{1/2} \tag{7}$$

and

$$\frac{1}{r} = \frac{\gamma m'}{h^2}(1 + \varepsilon\cos\phi) \tag{8}$$

Note that by substituting Eq. (7) into Eq. (5) and expressing the area of an ellipse as $\mathbf{S} = \pi a^2(1 - \varepsilon^2)^{1/2}$ we arrive at Kepler's third law,

$$T = \frac{2\pi}{(\gamma m')^{1/2}} a^{3/2} \tag{9}$$

The *energy* of the orbiting object can be calculated with ease by evaluating it at an extreme point, say the nearest point to the gravitational source, called pericenter or perifocus. As the energy is constant, it is immaterial where the calculation is made. Here the velocity has only an angular component so that the kinetic energy for a unit orbiting mass is $\frac{1}{2}v^2 = \frac{1}{2}r^2\phi^2$. The potential energy at pericenter is $\gamma m'/r_{\text{pe}}$ where r_{pe} is the distance of the unit mass from m', the focal point. Here $\gamma = 0$ so that by Eq. 8,

$$\frac{1}{r_{\text{pe}}} = \frac{\gamma m'}{h^2}(1 + \varepsilon) \tag{10}$$

On substituting Eq. (7), we find the total kinetic and potential energy to be

$$E = \frac{\gamma m'}{2a} \tag{11}$$

Our conclusion: All objects in orbit with the same major axes have identical periods and identical energies per unit mass. Knowledge of E is invaluable in determining an object's speed when its distance from the source is known and vice versa.

In the event that the orbiting object's mass is not negligibly small compared with that of the gravitational source, one must take note that the combined center of mass, from which the acceleration is described, no longer may be assumed to lie in the center of the gravitational source. This complicates our equations somewhat, for the accelerating force still is expressed relative to the center of the source (if spherical). The adjustment that results, when center of mass coordinates are transformed to relative coordinates in the expression for acceleration, requires our equations to take the form $\gamma(m' + m)$ wherever formerly $\gamma m'$ appeared. See Fig. 2. See also **Kepler's Laws of Planetary Motion**; and **Earth Orbiting Satellite Theory**.

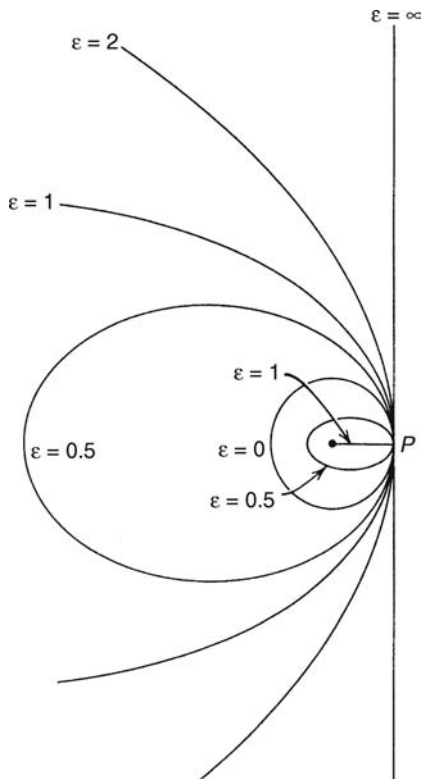

Fig. 2. Obits of differing eccentricities and major axes that pass through a common point. Higher speeds correspond to higher energies and longer major axes.

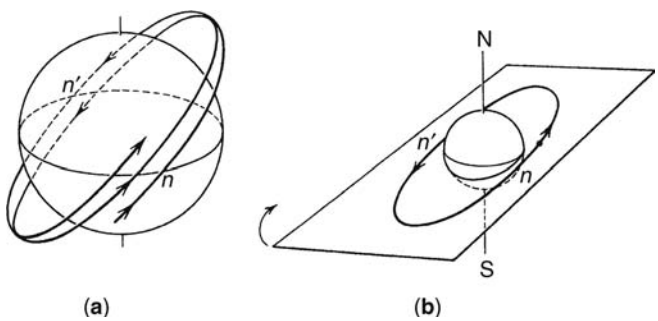

Fig. 3. (**a**) The orbit of an earth satellite. The earth's equatorial bulge causes retrograde motion of the points of intersection n and n' of the orbit and equatorial plane. This can alternatively be interpreted as a retrograde motion, about the north-south axis, of the plane containing the closed orbit. The plane containing the closed orbit. The plane moved in the direction shown by the arrow in (**b**), maintaining a constant angle with the axis.

Disturbances in the Central Field

The Earth, of course, is spherical only to a first approximation. More accurately, it is an ellipsoid of revolution about a minor axis — an oblate spheroid. Still more accurately, it appears to be slightly pear-shaped and, in addition, its figure is distorted by continuous local variations. The spheroidal figure, nevertheless, accounts for nearly all the anomalous effects of satellite orbits. For one thing, the gravitational force on the satellite is no longer centrally directed; the excessive mass in the equatorial plane produces a force on the satellite directed out of its orbital plane. The resultant torque causes the direction of the angular momentum vector to change, i.e., the plane containing the satellite's ellipse turns. The plane turns continuously about the polar axis maintaining its angle with the axis and with the equatorial plane constant. The turning rate is greatest for low orbits and small angles of inclination with the equator. For polar satellites, the plane remains fixed. A separate effect of this equatorial bulge perturbative force is the slow turning of the ellipse's major axis *within* the orbital plane. This effect vanishes at an inclination of 63.4°; the major axis turns backward at inclinations above this angle and forward below. See Fig. 3.

Rocket Propulsion

A rocket operates by the simple principle that if a small part of its total mass is ejected at high speed, the remaining mass will receive an impulse driving it in the opposite direction at a moderate speed. As $\delta\, m_e$, the propellant, leaves at speed v_e with respect to the rocket, the remaining rocket mass m receives a boost in speed dv such that

$$\delta m_{\text{e}} v_{\text{e}} = m\delta v \tag{12}$$

If additional equal propellant mass is ejected at the same speed, the boost in rocket speed is slightly greater than before as the rocket mass has been slightly depleted by the prior ejection. Indeed, if the residual rocket mass eventually were minuscule, its boost in speed could reach an enormous value. The integrated effect of these nonlinear boosts is found as

$$v_t - v_0 = v_{\text{e}} \log_e \frac{m_0}{m_t} \tag{13}$$

where v_0 and m_0 are the rocket speed and mass at some arbitrary initial time and v_t and m_t are the same quantities at some time t later.

From these simple considerations, it is apparent that the highest rocket velocities are attained if one increases the propellant speed as well as the mass ratio, m_0/m_t. The mass ratio can be maximized by obvious methods such as choosing a high-density propellant (which cuts the tankage requirement) or avoiding unnecessarily complicated apparatus for ejecting propellant at high speed. A nuclear rocket, for example, may perform well in its ability to eject propellant an order of magnitude higher in velocity than conventional chemical rockets; nevertheless, the penalty required in reactor weight and shielding severely limits its effectiveness.

Specific impulse is one performance characteristic that applies to the propellant's ability to be ejected at high speed regardless of the weight penalty required to do this. It is the impulse produced per mass of propellant ejected, or $m\delta v/\delta m_e$, or, by Eq. (12), simply v_e. In engineering usage, it is impulse per weight of propellant ejected, or v_e/g_e where g_e is the acceleration of gravity at the earth's surface. Its units are seconds, and it can be interpreted as the thrust produced by a rocket per weight of propellant ejected per second. By itself, thrust is of little importance, unless it is sustained for a significant time by a large reserve of propellant tankage. It is here that the mass ratio term in Eq. (13) would play an important role in any evaluation of a rocket's true performance.

Transfer Orbits

If one wishes to leave one orbit and enter another by rocket, an optimum path is generally chosen to minimize the total propellant required. Nevertheless, this should not be done at the expense of unduly long flight times, complicated guidance equipment, or high acceleration stresses. These would require unprofitable weight expenditures, which would offset the frugality in propellant tankage. See Fig. 4.

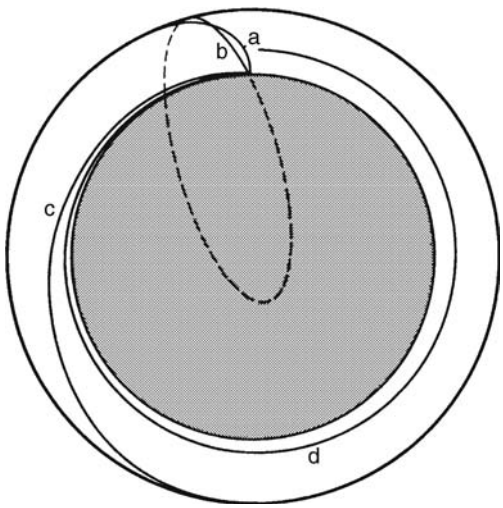

Fig. 4. Four launch trajectories into a satellite orbit about a planet. (**a**) If that planet has an atmosphere, the rocket may ascend in a "synergic" trajectory from the planetary surface to the final orbit, i.e., it cuts through the denser portions in an initially vertical path and gradually bends over into a horizontal path during burnout. (**b**) If there is no atmosphere it may ascend from the ground in a ballistic ellipse. This same ascent path may be chosen if the departure is from a parking orbit or "space platform" close to ground level. A far better choice would be (**c**) the Hohmann ellipse, with pericenter at the planet's surface and apocenter at the satellite orbit. Burnout time is assumed short in both this and the ballistic case. (**d**) A vehicle such as an ion rocket, which can sustain a microthrust for a very long time, cannot be launched from the ground but only from a parking orbit. It will spiral out to the desired altitude with few or many turns about the planet, depending on the magnitude of the thrust relative to that of the gravitational force.

Let us examine a simple but recurring example of a transfer problem, that of leaving a space platform in one circular orbit and entering another larger one concentric with the first. If the transfer path were radial or near radial (a so-called ballistic orbit) then one would have to launch at a large angle to the direction of motion of the platform, accomplished only by a velocity component opposed to the platform's motion. On reaching the outer platform, a soft landing can be made only by a substantial rocket velocity boost, tangent to the orbit. Clearly, the total propellant expenditure would be far greater than one alternative of launching the rocket in the direction of motion of the first platform with just sufficient speed to reach the outer circle, timed so that the outer platform will meet the spacecraft. The transfer orbit will be an ellipse cotangent with both circles. The outer platform will be moving much faster of course at the contact point as the major axis of its orbit is much greater [see Eq. (11)], but the difference in speed is not nearly as pronounced as for the ballistic transfer case. A differential speed increment at contact completes the maneuver.

The return trip, from an outer to inner circle, is made by following the second half of this cotangent ellipse, named the Hohmann transfer orbit after the German engineer who discovered its optimal property with regard to propellant expenditure. In the return case, the spacecraft is launched in opposition to the outer platform's motion. This removes kinetic energy and forces the spacecraft to fall in closer to the attractive center in order to make cotangent contact with the inner circle. The total propellant expenditure from the outer to the inner platform is the same as for the original journey.

An interesting question arises if one wishes to leave a platform for an outer orbit when it initially is in an elliptical orbit rather than a circle. Should we depart from apocenter where we are furthest from the gravitational source and closest to our destination? Or should we depart instead from some other point in the ellipse? Paradoxically, our best launch point is at pericenter, for here the largest possible amount of energy will be transferred to the spacecraft for a given expenditure of propellant. A given thrust applied for a given time interval will do more work on the spacecraft when it is moving fast, as at pericenter, for it covers a greater distance during the interval. This advantage offsets the undesirability of being at a lower potential energy point at pericenter.

Powered Trajectories

In the usual operation of a solid- or liquid-propelled rocket, the propellant is depleted in a time negligibly small compared with the total flight time. The trajectory analysis may generally be considered that of a free orbit subject to burnout initial conditions as in the discussion above. If, however, the propellant ejection is sustained over long periods, as in an ion-propelled rocket, the trajectory analysis is necessarily complicated, for, in addition to the varying gravitational force, the vehicle, of slowly diminishing mass, is subject to a thrust which may be changing both in direction and magnitude. Even one of the simplest thrust programs, a constant thrust in the direction of motion, requires an electronic computer analysis in order to obtain the position and velocity at future times.

The continuous-thrust trajectory is a spiral with many advantages over the orbital ellipses. First, the lower sustained thrust precludes the high acceleration stresses associated with rapid-burning chemical rockets. Much of the structural weight usually needed to withstand these stresses can be replaced by propellant. Also, flights to the extremities of a gravitational region may take a shorter time in a spiral trajectory. In a long Hohmann ellipse, for example, most of the journey is made at very low speed. In a powered spiral, on the other hand, the spacecraft could be made to move fast, for the thrust, though small, is integrated over many months.

The spiral concept is ideal for rockets where very high ejection velocities are feasible by using electromagnetic or electrostatic particle accelerators, but only at the expense of a low propellant flow rate and relatively heavy power-generating equipment. However, the propellant reserve, and thrust, could then last the required long time. Such an ion rocket with its very low thrust-to-weight ratio could hardly be expected to take off from the ground, and could only take off from an orbital platform. In the vacuum of space, the ion beam meets its ideal environment.

ASTRONAUTS. The 21st century promises the challenge for humans to live and work in space. The achievements of scientists, engineers, technicians, and specialists who will build and operate the International Space Station will be the legacy of the national Aeronautics and Space Administration's (NASA's) many years of experience in selecting and training astronauts to work on the frontier of space.

The National Aeronautics and Space Administration's (NASA) Lyndon B. Johnson Space Center (JSC), located in Houston, Texas, has been responsible for conducting the astronaut recruiting and selection process. This includes:

- establishing the astronaut staffing and selection requirements.
- issuing and releasing public announcements advertising the qualification requirements.
- appointing qualified members for rating panels and selection committees established for each recruiting campaign:
- reviewing and performing the initial screening of applicants;
- conducting personal interviews of those applicants who satisfy initial screening requirements; and
- making final recommendations for selecting of applicants who qualify for the astronaut training program.

From the outset of human spaceflight, prospective candidates for the astronaut training program have been recruited on the basis of selection criteria dictated by the requirements of the missions to which they would be assigned. These mission requirements have grown in complexity; each follow-on program is responsible for advancing the state of the art of human space explorations. Such requirements have evolved from the pioneering effort in Project Mercury to those of far-reaching ramifications demonstrated in Project Apollo for landing humans on the Moon and more in the Space Shuttle and International Space Station Program for sustaining human life and supporting human productivity for flights of long duration.

History of Astronaut Selection

In December 1958, President Dwight D. Eisenhower issued an edict limiting the pool of candidates for Project Mercury astronauts to military test pilots. Critics argued that this requirement excluded women, given the absence of female test pilots in the armed services to choose from and that the use of all military personnel in this highly visible position ran contrary to NASA's status as a civilian agency. However, Eisenhower's decision simplified and expedited NASA's selection process, eliminated the potential publicity blitz associated with an open call for applicants, and fit well with the highly technical and classified nature of certain aspects of the job. Screening boards for the Navy, Air Force, and Marines and a review by three aviation medicine specialists deemed 110 test pilots suitably qualified for further evaluation by the NASA Space Task Group, the organization charged with putting America's first human in space. Robert R. Gilruth, the Space Task Group Director, delegated all authority for selecting the Mercury astronauts to his deputy, Charles J. Donlan, and his handpicked board. Though rigorous medical and psychological tests provided a wealth of information on each potential astronaut, this first selection committee also weighed its impressions gained through personal interviews with each candidate. The committee regarded individual initiative and complementary technical expertise within the group as the deciding factors in March 1959 when they chose the seven test pilots who would be America's first men in space. In the following month, after approval by Gilruth and NASA management, the space agency publicly announced the names of the Mercury Seven astronauts. They were Air Force Captains L. Gordon Cooper, Jr., Virgil "Gus" Grissom, and Donald K. "Deke" Slayton; Marine Lieutenant Colonel John H. Glenn, Jr., Navy Lieutenant M. Scott Carpenter and Navy Lieutenant Commanders Walter M. Schirra, Jr., and Alan B. Shepard, Jr.

Each man flew in Project Mercury except Slayton, who was grounded for medical reasons. Sixteen years later, Slayton was an American crew member of the Apollo-Soyuz Test Project, the world's first international manned space flight.

Nine pilot astronauts were chosen in September 1962, and fourteen more were selected in October 1963. By then, prime emphasis had shifted away from flight experience and toward superior academic qualifications. In October 1964, applications were invited on the basis of educational background alone. These were the scientist astronauts, so called because the 400-plus applicants who met minimum requirements had a doctorate or equivalent experience in the natural sciences, medicine or engineering. Of these 400 applicants, six were selected in June 1965.

In April 1966, 19 pilot astronauts were named and in August 1967, 11 scientist astronauts were added to the program. When the Air Force Manned Orbiting Laboratory program was canceled in mid-1969, seven astronaut trainees transferred to NASA.

Shuttle Era Astronaut Candidate Recruiting

The first group of astronaut candidates for the space shuttle program was selected in January 1978. In July of that year, the 35 candidates began a rigorous training and evaluation period at NASA's Johnson Space Center (JSC), Houston, Texas, to qualify for subsequent assignment for future space shuttle flight crews. This group of 20 mission scientist astronauts and 15 pilots completed training and went from astronaut candidate status to astronaut (active status) in August 1979. Six of the 35 were women and four were minorities.

Eleven groups of pilots and mission specialists have been added since then: 19 in 1980, 17 in 1984, 13 in 1985, 15 in 1987, 23 in 1990, 19 in 1992, 19 in 1995, 35 in 1996, 25 in 1998, 17 in 2000, and 11 in 2004.

Selection and Training of Astronauts

In the future, the United States with its international partners Japan, Canada, Russia and the European Space Agency, will continue to operate a man-tended space station. From that orbiting depot, humans will continue their journeys to the Moon and Mars.

To respond to these needs, NASA accepts applications for the Astronaut Candidate Program as needed, normally every 2–4 years, for pilot and mission specialist categories. Both civilian and military personnel are considered for the program. Military personnel must apply through their parent service and be nominated by their service to NASA.

The astronaut candidate selection process was developed to select highly qualified individuals for human space programs. For mission specialists and pilot astronaut candidates, the education and experience requirements are at least a bachelor's degree from an accredited institution in engineering, biological science, physical science, or mathematics.

For mission specialist applicants, three years of related, progressively responsible professional experience must follow the degree. An advanced

degree is desirable and may be substituted for all or part of the experience requirement (i.e., master's degree = 1 year of work experience, doctoral degree = 3 years of professional experience). Pilot astronaut applicants must also meet the following requirements prior to submitting an application:

- At least 1,000 hours pilot-in-command time in jet aircraft; flight test experience is highly desirable.
- Ability to pass a NASA Class I space physical, which is similar to a military or civilian Class I flight physical, and includes the following specific standards: for vision-distance visual acuity — 20/100 or better uncorrected, correctable to 20/20, each eye. For Blood Pressure-140/90 measured in a sitting position.
- Height between 64 and 76 inches.

Mission specialists have similar requirements to pilot astronauts, except that the qualifying physical is a NASA Class II space physical, which is similar to a military or civilian Class II flight physical and includes the following specific standards: for vision-distance visual acuity — 20/200 or better uncorrected, correctable to 20/20, each eye. For Blood pressure-140/90 measured in a sitting position. Height requirements for mission specialists are between 58.5 and 76 inches.

The application package may be obtained by writing to the Astronaut Selection Office, Mail Code AHX, Johnson Space Center, Houston, TX, 77058-3696.

Applicants who meet the basic qualifications are evaluated by discipline panels. Those selected as finalists are screened during a week-long process of personal interviews, thorough medical evaluations, and orientation. The Astronaut Selection Board's recommendations are based on the applicant's education, training, and experience as well as unique qualifications and skills. Because several hundred applicants fulfill the requirements, the final selection is based largely on personal interviews. Astronauts are expected to be team players and highly skilled generalists with just the right amount of individuality and self-reliance to be effective crew members.

Selected applicants are designated astronaut candidates and assigned to the astronaut office at the Johnson Space Center for a 1 to 2 year training and evaluation program. Civilian candidates who successfully complete the training and evaluation and are selected as astronauts are expected to remain with NASA for at least 5 years. Successful military candidates are detailed to NASA for a specified tour of duty.

Salaries for civilian astronaut candidates are based on the Federal Government's General Schedule pay scales for grades GS-11 through GS-14, and are set in accordance with each individual's academic achievements and experience.

Space Shuttle Crew Positions

Commander/Pilot Astronauts. Pilot astronauts serve as both space shuttle commanders and pilots. During flight, the commander has onboard responsibility for the vehicle, crew, mission success, and safety of flight. The pilot assists the commander in controlling and operating the vehicle and may assist in the deployment and retrieval of satellites using the remote manipulator system (RMS), referred to as the robot arm or mechanical arm.

Mission Specialist Astronauts. Mission specialist astronauts work with the commander and the pilot and have overall responsibility for coordinating shuttle operations in the following areas: Shuttle systems, crew activity planning, consumables usage, and experiment/payload operations. Mission specialists are trained in the details of the Orbiter onboard systems, as well as the operational characteristics, mission requirements/ objectives, and supporting equipment/systems for each of the experiments conducted on their assigned missions. Mission specialists perform extravehicular activities (EVAs), or space walks, operate the remote manipulator system, and are responsible for payloads and specific experiment operations.

Payload Specialists. Payload specialists are persons other than NASA astronauts (including foreign nationals) who have specialized onboard duties; they may be added to shuttle crews if activities that have unique requirements are involved and more than the minimum crew size of five is needed.

First consideration for additional crew members is given to qualified NASA mission specialists. When payload specialists are required they are nominated by NASA, the foreign sponsor, or the designated payload sponsor. In the case of NASA or NASA-related payloads, the nominations are based on the recommendations of the appropriate Investigator Working Group (IWG).

Although payload specialists are not part of the Astronaut Candidate Program, they must have the appropriate education and training related to the payload or experiment. All applicants must meet certain physical requirements and must pass NASA space physical examinations with varying standards depending on classification.

Training

Astronaut Candidate Training. Astronaut candidates receive training at JSC near Houston, Texas. They attend classes on shuttle systems, in basic science and technology: mathematics, geology meteorology, guidance and navigation, oceanography, orbital dynamics, astronomy, physics, and materials processing are among the subjects. Candidates also receive training in land and water survival, scuba diving, and space suits.

As part of the Astronaut Candidate training program, Astronaut Candidates are required to complete military water survival prior to beginning their flying syllabus, and become SCUBA qualified to prepare them for the extravehicular activity training. Consequently, all Astronaut Candidates will be required to pass a swimming test during their first month of training. They must swim 3 lengths of a 25M pool in a flight suit and tennis shoes. The strokes allowed are freestyle, breast, and sidestroke. There is no time limit. They must also tread water continuously for 10 minutes.

Candidates are also exposed to the problems associated with high (hyperbaric) and low (hypobaric) atmospheric pressures in the altitude chambers and learn to deal with emergencies associated with these conditions. In addition, astronaut candidates are given exposure to the microgravity of space flight. A modified KC-135 jet aircraft produces periods of weightlessness for 20 seconds. During this brief period, astronauts experience the feeling of microgravity. The aircraft then returns to the original altitude and the sequence is repeated up to 40 times in a day.

Pilot astronauts maintain flying proficiency by flying 15 hours per month in NASA's fleet of 2-seat T-38 jets; they build up jet aircraft hours and also practice Orbiter landings in the Shuttle Training Aircraft, a modified corporate jet aircraft. Mission specialist astronauts fly a minimum of 4 hours per month.

Astronaut Formal Training. The astronauts begin their formal space transportation system training program during their year of candidacy by reading manuals and by taking computer-based training lessons on the various Orbiter systems ranging from propulsion to environmental control.

The next step in the training process is the single systems trainer (SST). Each astronaut is accompanied by an instructor who helps in the learning process about the operations of each Orbiter subsystem using checklists similar to those found on a mission. The checklists contain information on normal system operations and corrective actions for malfunctions. The astronauts are trained in the SSTs to operate each system, to recognize malfunctions, and to perform corrective actions.

Following the SST portion of the training program, the astronauts begin training in the complex Shuttle Mission Simulators (SMSs). The SMS provides training in all areas of shuttle vehicle operations and in all systems tasks associated with the major flight phases: prelaunch, ascent, orbit operations, entry and landing. The orbit training includes payload operation, payload deployment and retrieval, maneuvers, and rendezvous. Two additional simulators, a fixed base and a motion base, are used to train the astronauts.

The fixed base simulator is used for both specific mission/payload training and launch descent and landing training. It is the only trainer with complete fore and aft consoles, including an RMS console. A digital image generation system provides visual cues for out-the-window scenes of the entire mission, e.g., the Earth, stars, payloads and the landing runway. Missions can be simulated literally from launch to landing.

The motion base simulator is used to train pilots and commanders in the mission phases of launch, descent, and landing. Motion cues are provided by the 6-degrees-of-freedom motion system which also allows the flight deck to be rotated 90 degrees to simulate lift-off and ascent.

Astronauts begin their training in the SMS using generic training software until they are assigned to a particular mission, approximately 10 months before flight. Once they are assigned to a flight, astronauts train on a flight simulator with actual flight-specific training software.

During this last 11 weeks, the astronauts also train with the flight controllers in the Mission Control Center (MCC). The SMS and MCC are linked by computer in the same way the Orbiter and MCC are linked during an actual mission. The astronauts and flight controllers learn to work as a team, solving problems and working nominal and contingency mission timelines. Total hours in the SMS for the astronauts, after flight assignment, are about 300 hours.

In parallel with the SMS training there are several other part-task trainers that are used to prepare astronauts for shuttle missions. These trainers are in varying degrees of fidelity and each serve a particular purpose.

The Sonny Carter Training Facility, or Neutral Buoyancy Laboratory (NBL), provides controlled neutral buoyancy operations in the facility water tank to simulate the zero-g or weightless condition which is experienced by the spacecraft and crew during space flight. It is an essential tool for the design, testing and development of the space station and future NASA programs. For the astronaut, the facility provides important pre-flight training in becoming familiar with planned crew activities and with the dynamics of body motion under weightless conditions.

Several full-scale mockups and trainers are also used to train astronauts. The full fuselage trainer is a full-sized plywood Orbiter mockup with nonfunctional mid-deck and flight deck, and full-scale payload bay. It is used for onboard systems orientation and habitability training. Astronauts practice meal preparation, equipment stowage, trash management, use of cameras, and experiment familiarization. This trainer is also used for emergency egress training after shuttle landings.

The crew compartment trainer is a mockup of the forward section of the Orbiter crew station, without a payload bay, that can be tilted vertically. It is used to train for on-orbit habitability procedures and also emergency pad egress and bailout operations. The crew stations of both trainers are similar. The manipulator development facility is a full-scale mockup of the payload bay with full-scale hydraulically operated RMS, the mechanical arm on the Orbiter which is used to move payloads in and out of the payload bay. Mission specialists use this trainer to practice deploying and reberthing of payloads into the Orbiter.

Pilots training for a specific mission receive more intensive instruction in Orbiter approach and landing in Shuttle Training Aircraft (STA), which are four Gulfstream II business jets modified to perform like the Orbiter during landing. Because the Orbiter approaches landings at such a steep angle (17–20 degrees) and high speed (over 300 miles per hour), the STA approaches with its engines in reverse thrust and main landing gear down to increase drag and duplicate the unique glide characteristics of the Orbiter. Assigned pilots receive about 100 hours of STA training prior to a flight, which is equivalent to over 500 shuttle approaches. In between training sessions, the crew members continue to keep themselves up-to-date on the status of the space craft and payloads for their assigned mission. In addition, the astronauts study flight rules and flight data file procedures, and participate in mission-related technical meetings. They also participate in test and checkout activities at the NASA Kennedy Space Center in Florida, the launch site for the space shuttle.

The months of preparation pay off and the mission is a success; the actual mission will have far fewer contingencies than were practiced for. The accuracy of the simulations and training is remarkable. Astronauts often comment that only the noise and vibration of launch and the experience of weightlessness are missing from the practice sessions; everything else in training accurately duplicates the space experience.

The astronauts' mission continues even after the Orbiter has returned. The crew will spend several days in medical testing and debriefing, recounting their experiences for the benefit of future crews to assist in future training and to add to the space flight knowledge base.

Members of the media also receive a detailed post-flight briefing by the crew. Then, the studies and training that may eventually lead to another space flight are resumed.

Astronauts and the People who Selected them: A Compendium

The Original Seven. The initial astronaut selection began in January 1959, before human spaceflight operations began, when NASA asked the military services to screen personnel records for prospective candidates who met the qualifications outlined in Table 1. This preliminary review produced 508 military test pilots, of whom 110 satisfied all of the basic requirements. A subsequent examination of military and medical records reduced the total eligible to 69, all of whom were invited to Washington for a briefing on Project Mercury and a personal interview. It was on the basis of these interviews that 32 men were chosen to undergo detailed physical examination and stress testing; however, it became apparent during this phase that all of the candidates surpassed the established medical standards. Consequently, final screening concentrated on individual engineering and operational performance, and the seven best technically qualified were selected in April 1959 for the Mercury Program.

Note: All ranks for military and uniformed services officers referenced indicate the rank held when the individual was selected for the astronaut program.

- M. Scott Carpenter, Lt., USN. Born May 1, 1925. B.S. in Aeronautical Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/carpenter-ms.html
- L. Gordon Cooper, Capt., USAF. Born March 6, 1927. B.S. in Aeronautical Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/cooper-lg.html
- John H. Glenn, Jr., Lt. Col., USMC. Born July 18, 1921. B.S. in Engineering from Muskingum College. http://www.jsc.nasa.gov/Bios/htmlbios/glenn-j.html and http://www.grc.nasa.gov/WWW/PAO/html/jglenbio.htm
- Virgil I. Grissom, Capt., USAF. Born April 3, 1926. B.S. in Mechanical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/grissom-vi.html
- Walter M. Schirra, Jr., Lt. Comdr., USN. Born March 12, 1923. B.S. from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/schirra-wm.html
- Alan B. Shepard, Lt. Comdr., USN. Born November 18, 1923. B.S. from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/shepard-alan.html
- Donald K. Slayton, Capt., USAF. Born March 1, 1924. B.S. in Aeronautical Engineering from the University of Minnesota. http://www.jsc.nasa.gov/Bios/htmlbios/slayton.html

An ad hoc selection committee was appointed for each recruiting effort conducted in the search for candidates who qualified for the astronaut

TABLE 1. ASTRONAUT SELECTION HISTORY[A] 1958 TO 2000

Group	Date	Number selected	Max age	Max height	Min degree level	Jet pilot	TPS grad	Flying time	Experience	Outside help
1	Apr. 59	7	39	5′–10′	B.S.	Yes	Yes	1500		
2	Sept. 62	9	34	6′ –0′	B. S.	Yes	Yes	1500		
3	Oct. 63	14	32	6′ –0′	B.S.	Yes	Optional	1000		
4	June 65	6	34	6′ –0′	Ph.D.	No	No	No		NAS[b]
5	Apr. 66	19	34	6′ –0′	B.S.	Yes	Optional	1000		
6	Aug. 67	11	36	6′ –0′	Ph.D.	No	No	No		NAS[b]
7	Aug. 69	7	35	Transferred to NASA upon cancellation of USAF MOL program						
8 thru 18	78 to ′00									
Pilot			N/A	64 TO 76 in	B.S.	Yes	Preferable	1000		
Mssn spec			N/A	58.5 TO 76 in	B.S.	No			3 years	

[a]All selections required U.S. citizenship.
[b]NAS is the National Academy of Science.

training program. Participating in the selection of the original seven were Charles J. Donlan, NASA Space Task Group; A. O. Gamble, NASA Headquarters; Robert R. Gilruth, NASA Space Task Group; and Warren J. North, NASA Headquarters.

Group 2. In April 1962, an announcement was issued from Houston to recruit a second group of astronauts to train for the Gemini and Apollo Programs. Minimum qualification standards were published and disseminated to aircraft companies, government agencies, military services, the Society of Experimental Test Pilots, and the news media (see Table 1). A total of 250 applications was received from civilian and military sources. Each candidate who satisfied the five basic standards was asked to complete a variety of forms describing academic credentials and flight and work experience in detail. Each was also asked to submit to a thorough physical/medical examination and to forward the results to the Johnson Space Center (then the Manned Spacecraft Center) in Houston, Texas. In June 1962, a preliminary selection committee reviewed this additional information submitted by the individual candidates and selected 32 of the most qualified applicants to participate in further examinations, tests, and personal interviews. Nine pilot astronauts comprised the group finally selected in September 1962:

- Neil A. Armstrong, civilian. Born August 5, 1930. B.S. in Aeronautical Engineering from Purdue University and attended graduate school at the University of Southern California. http://www.jsc.nasa.gov/Bios/htmlbios/armstrong-na.html
- Frank Borman, Maj., USAF. Born March 14, 1928. B.S. in Aeronautical Engineering from the U.S. Military Academy and M.S. in Aeronautical Engineering from the California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/borman-f.html
- Charles Conrad, Jr., Lt., USN. Born June 2, 1930. B.S. in Aeronautical Engineering from Princeton University. http://www.jsc.nasa.gov/Bios/htmlbios/conrad-c.html
- James A. Lovell, Jr., Lt. Comdr., USN. Born March 25, 1928. B.S. from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/lovell-ja.html
- James A. McDivitt, Capt., USAF. Born June 10, 1929. B.S. in Aeronautical Engineering from the University of Michigan. http://www.jsc.nasa.gov/Bios/htmlbios/mcdivitt-ja.html
- Elliot M. See, Jr., civilian. Born July 23, 1927. B.S. from the U.S. Merchant Marine Academy and M.S. in Engineering from the University of California at Los Angeles. http://www.jsc.nasa.gov/Bios/htmlbios/see-em.html
- Thomas P. Stafford, Capt., USAF. Born September 17, 1930. B.S. from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/stafford-tp.html
- Edward H. White II, Capt., USAF. Born November 14, 1930. B.S. from the U.S. Military Academy and M.S. in Aeronautical Engineering from the University of Michigan. http://www.jsc.nasa.gov/Bios/htmlbios/white-eh.html
- John W. Young, Lt. Comdr., USN. Born September 24, 1930. B.S. in Aeronautical Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/young.html

The committee for the selection of Group 2 included Warren J. North, NASA JSC; Alan B. Shepard, Jr., NASA JSC; and Donald K. Slayton, NASA JSC.

Group 3. A third call for applications for the astronaut process was issued in June 1963. For this group, the requirement for test pilot school was optional (see Table 1), and the required jet pilot time was reduced to 1000 hours. With this decrease in actual flying requirements, increased emphasis was given to academic areas. A total of 720 applications was received — 228 from civilians and 492 from military personnel. Of the 490 certified eligibles, 136 were referred for final screening by the NASA selection board. Fourteen new astronauts were named in October 1963. Two civilians, seven Air Force pilots, four Navy aviators, and one Marine Corps aviator comprised this third group of trainees:

- Edwin E. Aldrin, Jr., Maj., USAF. Born January 20, 1930. B.S. from the U.S. Military Academy and Sc.D. in Astronautics from Massachusetts Institute of Technology. http://www1.jsc.nasa.gov/er/seh/aldrin.htm
- William A. Anders, Capt., USAF. Born October 17, 1933. B.S. from U.S. Naval Academy and M.S. in Nuclear Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/anders-wa.html
- Charles A. Bassett II, Capt., USAF. Born December 30, 1931. B.S. in Electrical Engineering from Texas Technological University. http://www.jsc.nasa.gov/Bios/htmlbios/bassett-ca.html
- Alan L. Bean, Lt., USN. Born March 15, 1932. B.S. in Aeronautical Engineering from the University of Texas. http://www.jsc.nasa.gov/Bios/htmlbios/bean-al.html
- Eugene A. Cernan, Lt., USN. Born March 14, 1934. B.S. in Electrical Engineering from Purdue University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/cernan-ea.html
- Roger B. Chaffee, Lt., USN. Born February 15, 1935. B.S. in Aeronautical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/chaffee-rb.html
- Michael Collins, Capt., USAF. Born October 31, 1930. B.S. from the U.S. Military Academy. http://www.jsc.nasa.gov/Bios/htmlbios/collins-m.html
- R. Walter Cunningham, civilian. Born March 16. 1932. B.A. and M.A. in Physics from the University of California at Los Angeles. http://vesuvius.jsc.nasa.gov/er/seh/cunning.html
- Donn F. Eisele, Capt., USAF. Born June 23, 1930. B.S. from the U.S. Naval Academy and M.S. in Astronautics from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/eisele-df.html
- Theodore C. Freeman, Capt., USAF. Born February 18, 1930. B.S. from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the University of Michigan. http://www.jsc.nasa.gov/Bios/htmlbios/freeman-tc.html
- Richard F. Gordon, Lt. Comdr., USN. Born October 5, 1929. B.S. in Chemistry from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/gordon-rf.html
- Russell L. Schweickart, civilian. Born October 25, 1935. B.S. in Aeronautical Engineering and M.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/schweickart-rl.html
- David R. Scott, Capt., USAF. Born June 6, 1932. B.S. from the U.S. Military Academy, and M.S. and M.E. in Aeronautics and Astronautics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/scott-dr.html
- Clifton C. Williams, Jr., Capt., USMC. Born September 26, 1932. B.S. in Mechanical Engineering from Auburn University. http://www.jsc.nasa.gov/Bios/htmlbios/williams-cc.html

The selection committee members for Group 3 were John H. Glenn, Jr., NASA JSC; Warren J. North, NASA JSC; Walter M. Schirra, Jr., NASA JSC; Alan B. Shepard, Jr., NASA JSC; and Donald K. Slayton, NASA JSC.

Group 4 (Scientist-Astronauts). NASA began recruiting for its first group of scientist-astronauts in October 1964. For this group, flying status was desirable but not a mandatory prerequisite for selection (see Table 1). However, each of those selected was required to pass a Class I military flight physical examination before acceptance to the training program. Emphasis was on graduate work in the natural sciences, such as physics, medicine, engineering, or comparable occupational experience. A total of 1492 letters of interest was received in Houston by January 1965. Some were informal inquiries, but 909 were formal applications. Of the latter, 424 qualified under the minimum criteria established and were forwarded to the National Academy of Sciences in Washington DC for evaluation. The Academy evaluated these applications for conformity with scientific criteria developed cooperatively with the NASA Office of Space and Applications and recommended 16 candidates for final consideration. These 16 applicants underwent thorough physical examinations and stress testing, and six were selected in June 1965 for training as scientist-astronauts. One geologist, two physicians, and three physicists comprised the group, and two in the group were qualified jet pilots. Those without jet pilot experience underwent one year's flight training before entering the regular astronaut training program. The following were selected:

- Owen K. Garriott, civilian. Born November 22, 1930. B.S. in Electrical Engineering from the University of Oklahoma and M.S. and Ph.D. in

Electrical Engineering from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/garriott-ok.html

- Edward G. Gibson, civilian. Born November 8, 1936. B.S. in Engineering from the University of Rochester and M.S. in Engineering and Ph.D. in Engineering and Physics from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/gibson-eg.html
- Duane E. Graveline, civilian. Born March 2, 1931. Ph.D./M.D. from the University of Vermont and M.S. in Public Health from Walter Reed Army Medical Center. http://instantlearning.net/space/sehhtml/graveline.htm
- Joseph P. Kerwin, Lt. Comdr., USN. Born February 19, 1932. B.A. in Philosophy from the College of the Holy Cross and M.D. from Northwestern University Medical School. http://www.jsc.nasa.gov/Bios/htmlbios/kerwin-jp.html
- F. Curtis Michel, civilian. Born June 5, 1934. B.S. and Ph.D. in Physics from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/michel-fc.html
- Harrison H. Schmitt, civilian. Born July 3, 1935. B.S. in Science from California Institute of Technology and Ph.D. in Geology from Harvard University. http://www.jsc.nasa.gov/Bios/htmlbios/schmitt-hh.html

The selection committee for Group 4 consisted of the following members from the National Academy of Sciences Board: Dr. Allan H. Brown, Department of Biology, Joseph Leidy Laboratory of Biology, University of Pennsylvania; Professor L.D. Carlson, Department of Physiology, University of California Medical School; Professor Frederick L. Ferris, Jr., Educational Services, Inc.; Dr. Thomas Gold, Chairman, Astronomy Department, Director, Center for Radio, Physics and Space Research, Cornell University; Dr. H. Keffer Hartline, Rockefeller University; Dr. Clifford T. Morgan, Department of Psychology, University of California; Dr. Eugene M. Shoemaker, Astrogeology Branch, U.S. Geological Survey; Dr. Robert Speed, Department of Geology, Northwestern University; and Professor Aaron C. Waters, Department of Geology, University of California.

The NASA Board consisted of the following individuals: Charles A. Berry, M.D., NASA JSC; John F. Clark, NASA Goddard Space Flight Center (GSFC); Maxime A. Faget, NASA JSC; Warren J. North, NASA JSC; Alan B. Shepard, Jr., NASA JSC; and Donald K. Slayton, NASA JSC.

Group 5. The Johnson Space Center launched its fifth recruiting drive in September 1965. Eligibility requirements were basically the same as those used in selecting the third group of astronaut trainees (see Table 1). A total of 510 applications was received, of which 158 (100 military and 58 civilians) met basic requirements. The previously established screening procedures were followed, yielding 19 pilot-astronauts who were selected in April 1966. Selectees were:

- Vance D. Brand, civilian. Born May 9, 1931. B.S. in Business and Aeronautical Engineering from the University of Colorado and MBA from the University of California at Los Angeles. http://www.jsc.nasa.gov/Bios/htmlbios/brand.html
- John S. Bull, Lt., USN. Born September 25, 1934. B.S. in Mechanical Engineering from Rice University. http://www.jsc.nasa.gov/Bios/htmlbios/bull-js.html
- Gerald P. Carr, Maj., USMC. Born August 22, 1932. B.S. in Mechanical Engineering from the University of Southern California, B.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School, and M.S. in Aeronautical Engineering from Princeton University. http://www.jsc.nasa.gov/Bios/htmlbios/carr-gp.html
- Charles M. Duke, Jr., Capt., USAF. Born October 3, 1935. B.S. in Naval Sciences from the U.S. Naval Academy and M.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/duke-cm.html
- Joe H. Engle, Capt., USAF. Born August 26, 1932. B.S. in Aeronautical Engineering from the University of Kansas. http://www.jsc.nasa.gov/Bios/htmlbios/engle-jh.html
- Ronald E. Evans, Lt. Comdr., USN. Born November 10, 1933. B.S. in Electrical Engineering from the University of Kansas and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/evans-re.html
- Edward G. Givens, Jr., Maj., USAF. Born January 5, 1930. B.S. in Naval Sciences from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/givens-eg.html
- Fred W. Haise, Jr., civilian. Born November 14, 1933. B.S. in Aeronautical Engineering from the University of Oklahoma. http://www.jsc.nasa.gov/Bios/htmlbios/haise-fw.html
- James B. Irwin, Maj., USAF. Born March 17, 1930. B.S. in Naval Sciences from the U.S. Naval Academy and M.S. in Aeronautical Engineering and Instrumentation Engineering from the University of Michigan. http://www.jsc.nasa.gov/Bios/htmlbios/irwin-jb.html
- Don L. Lind, civilian. Born May 18, 1930. B.S. in Physics from the University of Utah and Ph.D. in High Energy Nuclear Physics from the University of California at Berkeley. http://www.jsc.nasa.gov/Bios/htmlbios/lind-dl.html
- Jack R. Lousma, Capt., USMC. Born February 29, 1936. B.S. in Aeronautical Engineering from the University of Michigan and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/lousma-jr.html
- Thomas K. Mattingly II, Lt., USN. Born March 17, 1936. B.S. in Aeronautical Engineering from Auburn University. http://www.jsc.nasa.gov/Bios/htmlbios/mattingly-tk.html
- Bruce McCandless II, Lt., USN. Born June 8, 1937. B.S. in Naval Sciences from the U.S. Naval Academy and M.S. in Electrical Engineering from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/mccandless-b.html
- Edgar D. Mitchell, Comdr., USN. Born September 17, 1930. B.S. in Industrial Management from Carnegie Institute of Technology, B.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School, and Sc.D. in Aeronautics and Astronautics from Massachusetts Institute of Technology. http://vesuvius.jsc.nasa.gov/er/seh/mitchell.htm
- William R. Pogue, Maj., USAF. Born January 23, 1930. B.S. in Education from Oklahoma Baptist University and M.S. in Mathematics from Oklahoma State University. http://instantlearning.net/space/sehhtml/pogue.htm
- Stuart A. Roosa, Capt., USAF. Born August 16, 1933. B.S. in Aeronautical Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/roosa-sa.html
- John L. Swigert, Jr., civilian. Born August 30, 1931. B.S. in Mechanical Engineering from the University of Colorado, M.S. in Aerospace Science from Rensselaer Polytechnic Institute, and M.S. in Business Administration from the University of Hartford. http://www.jsc.nasa.gov/Bios/htmlbios/swigert-jl.html
- Paul J. Weitz, Lt. Comdr., USN. Born July 25, 1932. B.S. in Aeronautical Engineering from Pennsylvania State University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/weitz-pj.html
- Alfred M. Worden, Capt., USAF. Born February 7, 1932. B.S. from the U.S. Military Academy and M.S. in Aeronautical/Astronautical Engineering and Instrumentation Engineering from the University of Michigan. http://www.jsc.nasa.gov/Bios/htmlbios/worden-am.html

The selection committee members for Group 5 were Charles Conrad, Jr., NASA JSC; L. Gordon Cooper, Jr., NASA JSC; Virgil I. Grissom, NASA JSC; Warren J. North, NASA JSC; Donald K. Slayton, NASA JSC; Clifton C. Williams, Jr., NASA JSC; and John W. Young, NASA JSC.

Group 6 (Scientist-Astronauts). In September 1966, NASA requested the National Academy of Sciences to nominate a second group of scientist-astronauts. NASA encouraged the Academy to seek experienced scientists of exceptional ability "to conduct scientific experiments in manned orbiting satellites and to observe and investigate the lunar surface and circumterrestrial space." The Academy then issued its announcement stating: "The quality most needed by a scientist serving as an astronaut might be summed up by the single word "perspicacity." The task requires an exceptionally astute and imaginative observer but also one whose observations are accurate and impartial. He must, from among the thousands of items he might observe, quickly pick out those that are significant, spot the anomalies, and investigate them. He must discriminate fine detail and subtle insight into a general pattern, and select and devise key observations to test working hypotheses. The selection criteria and procedures were comparable to those used in choosing the first group of scientist-astronauts (see Table 1). Nine-hundred applicants responded, but the Academy recommended only 69 for NASA's final consideration. Of this number, 11 were chosen:

- Joseph P. Allen IV, civilian. Born June 27, 1937. B.A. in Math-Physics from De Pauw University and M.S. and Ph.D. in Physics from Yale University. http://www.jsc.nasa.gov/Bios/htmlbios/allen-jp.html
- Philip K. Chapman, civilian. Born March 5, 1935. B.S. in Physics and Mathematics from Sydney University; M.S. in Aeronautics and Astronautics and Sc.D. in Instrumentation from Massachusetts Institute of Technology. http://experts.about.com/e/p/ph/Philip_K._Chapman.htm and ikipedia.org/wiki/Philip_K._Chapman
- Anthony W. England, civilian. Born May 15, 1942. B.S. and M.S. in Geology and Physics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/england-aw.html
- Karl G. Henize, civilian. Born October 17, 1926. B.A. in Mathematics and M.A. in Astronomy from the University of Virginia and Ph.D. in Astronomy from the University of Michigan. http://www.jsc.nasa.gov/Bios/htmlbios/henize.html
- Donald L. Holmquest, civilian. Born April 7, 1939. B.S. in Electrical Engineering from Southern Methodist University and doctorates in Medicine and Physiology from Baylor University. http://instantlearning.net/space/sehhtml/holm.htm
- William B. Lenoir, civilian. Born March 14, 1939. B.S., M.S., and Ph.D. in Electrical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/lenoir-wb.html
- John A. Llewellyn, civilian. Born April 22, 1933. B.S. and Ph.D. in Chemistry from the University College of Cardiff. http://instantlearning.net/space/sehhtml/llewelly.htm
- F. Story Musgrave, civilian. Born August 19, 1935. B.S. in Mathematics and Statistics from Syracuse University, M.B.A. in Operations Analysis and Computer Programming from the University of California at Los Angeles, B.A. in Chemistry from Mariettta College, M.D. from Columbia University, and M.S. in Biophysics from the University of Kentucky. http://www.jsc.nasa.gov/Bios/htmlbios/musgrave.html
- Brian T. O'Leary, civilian. Born January 27, 1940. B.A. in Physics from Williams College, M.A. in Astronomy from Georgetown University, and Ph.D. in Astronomy from the University of California at Berkeley. http://instantlearning.net/space/sehhtml/oleary.htm
- Robert A. R. Parker, civilian. Born December 14, 1936. B.A. in Astronomy and Physics from Amherst College and Ph.D. in Astronomy from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/parker-rar.html
- William E. Thornton, civilian. Born April 14, 1929. B.S. in Physics and M.D. from the University of North Carolina. http://www.jsc.nasa.gov/Bios/htmlbios/thornton-w.html

The Group 6 selection committee members from the National Academy of Sciences Board were Dr. Allan H. Brown, Department of Biology, Joseph Leidy Laboratory of Biology, University of Pennsylvania; Professor L.D. Carlson, Department of Physiology, University of California Medical School; Dr. Arthur B. Dubois, Division of Graduate Medicine, Department of Physiology, University of Pennsylvania; and Dr. H. Keffer Hartline, Rockefeller University.

The Life Sciences Subpanel members were Dr. George V. LeRoy, Medical Director, Metropolitan Hospital, Detroit, Michigan; Dr. Clifford T. Morgan, Department of Psychology, University of California; and Dr. Norton Nelson, Provost, University Heights Center, New York University.

The Physical Sciences Subpanel members were Dr. Edward W. Cannon, Chief, Applied Mathematics Division, National Bureau of Standards; Professor Frederick L. Ferris, Jr., Educational Services, Inc.; Dr. Harry H. Hess, Department of Geology, Princeton University; Dr. John D. Hoffmann, Chief, Polymers Division, National Bureau of Standards; Dr. Phillip Mange, Naval Research Laboratory; Dr. Eberhardt Rechtin, Assistant Director for Tracking and Data Acquisition, NASA JPL; Dr. Eugene M. Shoemaker, Astrogeology Branch, U.S. Geological Survey; Dr. Shirleigh Silverman, Associate Director of Academics Liaison, National Bureau of Standards; Professor Philip N. Slater, Research Professor, Stewart Observatories, University of Arizona; Dr. Robert Speed, Department of Geology, Northwestern University; Professor Edward C, Stevenson, Professor of Electrical Engineering, University of Virginia; Professor Aaron C. Waters, Department of Geology, University of California; and Dr. Arthur H. Waynick, Director, Ionosphere Research Laboratory, Pennsylvania State University.

The NASA Board members were Charles A. Berry, M.D., NASA JSC; Maxime A. Faget, NASA JSC; Owen K. Garriott, Ph.D., NASA JSC; Wilmot N. Hess, NASA JSC; Alan B. Shepard, Jr., NASA JSC; Donald K. Slayton, NASA JSC; and Robert F. Thompson, NASA JSC.

Group 7. This group of seven pilot astronauts, transferred to NASA from the USAF Manned Orbiting Laboratory (MOL) Program when it was cancelled in August 1969. Although there were 13 in the MOL contingent, NASA absorbed only those under the age of 35:

- Karol J. Bobko, Maj., USAF. Born December 23, 1937. B.S. from the U.S. Air Force Academy and M.S. in Aerospace Engineering from the University of Southern California. http://www.jsc.nasa.gov/Bios/htmlbios/bobko-kj.html
- Robert L. Crippen, Lt. Comdr., USN. Born September 11, 1937. B.S. in Aerospace Engineering from the University of Texas. http://www.jsc.nasa.gov/Bios/htmlbios/crippen-rl.html
- C. Gordon Fullerton, Maj., USAF. Born October 11, 1936. B.S. and M.S. in Mechanical Engineering from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/fullerton-cg.html
- Henry W. Hartsfield, Maj., USAF. Born November 21, 1933. B.S. in Physics from Auburn University. http://www.jsc.nasa.gov/Bios/htmlbios/hartsfield-hw.html
- Robert F. Overmyer, Maj., USMC. Born July 14, 1936. B.S. in Physics from Baldwin-Wallace College and M.S. in Aeronautics from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/overmyer.html
- Donald H. Peterson, Maj., USAF. Born October 22, 1933. B.S. from the U.S. Military Academy and M.S. in Nuclear Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/peterson-dh.html
- Richard H. Truly, Lt. Comdr., USN. Born November 12, 1937. B.S. in Aeronautical Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/truly-rh.html

Group 8 — Space Shuttle Astronauts. In 1978, NASA selected 35 astronaut candidates as the first group to support the Space Shuttle program. One of the 15 pilots was African-American. Six females, two African-Americans, and one Asian-Pacific Islander were among the 20 mission specialists. The candidates reported to the Johnson Space Center on July 1, 1978 to begin a challenging training and evaluation program that included Orbiter Systems training, science and enrichment briefings, and T-38 flight training. After successfully completing this program, the following candidates were qualified as astronauts and received technical assignments within the Astronaut Office to prepare them further for an assignment to a Space Shuttle mission:

- Guion S. Bluford, Jr., Maj., USAF. Born November 22, 1942. B.S. in Aerospace Engineering from Pennsylvania State University, M.S. in Aerospace Engineering from the Air Force Institute of Technology, and Ph.D. in Aerospace Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/bluford-gs.html
- Daniel C. Brandenstein, Lt. Comdr., USN. Born January 17, 1943. B.S. in Mathematics and Physics from the University of Wisconsin-River Falls. http://www.jsc.nasa.gov/Bios/htmlbios/brandenstein-dc.html
- James F. Buchli, Lt. Col., USMC. Born June 20, 1945. B.S. from U.S. Naval Academy and M.S. in Aeronautical Systems from the University of West Florida. http://www.jsc.nasa.gov/Bios/htmlbios/buchli-jf.html
- Michael L. Coats, Lt. Comdr., USN. Born January 16, 1946. B.S. from the U.S. Naval Academy, M.S. in the Administration of Science and Technology from George Washington University, and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/coats-ml.html
- Richard O. Covey, Maj., USAF. Born August 1, 1946. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Aeronautics and Astronautics from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/covey-ro.html
- John O. Creighton, Lt. Comdr., USN. Born April 28, 1943. B.S. from the U.S. Naval Academy and M.S. in the Administration of Science and Technology from George Washington University. http://www.jsc.nasa.gov/Bios/htmlbios/creighton-jo.html
- John M. Fabian, Maj., USAF. Born January 28, 1939. B.S. in Mechanical Engineering from Washington State University, M.S. in

Aerospace Engineering from the Air Force Institute of Technology, and Ph.D. in Aeronautics/Astronautics from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/fabian-jm.html

- Anna L. Fisher. Born August 24, 1949. B.S. in Chemistry from the University of California, Los Angeles and M.D. from the University of California, Los Angeles, School of Medicine. http://www.jsc.nasa.gov/Bios/htmlbios/fisher-a.html
- Dale A. Gardner, Lt., USN. Born November 8, 1948. B.S. in Engineering Physics from the University of Illinois. http://www.jsc.nasa.gov/Bios/htmlbios/gardner-da.html
- Robert L. Gibson, Lt., USN. Born October 30, 1946. B.S. in Aeronautical Engineering from California Polytechnic State University. http://www.jsc.nasa.gov/Bios/htmlbios/gibson.html
- Frederick D. Gregory, Maj., USAF. Born January 7, 1941. B.S. from the U.S. Air Force Academy and M.S. in Information Systems from George Washington University. http://www.jsc.nasa.gov/Bios/htmlbios/gregory-fd.html
- Stanley D. Griggs. Born September 7, 1939. B.S. from U.S. Naval Academy and M.S.A. in Management Engineering from George Washington University. http://www.jsc.nasa.gov/Bios/htmlbios/griggs.html
- Terry J. Hart. Born October 27, 1946. B.S. in Mechanical Engineering from Lehigh University, and M.S. in Mechanical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/hart-tj.html
- Frederick H. Hauck, Comdr., USN. Born April 11, 1941. B.S. in General Physics from Tufts University and M.S. in Nuclear Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/hauck-fh.html
- Steven A. Hawley. Born December 12, 1951. B.A. in Astronomy and Physics from the University of Kansas, and Ph.D. in Astronomy from the University of California, Santa Cruz. http://www.jsc.nasa.gov/Bios/htmlbios/hawley.html
- Jeffrey A. Hoffman. Born November 2, 1944. B.A. in Astronomy from Amherst College, and Ph.D. in Astrophysics from Harvard University. http://www.jsc.nasa.gov/Bios/htmlbios/hoffman.html
- Shannon W. Lucid. Born January 14, 1943. B.S. in Chemistry from the University of Oklahoma, M.S. in Biochemistry from the University of Oklahoma, and Ph.D. in Biochemistry from the University of Oklahoma. http://www.jsc.nasa.gov/Bios/htmlbios/lucid.html
- Jon A. McBride, Lt. Comdr., USN. Born August 14, 1943. B.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/mcbride-ja.html
- Ronald E. McNair. Born October 21, 1950. B.S. in Physics from the North Carolina A&T University and Ph.D. in Physics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/mcnair.html
- Richard M. Mullane, Capt., USAF. Born September 10, 1945. B.S. from the U.S. Military Academy and M.S. in Aeronautical Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/mullane-rm.html
- Steven R. Nagel, Capt., USAF. Born October 27, 1946. B.S. in Aeronautical/Astronautical Engineering from the University of Illinois. http://www.jsc.nasa.gov/Bios/htmlbios/nagel.html
- George D. Nelson. Born July 13, 1950. B.S. in Physics from Harvey Mudd University, M.S. in Astronomy from the University of Washington, and Ph.D. in Astronomy from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/nelson-gd.html
- Ellison S. Onizuka, Capt., USAF. Born June 24, 1946. B.S. in Aerospace Engineering from the University of Colorado and M.S. in Aerospace Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/onizuka.html
- Judith A. Resnik. Born April 5, 1949. B.S. in Electrical Engineering from Carnegie-Mellon University and Ph.D. in Electrical Engineering from the University of Maryland. http://www.jsc.nasa.gov/Bios/htmlbios/resnik.html
- Sally K. Ride. Born May 26, 1951. B.S. in Physics from Stanford University, B.A. in English from Stanford University, and Ph.D. in Physics from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/ride-sk.html
- Francis R. Scobee, Maj., USAF. Born May 19, 1939. B.S. in Aerospace Engineering from the University of Arizona. http://www.jsc.nasa.gov/Bios/htmlbios/scobee.html
- Margaret R. Seddon. Born November 8, 1947. B.A. in Physiology from the University of California, Berkeley, and M.D. from the University of Tennessee College of Medicine. http://www.jsc.nasa.gov/Bios/htmlbios/seddon.html
- Brewster H. Shaw, Capt., USAF. Born May 16, 1945. B.S. in Engineering Mechanics from the University of Wisconsin and M.S. in Engineering Mechanics from the University of Wisconsin. http://www.jsc.nasa.gov/Bios/htmlbios/shaw-bh.html
- Loren J. Shriver, Capt., USAF. Born September 23, 1944. B.S. from the U.S. Air Force Academy and M.S. in Astronautics from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/shriver.html
- Robert L. Stewart, Maj., U.S. Army. Born August 13, 1942. B.S. in Mathematics from the University of Southern Mississippi and M.S. in Aerospace Engineering from the University of Texas, Arlington. http://www.jsc.nasa.gov/Bios/htmlbios/stewart-rl.html
- Kathryn D. Sullivan. Born October 3, 1951. B.S. in Earth Sciences from the University of California, Santa Cruz, and Ph.D. in Geology from Dalhousie University. http://www.jsc.nasa.gov/Bios/htmlbios/sullivan-kd.html
- Norman E. Thagard. Born July 3, 1943. B.S. in Engineering Science from Florida State University, M.S. in Engineering Science from Florida State University, and M.D. from the University of Texas Southwestern Medical School. http://www.jsc.nasa.gov/Bios/htmlbios/thagard.html
- James D. van Hoften. Born June 11, 1944. B.S. in Civil Engineering from the University of California, Berkeley, M.S. in Hydraulic Engineering from Colorado State University, and Ph.D. in Fluid Mechanics from Colorado State University. http://www.jsc.nasa.gov/Bios/htmlbios/vanhoften-jda.html
- David M. Walker, Lt. Comdr., USN. Born May 20, 1944. B.S. from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/walker.html
- Donald E. Williams, Lt. Comdr., USN. Born February 13, 1942. B.S. in Mechanical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/williams-de.html

The following individuals were on the rating and selection board for Group 8: George W.S. Abbey, Joseph D. Atkinson, Jr., Ph.D.; Vance D. Brand; Edward Gibson, Ph.D.; Carolyn Huntoon, Ph.D.; Joseph P. Kerwin, M.D.; Jack R. Lister; Glynn S. Lunney; Robert A. Parker; Robert O. Piland; Martin L. Raines; Duane L. Ross; Donald K. Slayton; James H. Trainor, Ph.D.; and John W. Young. Dr. James Tainor was from the NASA GSFC; the remainder were from NASA JSC.

Group 9. NASA selected 19 astronaut candidates for the Space Shuttle program in 1980. The eight pilots and 11 mission specialists included the first Hispanic mission specialist and the first candidate selected from the U.S. Army. The candidates reported to the Johnson Space Center on July 7, 1980 to begin their training and evaluation program. The 1980 astronaut candidate class included:

- James P. Bagian. Born February 22, 1952. B.S. in Mechanical Engineering from Drexel University and M.D. from Thomas Jefferson University. http://www.jsc.nasa.gov/Bios/htmlbios/bagian.html
- John E. Blaha, Lt. Col., USAF. Born August 26, 1942. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.S. in Astronautical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/blaha.html
- Charles F. Bolden, Jr., Maj., USMC. Born August 19, 1946. B.S. in Electrical Engineering from the U.S. Naval Academy and M.S. in Systems Management from the University of California. http://www.jsc.nasa.gov/Bios/htmlbios/bolden-cf.html
- Roy D. Bridges, Jr., Maj., USAF. Born July 19, 1943. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Astronautics from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/bridges.html
- Franklin R. Chang. Born April 5, 1950. B.S. in Mechanical Engineering from the University of Connecticut and Ph.D. in Physics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/chang.html
- Mary L. Cleave. Born February 5, 1947. B.S. in Biology from Colorado State University, M.S. in Botany from Utah State University, and Ph.D. in Civil Engineering from Utah State University. http://www.jsc.nasa.gov/Bios/htmlbios/cleave-ml.html

- Bonnie J. Dunbar. Born March 3, 1949. B.S. in Ceramic Engineering from the University of Washington and M.S. in Ceramic Engineering from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/dunbar.html
- William F. Fisher. Born April 1, 1946. B.S. in Psychology from Stanford University, M.S. in Engineering Science from the University of Houston and M.D. from the University of Florida College of Medicine. http://www.jsc.nasa.gov/Bios/htmlbios/fisher-wf.html
- Guy S. Gardner, Maj., USAF. Born January 6, 1948. B.S. in Aeronautical Engineering from the U.S. Air Force Academy and M.S. in Aeronautical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/gardner-gs.html
- Ronald J. Grabe, Maj., USAF. Born June 13, 1945. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Aeronautics from the Technishe Hochschule, Darmstadt, Germany. http://www.jsc.nasa.gov/Bios/htmlbios/grabe-rj.html
- David C. Hilmers, Capt., USMC. Born January 28, 1950. B.S. in Mathematics from Cornell College and M.S. in Electrical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/hilmers-dc.html
- David C. Leestma, Lt. Comdr., USN. Born May 6, 1949. B.S. in Aeronautical Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/leestma.html
- John M. Lounge. Born June 28, 1946. B.S. in Mathematics from the U.S. Naval Academy and M.S. in Astrophysics from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/lounge-jm.html
- Bryan D. O'Connor, Maj., USMC. Born September 6, 1946. B.S. in Naval Science from the U.S. Naval Academy and M.S. in Aeronautical Systems from the University of West Florida. http://www.jsc.nasa.gov/Bios/htmlbios/oconnor-bd.html
- Richard N. Richards, Lt. Comdr., USN. Born August 24, 1946. B.S. in Chemical Engineering from the University of Missouri and M.S. in Aeronautical Systems from the University of West Florida. http://www.jsc.nasa.gov/Bios/htmlbios/richards.html
- Jerry L. Ross, Capt., USAF. Born January 20, 1948. B.S. in Mechanical Engineering form Purdue University and M.S. in Mechanical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/ross.html
- Michael J. Smith, Lt. Comdr., USN. Born April 30, 1945. B.S. in Aeronautical Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/smith-michael.html
- Sherwood C. Spring, Maj., U.S. Army. Born September 3, 1944. B.S. in Engineering from the U.S. Military Academy and M.S. in Aerospace Engineering from the University of Arizona. http://www.jsc.nasa.gov/Bios/htmlbios/spring-sc.html
- Robert C. Springer, Maj., USMC. Born May 21, 1942. B.S. in Naval Science from the U.S. Naval Academy, and M.S. in Operations Research from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/springer-rc.html

The following individuals served on the rating panel and the astronaut candidate selection board for Group 9: George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Joseph P. Allen, IV, Ph.D.; Vance D. Brand; Harvey L. Hartman; Gregory W. Hayes; Jay F. Honeycutt; Carolyn L. Huntoon Ph.D.; William B. Lenoir, Ph.D.; Robert O. Piland; James H. Trainor, Ph.D.; Paul J. Weitz; and John W. Young. Dr. Trainor was from NASA GSFC, and the remainder were from NASA JSC.

Group 10. In 1984, NASA selected 17 astronaut candidates for the Space Shuttle program. One of the seven pilots was Hispanic, and three of the 10 mission specialists were female. The astronaut candidates who began training at the Johnson Space Center on July 1, 1984 included:

- James C. Adamson, Maj., U.S. Army. Born March 3, 1946. B.S. in Engineering from the U.S. Military Academy and M.S. in Aeronautical and Mechanical Engineering from Princeton University. http://www.jsc.nasa.gov/Bios/htmlbios/adamson-jc.html
- Mark N. Brown, Capt., USAF. Born November 18, 1951. B.S. in Aeronautical and Astronautical Engineering from Purdue University and M.S. in Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/brown-mn.html
- Kenneth D. Cameron, Maj., USMC. Born November 29, 1949. B.S. in Aeronautics and Astronautics form Massachusetts Institute of Technology and M.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/cameron.html
- Manley L. Carter, Jr., Comdr., USN. Born August 15, 1947. B.A. in Chemistry from Emory University and M.D. from Emory University. http://www.jsc.nasa.gov/Bios/htmlbios/carter.html
- John H. Casper, Lt. Col., USAF. Born July 9, 1943. B.S. in Astronautics and Engineering Science from the U.S. Airforce Academy and M.S. in Astronautics from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/casper.html
- Frank L. Culbertson, Jr., Lt. Comdr., USN. Born May 15, 1949. B.S. in Aerospace Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/culberts.html
- Sidney M. Gutierrez, Capt., USAF. Born June 27, 1951. B.S. in Aerospace Engineering from the U.S. Air Force Academy and M.A. in Management from Webster College. http://www.jsc.nasa.gov/Bios/htmlbios/gutierrez-sm.html
- Lloyd B. Hammond, Jr., Capt., USAF. Born January 16, 1952. B.S. in Engineering Mechanics from the U.S. Air Force Academy and M.S. in Engineering Mechanics from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/hammond.html
- Marsha S. Ivins. Born April 15, 1951. B.S. in Aerospace Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/ivins.html
- Mark C. Lee, Capt., USAF. Born August 14, 1952. B.S. in Civil Engineering from the U.S. Air Force Academy and M.S. in Mechanical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/lee.html
- George D. Low. Born February 19, 1956. B.S. in Physics from Washington and Lee University, B.S. in Mechanical Engineering from Cornell University and M.S. in Aeronautics and Astronautics from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/low.html
- Michael J. McCulley, Lt. Comdr., USN. Born August 4, 1943. B.S. in Metallurgical Engineering from Purdue University and M.S. in Metallurgical Engineering from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/mcculley.html
- William M. Shepherd, Lt. Comdr., USN. Born July 26, 1949. B.S. in Aerospace Engineering from the U.S. Naval Academy, M.S. in Mechanical Engineering from Massachusetts Institute of Technology, and M.S. in Ocean Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/shepherd.html
- Ellen L. Shulman. Born April 27, 1953. B.A. in Geology from the State University of New York at Buffalo and M.D. from Cornell University. http://www.spacefacts.de/bios/astronauts/english/baker_ellen.htm
- Kathryn C. Thornton. Born August 17, 1952. B.S. in Physics from Auburn University, M.S. in Physics from the University of Virginia, and Ph.D. in Physics from the University of Virginia. http://www.jsc.nasa.gov/Bios/htmlbios/thornt-k.html
- Charles L. Veach. Born September, 18, 1944. B.S. in Engineering Management from the U.S. Air Force Academy. http://www.jsc.nasa.gov/Bios/htmlbios/veach.html
- James D. Wetherbee, Lt., USN. Born November 27, 1952. B.S. in Aerospace Engineering from the University of Notre Dame. http://www.jsc.nasa.gov/Bios/htmlbios/wetherbe.html

The members of the rating panel and selection committee for Group 10 included George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Joseph P. Allen IV, Ph.D.; Gregory W. Hayes; Jay F. Honeycutt; Carolyn L. Huntoon, Ph.D.; Robert A.R. Parker, Ph.D.; Duane L. Ross; Paul J. Weitz; and John W. Young. All were from NASA JSC.

Group 11. An additional 13 candidates were selected to train for the astronaut corps in 1985. This group of six pilots and seven mission specialists included two females. They reported to the Johnson Space Center on August 1, 1985. The astronaut candidates were:

- Jerome Apt. Born April 28, 1949. B.S. in Physics from Harvard College and Ph.D. in Physics from the Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/apt.html
- Michael A. Baker, Lt. Comdr., USN. Born October 27, 1953. B.S. in Aerospace Engineering from the University of Texas. http://www.jsc.nasa.gov/Bios/htmlbios/baker-m.html

- Robert D. Cabana, Maj., USMC. Born January 23, 1949. B.S. in Mathematics from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/cabana.html
- Brian Duffy, Capt., USAF. Born June 20, 1953. B.S. in Mathematics from the U.S. Air Force Academy and M.S. in Systems Management from the University of Southern California. http://www.jsc.nasa.gov/Bios/htmlbios/duffy.html
- Charles D. Gemar, Capt., U.S. Army. Born August 4, 1955. B.S. in Engineering from the U.S. Military Academy. http://www.jsc.nasa.gov/Bios/htmlbios/gemar.html
- Linda M. Godwin. Born July 2, 1952. B.S. in Mathematics from Southeast Missouri State, M.S. in Physics from the University of Missouri, and Ph.D. in Physics from the University of Missouri. http://www.jsc.nasa.gov/Bios/htmlbios/godwin.html
- Terence T. Henricks, Maj., USAF. Born July 5, 1952. B.S. in Civil Engineering from the U.S. Air Force Academy and M.S. in Public Administration from Golden Gate University. http://www.jsc.nasa.gov/Bios/htmlbios/henricks.html
- Richard J. Hieb. Born Sept 21, 1955. B.S. in Mathematics and Physics from Northwest Nazarene College and M.S. in Aerospace Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/hieb.html
- Tamara E. Jernigan. Born May 7, 1959. B.S. in Physics from Stanford University, M.S. in Engineering Science from Stanford University, and M.S. in Astronomy from the University of California at Berkeley. http://www.jsc.nasa.gov/Bios/htmlbios/jernigan.html
- Carl J. Meade, Capt., USAF. Born November 16, 1950. B.S. in Electronics Engineering from the University of Texas and M.S. in Electronics Engineering from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/meade.html
- Stephen S. Oswald. Born June 30, 1951. B.S. in Aerospace Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/oswald.html
- Stephen D. Thorne, Lt. Comdr., USN. Born February 11, 1953. B.S. in Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/thorne.html
- Pierre J. Thuot, Lt., USN. Born May 19, 1955. B.S. in Physics from the U.S. Naval Academy and M.S. in Systems Management from the University of Southern California. http://www.jsc.nasa.gov/Bios/htmlbios/thuot.html

The Group 11 rating panel and selection committee members were George W. S Abbey; Joseph D. Atkinson, Jr., Ph.D.; Karol J. Bobko; Daniel C. Brandenstein; Mary L. Cleave, Ph.D.; Richard O. Covey; Anna L. Fisher, M.D.; David C. Leestma; George D. Nelson, Ph.D.; Ellison S. Onizuka; Sally K. Ride, Ph.D.; Duane L. Ross; Loren J. Shriver; Paul J. Weitz; Donald E. Williams; and John W. Young. All were from NASA JSC.

Group 12. The 15 astronaut candidates selected in 1987 consisted of seven pilots and eight mission specialists, including the first African-American female and the first candidate from the U.S. Coast Guard. The following astronaut candidates reported to Johnson Space Center on August 17, 1987, to begin training:

- Thomas D. Akers, Capt., USAF. Born May 20, 1951. B.S. in Applied Mathematics from the University of Missouri-Rolla and M.S. in Applied Mathematics from the University of Missouri-Rolla. http://www.jsc.nasa.gov/Bios/htmlbios/akers.html
- Andrew M. Allen, Capt., USMC. Born August 4, 1955. B.S. in Mechanical Engineering from Villanova University. http://www.jsc.nasa.gov/Bios/htmlbios/allen-a.html
- Kenneth D. Bowersox, Lt., USN. Born November 14, 1956. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Mechanical Engineering from Columbia University. http://www.jsc.nasa.gov/Bios/htmlbios/bowersox.html
- Curtis L. Brown, Capt., USAF. Born March 11, 1956. B.S. in Electrical Engineering from the U.S. Air Force Academy. http://www.jsc.nasa.gov/Bios/htmlbios/brown-c.html
- Kevin P. Chilton, Maj., USAF. Born November 3, 1954. B.S. in Engineering Science from the U.S. Air Force Academy and M.S. in Engineering Mechanics from Columbia University. http://www.jsc.nasa.gov/Bios/htmlbios/chilton.html
- Jan D. Dozier. Born November 1, 1953. B.S. in Biology from the Georgia Institute of Technology, B.S. in Mechanical Engineering from Auburn University, M.S. in Mechanical Engineering from the University of Alabama and Ph.D. in Mechanical Engineering from the University of Alabama. http://www.jsc.nasa.gov/Bios/htmlbios/foale.html
- C. Michael Foale. Born January 6, 1957. B.A. in Physics from Cambridge University, M.A. in Physics from Cambridge University and Ph.D. in Physics from Cambridge University (England).
- Gregory J. Harbaugh. Born January 15, 1956. B.S. in Aeronautical and Astronautical Engineering from Purdue University and M.S. in Physical Science from the University of Houston-Clear Lake. http://www.jsc.nasa.gov/Bios/htmlbios/harbaugh.html
- Mae C. Jemison. Born October 17, 1956. B.S. in Chemical Engineering from Stanford University and M.D. from Cornell University. http://www.jsc.nasa.gov/Bios/htmlbios/jemison-mc.html
- Donald R. McMonagle, Maj., USAF. Born May 14, 1952. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.S. in Mechanical Engineering from California State University-Fresno. http://www.jsc.nasa.gov/Bios/htmlbios/mcmonagl.html
- Bruce E. Melnick, Lt. Comdr., USCG. Born December 5, 1949. B.S. in Ocean Engineering from the U.S. Coast Guard Academy and M.S. in Aeronautical Systems from the University of West Florida. http://www.jsc.nasa.gov/Bios/htmlbios/melnick-be.html
- William F. Readdy, Lt. Comdr., USN. Born January 24, 1952. B.S. in Aeronautical Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/readdy.html
- Kenneth S. Reightler, Jr., Lt. Comdr., USN. Born March 24, 1951. B.S. in Aerospace Engineering from the U.S. Naval Academy, M.S. in Systems Management from the University of Southern California, and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/reightle.html
- Mario Runco, Jr., Lt. Comdr., USN. Born January 26, 1952. B.S. in Meteorology from City College of New York and M.S. in Meteorology from Rutgers University. http://www.jsc.nasa.gov/Bios/htmlbios/runco.html
- James S. Voss, Maj., U.S. Army. Born March 3, 1949. B.S. in Aerospace Engineering from Auburn University and M.S. in Aerospace Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/voss-ji.html

The following individuals served on the rating panel and selection board for Group 12: George W.S. Abbey; Joseph D. Atkinson, Jr., Ph.D.; Daniel C. Brandenstein; Anna L. Fisher, M.D.; Carolyn L. Huntoon, Ph.D.; David C. Leestma; George D. Nelson, Ph.D.; Duane L. Ross; Loren J. Shriver; Paul J. Weitz; and John W. Young. All were from NASA JSC.

Group 13. The 23 astronaut candidates selected in 1990 included 7 pilots and 16 mission specialists. Among the candidates was the first female selected as a pilot and the first Hispanic female selected as a mission specialist. The following astronaut candidates began training at the Johnson Space Center on July 15, 1990:

- Daniel W. Bursch, Lt. Comdr., USN. Born July 25, 1957. B.S. in Physics from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/bursch.html
- Leroy Chiao. Born August 28, 1960. B.S. in Chemical Engineering from the University of California-Berkeley, M.S. in Chemical Engineering from the University of California-Santa Barbara, and Ph.D. in Chemical Engineering from the University of California-Santa Barbara. http://www.jsc.nasa.gov/Bios/htmlbios/chiao.html
- Michael R. U. Clifford, Maj., U.S. Army. Born October 13, 1952. B.S. in Basic Science from the U.S. Military Academy and M.S. in Aerospace Engineering from the Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/clifford.html
- Kenneth D. Cockrell. Born April 9, 1950. B.S. in Mechanical Engineering from the University of Texas and M.S. in Aeronautical Systems from the University of Florida. http://www.jsc.nasa.gov/Bios/htmlbios/cockrell.html
- Eileen M. Collins, Maj., USAF. Born November 19, 1956. B.A. in Mathematics from Syracuse University, M.S. in Operations Research from Stanford University, and M.A. in Space Systems Management from Webster University. http://www.jsc.nasa.gov/Bios/htmlbios/collins.html

- William G. Gregory, Capt., USAF. Born May 14, 1957. B.S. in Engineering Science from the U.S. Air Force Academy, M.S. in Engineering Mechanics from Columbia University, and M.S. in Management from Troy State. http://www.jsc.nasa.gov/Bios/htmlbios/gregor-w.html
- James D. Halsell, Maj., USAF. Born September 29, 1956. B.S. in Engineering from the U.S. Air Force Academy, M.S. in Management from Troy State, and M.S. in Space Operations from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/halsell.html
- Bernard A. Harris, Jr. Born June 26, 1956. B.S. in Biology from the University of Houston and M.D. from Texas Tech University. http://www.jsc.nasa.gov/Bios/htmlbios/harris.html
- Susan J. Helms, Capt., USAF. Born February 26, 1958. B.S. in Aerospace Engineering from the U.S. Air Force Academy and M.S. in Aeronautics/Astronautics from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/helms.html
- Thomas D. Jones. Born January 22, 1955. B.S. in Basic Science from the U.S. Air Force Academy and Ph.D. in Planetary Science from the University of Arizona. http://www.jsc.nasa.gov/Bios/htmlbios/jones.html
- William S. McArthur, Jr., Maj., U.S. Army. Born July 26, 1951. B.S. in Applied Sciences and Engineering from the U.S. Military Academy and M.S. in Aerospace Engineering from the Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/mcarthur.html
- James H. Newman. Born October 16, 1956. B.A. in Physics from Dartmouth College, M.A. in Physics from Rice University, and Ph.D. in Physics from Rice University. http://www.jsc.nasa.gov/Bios/htmlbios/newman.html
- Ellen Ochoa. Born May 10, 1958. B.S. in Physics from San Diego State, M.S. in Electrical Engineering from Stanford University, and Ph.D. in Electrical Engineering from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/ochoa.html
- Charles J. Precourt, Maj., USAF. Born June 29, 1955. B.S. in Aeronautical Engineering from the U.S. Air Force Academy and M.S. in Management from Golden Gate University. http://www.jsc.nasa.gov/Bios/htmlbios/precourt.html
- Richard A. Searfoss, Maj., USAF. Born June 6, 1956. B.S. in Aerospace Engineering from the U.S. Air Force Academy and M.S. in Aerospace Engineering from the California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/searfoss.html
- Ronald M. Sega. Born December 4, 1952. B.S. in Physics and Mathematics from the U.S. Air Force Academy, M.S. in Physics from Ohio State, and Ph.D. in Electrical Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/sega.html
- Nancy J.Currie, Capt., U.S. Army. Born December 29, 1958. B.A. in Biological Science from Ohio State and M.S. in Safety Engineering from the University of Southern California, and a doctorate in industrial engineering from the University of Houston. http://www.jsc.nasa.gov/Bios/htmlbios/currie.html
- Donald A. Thomas. Born May 6, 1955. B.S. in Physics from Case Western University, M.S. in Materials Science from Cornell University, and Ph.D. in Materials Science from Cornell University. http://www.jsc.nasa.gov/Bios/htmlbios/thomas-d.html
- Janice E. Voss. Born October 8, 1956. B.S. in Engineering Science from Purdue University, M.S. in Electrical Engineering from Massachusetts Institute of Technology, and Ph.D. in Aeronautics/Astronautics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/voss-jan.html
- Carl E. Walz, Capt., USAF. Born September 6, 1955. B.S. in Physics from Kent State and M.S. in Physics from John Carroll University. http://www.jsc.nasa.gov/Bios/htmlbios/walz.html
- Terrence W. Wilcutt, Maj., USMC. Born October 31, 1949. B.A. in Mathematics from Western Kentucky University. http://www.jsc.nasa.gov/Bios/htmlbios/wilcutt.html
- Peter J. K. Wisoff. Born August 16, 1958. B.S. in Physics from the University of Virginia, M.S. in Physics from Stanford University, and Ph.D. in Applied Physics from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/wisoff.html
- David A. Wolf. Born August 23, 1956. B.S. in Electrical Engineering from Purdue University and M.D. from Indiana University. http://www.jsc.nasa.gov/Bios/htmlbios/wolf.html

The rating panel and selection board members for the 1990 astronaut candidate class were Joseph D. Atkinson, Jr., Ph.D.; Charles F. Bolden; Daniel C. Brandenstein; Mary L. Cleave, Ph.D.; Michael L. Coats; Richard O. Covey; Steven A. Hawley, Ph.D.; Jeffrey A. Hoffman, Ph.D.; Carolyn L. Huntoon, Ph.D.; Robert A.R. Parker, Ph.D.; Donald R. Puddy; Duane L. Ross; Jerry L. Ross; Rhea Seddon, M.D.; and John W. Young. All were from NASA JSC.

Group 14. In 1992, NASA selected 19 new astronaut candidates in support of the Space Shuttle program. The group consisted of four pilots and 15 mission specialists, including nine civilians and 10 military officers. The following astronaut candidates reported to the Johnson Space Center on August 3, 1992 to begin their training and evaluation program:

- Daniel T. Barry. Born December 30, 1953. B.S. in Electrical Engineering from Cornell University, M.S.E. in Electrical Engineering and Computer Science from Princeton University, M.A. in Electrical Engineering and Computer Science from Princeton University, Ph.D. in Electrical Engineering and Computer Science from Princeton University, and M.D. from the University of Miami. http://www.jsc.nasa.gov/Bios/htmlbios/barry.html
- Charles E. Brady, Jr., M.D., Comdr., USN. Born August 12, 1951. Premed at the University of North Carolina at Chapel Hill and M.D. from Duke University. http://www.jsc.nasa.gov/Bios/htmlbios/brady.html
- Catherine G. Coleman, Ph.D., Capt., USAF. Born December 14, 1960. B.S. in Chemistry from Massachusetts Institute of Technology and Ph.D. in Polymer Science and Engineering from the University of Massachusetts. http://www.jsc.nasa.gov/Bios/htmlbios/coleman.html
- Michael L. Gernhardt. Born May 4, 1956. B.S. in Physics from Vanderbilt University, M.S. in Bioengineering from the University of Pennsylvania, and Ph.D. in Bioengineering from the University of Pennsylvania. http://www.jsc.nasa.gov/Bios/htmlbios/gernhard.html
- John M. Grunsfeld. Born October 10, 1958. B.S. in Physics from the Massachusetts Institute of Technology, M.S. in Physics from the University of Chicago, and Ph.D. in Physics from the University of Chicago. http://www.jsc.nasa.gov/Bios/htmlbios/grunsfel.html
- Scott J. Horowitz, Ph.D., Capt., USAF. Born March 24, 1957. B.S. in Engineering from California State University at Northridge, M.S. in Aerospace Engineering from Georgia Tech, and Ph.D. in Aerospace Engineering from the Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/horowitz.html
- Brent W. Jett, Jr., Lt. Comdr., USN. Born October 5, 1958. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/jett.html
- Kevin R. Kregel. Born September 16, 1956. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.P.A. in Public Administration from Troy State University. http://www.jsc.nasa.gov/Bios/htmlbios/kregel.html
- Wendy B. Lawrence, Lt. Comdr., USN. Born July 2, 1959. B.S. in Ocean Engineering from the U.S. Naval Academy and M.S. in Ocean Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/lawrence.html
- Jerry M. Linenger, Comdr., USN. Born January 16, 1955. B.S. in Bioscience from the U.S. Naval Academy, M.D. from Wayne State University, M.S. in Systems Management, M.P.H. from the University of North Carolina, and Ph.D. in Epidemiology from the University of North Carolina. http://www.jsc.nasa.gov/Bios/htmlbios/linenger.html
- Richard M. Linnehan, D.V.M., Capt., U.S. Army. Born September 19, 1957. B.S. in Zoology from the University of New Hampshire and D.V.M. from Ohio State University. http://www.jsc.nasa.gov/Bios/htmlbios/linnehan.html
- Michael E. Lopez-Alegria, Lt. Comdr., USN. Born May 30, 1958. B.S. in Systems Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/lopez-al.html
- Scott E. Parazynski. Born July 28, 1961. B.S. in Biology from Stanford University and M.D. from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/parazyns.html
- Kent V. Rominger, Lt. Comdr., USN. Born August 7, 1956. B.S. in Civil Engineering from Colorado State University and M.S. in

Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/rominger.html

- Winston E. Scott, Comdr., USN. Born August 6, 1950. B.A. in Music from Florida State University and M.S. in Aeronautical Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/scott.html
- Steven L. Smith. Born December 30, 1958. B.S. in Electrical Engineering from Stanford University, M.S. in Electrical Engineering from Stanford University, and M.B.A. from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/smith-s.html
- Joseph R. Tanner. Born January 21, 1950. B.S. in Mechanical Engineering from the University of Illinois. http://www.jsc.nasa.gov/Bios/htmlbios/tanner.html
- Andrew S.W. Thomas. Born December 18, 1951. B.E. in Mechanical Engineering from the University of Adelaide (Australia) and Ph.D. in Mechanical Engineering from the University of Adelaide (Australia). http://www.jsc.nasa.gov/Bios/htmlbios/thomas-a.html
- Mary E. Weber. Born August 24, 1962. B.S. in Chemical Engineering from Purdue University and Ph.D. in Chemistry from the University of California-Berkeley. http://www.jsc.nasa.gov/Bios/htmlbios/weber.html

The following persons served on the rating panel and astronaut candidate selection board in 1991: Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Robert D. Cabana; Franklin R. Chang-Diaz, Ph.D.; Richard O. Covey; Bonnie J. Dunbar, Ph.D.; Robert L. Gibson; Linda M. Godwin, Ph.D.; Jeffrey A. Hoffman, Ph.D.; Carolyn L. Huntoon, Ph.D.; Roger L. Kroes, Ph.D.; David C. Leestma; Paul Lowman, Ph.D.; Donald R. McMonagle; Donald R. Puddy; Duane L. Ross; Rhea Seddon, M.D.; William M. Shepherd; Loren J. Shriver; Kathryn D. Sullivan, Ph.D.; Kathryn C. Thornton, Ph.D.; James D. Wetherbee; and John W. Young. Dr. Kroes was from NASA Marshall Space Flight Center (MSFC) and Dr. Lowman was from NASA marshall space flight center (GSFC). The others were from NASA JSC.

Group 15. The 1995 astronaut candidate class consisted of 10 pilot candidates, including two female pilots, and nine mission specialists. The 19 astronaut candidates were selected through a highly competitive process that evaluated their education, experience, and ability to work as members of a team. This was the first astronaut class to receive training on both the Space Shuttle and the International Space Station programs. The 1995 astronaut candidates included:

- Scott D. Altman, Lt. Comdr., USN. Born August 15, 1959. B.S. in Aeronautical and Astronautical Engineering from the University of Illinois and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/altman.html
- Michael P. Anderson, Maj., USAF. Born December 25, 1959. B.S. in Physics and Astronomy from the University of Washington and M.S. in Physics from Creighton University. http://www.jsc.nasa.gov/Bios/htmlbios/anderson.html
- Jeffrey S. Ashby, Comdr., USN. Born June 16, 1954. B.S. in Mechanical Engineering from the University of Idaho and M.S. in Aviation Systems from the University of Tennessee. http://www.jsc.nasa.gov/Bios/htmlbios/ashby.html
- Michael J. Bloomfield, Maj., USAF. Born March 16, 1959. B.S. in Engineering Mechanics from the U.S. Air Force Academy and M.S. in Engineering Management from Old Dominion University. http://www.jsc.nasa.gov/Bios/htmlbios/bloomfie.html
- Kalpana Chawla. Born July 1, 1961. B.S. in Aeronautical Engineering from Punjab Engineering College in India, M.S. in Aerospace Engineering from the University of Texas, and Ph.D. in Aerospace Engineering from the University of Colorado. http://www.jsc.nasa.gov/Bios/htmlbios/chawla.html
- Robert Curbeam, Jr., Lt. Comdr., USN. Born March 5, 1962. B.S. in Aerospace Engineering from the U.S. Naval Academy, M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School, and Degree of Aeronautical and Astronautical Engineer from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/curbeam.html
- Joe F. Edwards, Jr., Lt. Comdr., USN. Born February 3, 1958. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aviation from the University of Tennessee at Knoxville. http://www.jsc.nasa.gov/Bios/htmlbios/edwards.html
- Dominic L. Gorie, Comdr., USN. Born May 2, 1957. B.S. in Ocean Engineering from the U.S. Naval Academy and M.S. in Aviation Systems from the University of Tennessee at Knoxville. http://www.jsc.nasa.gov/Bios/htmlbios/gorie.html
- Kathryn P. Hire. Born August 26, 1959. B.S. in Engineering Management from the U.S. Naval Academy and M.S. in Space Technology from the Florida Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/hire.html
- Rick D. Husband, Maj., USAF. Born July 12, 1957. B.S. in Mechanical Engineering from Texas Tech University and M.S. in Mechanical Engineering from California State University. http://www.jsc.nasa.gov/Bios/htmlbios/husband.html
- Janet L. Kavandi. Born July 17, 1959. B.S. in Chemistry from Missouri Southern State College, M.S. in Chemistry from the University of Missouri- Rolla, and Ph.D. in Analytical Chemistry from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/kavandi.html
- Steven W. Lindsey, Maj., USAF. Born August 24, 1960. B.S. in Engineering Sciences from the U.S. Air Force Academy and M.S. in Aerospace Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/lindsey.html
- Edward T. Lu. Born July 1, 1963. B.S. in Electrical Engineering from Cornell University and Ph.D. in Applied Physics from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/lu.html
- Pamela A. Melroy, Maj., USAF. Born September 17, 1961. B.S. in Physics and Astronomy from Wellesley College and M.S. in Earth and Planetary Sciences from the Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/melroy.html
- Carlos I. Noriega, Maj., USMC. Born October 8, 1959. B.S. in Computer Science from the University of Southern California, M.S. in Computer Science from the U.S. Naval Postgraduate School, and M.S. in Space Systems Operations from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/noriega.html
- James F. Reilly. Born March 18, 1954. B.S. in Geosciences from the University of Texas, M.S. in Geosciences from the University of Texas, and Ph.D. in Geosciences from the University of Texas. http://www.jsc.nasa.gov/Bios/htmlbios/reilly.html
- Stephen K. Robinson. Born October 26, 1955. B.S. in Mechanical and Aeronautical Engineering from the University of California, M.S. in Mechanical Engineering from Stanford University and Ph.D. in Mechanical Engineering from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/robinson.html
- Susan L. Still, Lt., USN. Born October 24, 1961. B.S. in Aeronautical Engineering from Embry-Riddle University and M.S. in Aerospace Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/still.html
- Frederick W. Sturckow, Capt., USMC. Born August 11, 1961. B.S. in Mechanical Engineering from California Polytechnic State University. http://www.jsc.nasa.gov/Bios/htmlbios/sturckow.html

The 1994 rating panel and astronaut candidate selection board members were Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Kenneth D. Cameron; Kevin P. Chilton; Michael R. Clifford; Brian Duffy; Michael Foale, Ph.D.; Robert L. Gibson; Estella H. Gillette; Linda M. Godwin, Ph.D.; Frederick D. Gregory; James F. Harrington; Bernard A. Harris, M.D.; Steven A. Hawley, Ph.D.; Gregory W. Hayes; Carolyn L. Huntoon, Ph.D.; Tamara E. Jernigan, Ph.D.; Roger L. Kroes, Ph.D.; Mark C. Lee; David C. Leestma; Paul D. Lowman, Ph.D.; David H. Mobley; John F. Muratore; Steven R. Nagel; Ellen Ochoa, Ph.D.; Stephen S. Oswald; Duane L. Ross; Jerry L. Ross; Pierre J. Thuot; James S. Voss; James D. Wetherbee; and John W. Young. Mr. Harrington was from the NASA KSC, Dr. Kroes was from NASA MSFC, and Dr. Lowman was from NASA GSFC. The others were from NASA JSC.

Group 16. In 1996, NASA selected 35 astronaut candidates in support of the Space Shuttle and Space Station programs. This was the largest astronaut candidate class since the first group of Shuttle astronauts was selected in 1978. The 10 pilots and 25 mission specialists included three African-American females and a pair of identical twins. On 12 August 1996, the candidates began a curriculum including extensive Space Shuttle and Space Station training. Upon successful completion of their training, they were qualified as astronauts and began supporting long-duration missions on the International Space Station. The 1996 candidates included:

- David M. Brown, Comdr., USN. Born April 16, 1956. B.S. in Biology from the College of William and Mary and M.D. from Eastern Virginia Medical School. http://www.jsc.nasa.gov/Bios/htmlbios/brown.html
- Daniel C. Burbank, Lt. Comdr., USCG. Born July 27, 1961. B.S. in Electrical Engineering from the U.S. Coast Guard Academy and M.S. in Aeronautical Science from Embry-Riddle Aeronautical University. http://www.jsc.nasa.gov/Bios/htmlbios/burbank.html
- Yvonne D. Cagle. Born April 24, 1959. B.A. in Biochemistry from San Francisco State University and M.D. from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/cagle.html
- Fernando Caldeiro. Born June 12, 1958. B.S. in Mechanical Engineering from the University of Arizona and M.S. in Engineering Management from the University of Central Florida. http://www.jsc.nasa.gov/Bios/htmlbios/caldeiro.html
- Charles J. Camarda. Born May 8, 1952. B.S. in Aerospace Engineering from Polytechnic Institute of New York, M.S. in Engineering Science from George Washington University, and Ph.D. in Aerospace Engineering from Virginia Polytechnic Institute. http://www.jsc.nasa.gov/Bios/htmlbios/camarda.html
- Duane G. Carey, Maj., USAF. Born April 30, 1957. B.S. in Aerospace Engineering and Mechanics from the University of Minnesota-Minneapolis and M.S. in Aerospace Engineering from the University of Minnesota-Minneapolis. http://www.jsc.nasa.gov/Bios/htmlbios/carey.html
- Laurel B. Clark, Lt. Comdr., USN. Born March 10, 1961. B.S. in Zoology from the University of Wisconsin-Madison and M.D. from the University of Wisconsin-Madison. http://www.jsc.nasa.gov/Bios/htmlbios/clark.html
- Edward M. Fincke, Capt., USAF. Born March 14, 1967. B.S. in Aeronautics and Astronautics, and Earth, Atmospheric, and Planetary Sciences from Massachusetts Institute of Technology, and M.S. in Aeronautics and Astronautics from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/fincke.html
- Patrick G. Forrester, Lt. Col., U.S. Army. Born March 31, 1957. B.S. in Applied Sciences and Engineering from the U.S. Military Academy and M.S. in Mechanical and Aerospace Engineering from the University of Virginia. http://www.jsc.nasa.gov/Bios/htmlbios/forreste.html
- Stephen N. Frick, Lt. Comdr., USN. Born September 30, 1964. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/frick.html
- John B. Herrington, Lt. Comdr., USN. Born September 14, 1958. B.S. in Applied Mathematics from the University of Colorado and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/herringt.html
- Joan E. Higginbotham. Born August 3, 1964. B.S. in Electrical Engineering from Southern Illinois, M.S. in Management from Florida Institute of Technology, and M.S. in Space Systems from Florida Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/higginbo.html
- Charles O. Hobaugh, Capt., USMC. Born November 5, 1961. B.S. in Aerospace Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/hobaugh.html
- James M. Kelly, Capt., USAF. Born May 14, 1964. B.S. in Astronautical Engineering from the U.S. Air Force Academy. http://www.jsc.nasa.gov/Bios/htmlbios/kellyjm.html
- Mark E. Kelly, Lt., USN. Born February 21, 1964. B.S. in Marine Engineering and Nautical Science from the U.S. Merchant Marine Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/kellyme.html
- Scott J. Kelly, Lt., USN. Born February 21, 1964. B.S. in Electrical Engineering from the State University of New York Maritime College. http://www.jsc.nasa.gov/Bios/htmlbios/kellysj.html
- Paul S. Lockhart, Maj., USAF. Born April 28, 1956. B.A. in Mathematics from Texas Tech University and M.S. in Aerospace Engineering from the University of Texas. http://www.jsc.nasa.gov/Bios/htmlbios/lockhart.html
- Christopher J. Loria, Maj., USMC. Born July 9, 1960. B.S. in General Engineering from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/loria.html
- Sandra H. Magnus. Born October 30, 1964. B.S. in Physics from the University of Missouri-Rolla, M.S. in Electrical Engineering from the University of Missouri-Rolla, and Ph.D. in Materials Science and Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/magnus.html
- Michael J. Massimino. Born August 19, 1962. B.S. in Industrial Engineering from Columbia University, M.S. in Mechanical Engineering and Technology and Policy from Massachusetts Institute of Technology, and Ph.D. in Mechanical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/massimin.html
- Richard A. Mastracchio. Born February 11, 1960. B.S. in Electrical Engineering and Computer Science from the University of Connecticut, M.S. in Electrical Engineering from Rensselaer Polytechnic Institute, and M.S. in Physical Sciences from the University of Houston-Clear Lake. http://www.jsc.nasa.gov/Bios/htmlbios/mastracc.html
- William C. McCool, Lt. Comdr., USN. Born September 23, 1961. B.S. in Applied Science from the U.S. Naval Academy, M.S. in Computer Science from the University of Maryland, and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/mccool.html
- Lee M. Morin, Comdr., USN. Born September 9, 1952. B.S. in Mathematics and Electrical Science from the University of New Hampshire, M.S. in Biochemistry from New York University, M.D. from New York University, Ph.D. in Microbiology from New York University, and M.P.H. from the University of Alabama at Birmingham. http://www.jsc.nasa.gov/Bios/htmlbios/morin.html
- Lisa M. Nowak, Lt. Comdr., USN. Born May 10, 1963. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/nowak.html
- Donald R. Pettit. Born April 20, 1955. B.S. in Chemical Engineering from Oregon State University and Ph.D. in Chemical Engineering from the University of Arizona. http://www.jsc.nasa.gov/Bios/htmlbios/pettit.html
- John L. Phillips. Born April 15, 1951. B.S. in Mathematics and Russian from the U.S. Naval Academy, M.S. in Aeronautical Systems from the University of West Florida, M.S. in Geophysics and Space Physics from the University of California, and Ph.D. in Geophysics and Space Physics from the University of California. http://www.jsc.nasa.gov/Bios/htmlbios/phillips.html
- Mark L. Polansky. Born June 2, 1956. B.S. in Aeronautical and Astronautical Engineering from Purdue University and M.S. in Aeronautics and Astronautics from Purdue University. http://www.jsc.nasa.gov/Bios/htmlbios/polansky.html
- Paul W. Richards. Born May 20, 1964. B.S. in Mechanical Engineering from Drexel University and M.S. in Mechanical Engineering from the University of Maryland. http://www.jsc.nasa.gov/Bios/htmlbios/richardsp.html
- Piers J. Sellers. Born April 11, 1955. B.S. in Ecological Science from the University of Edinburgh (Scotland) and Ph.D. in Biometeorology from Leeds University (United Kingdom). http://www.jsc.nasa.gov/Bios/htmlbios/sellers.html
- Heidemarie M. Stefanyshyn-Piper, Lt. Comdr., USN. Born February 7, 1963. B.S. in Mechanical Engineering from Massachusetts Institute of Technology and M.S. in Mechanical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/stefanys.html
- Daniel M. Tani. Born February 1, 1961. B.S. in Mechanical Engineering from Massachusetts Institute of Technology and M.S. in Mechanical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/tani.html
- Rex J. Walheim, Capt., USAF. Born October 10, 1962. B.S. in Mechanical Engineering from the University of California-Berkeley and M.S. in Industrial Engineering from the University of Houston. http://www.jsc.nasa.gov/Bios/htmlbios/walheim.html
- Peggy A. Whitson. Born February 9, 1960. B.S. in Biology and Chemistry from Iowa Wesleyan College and Ph.D. in Biochemistry from Rice University. http://www.jsc.nasa.gov/Bios/htmlbios/whitson.html
- Jeffrey N. Williams, Maj., U.S. Army. Born January 18, 1958. B.S. in Applied Sciences and Engineering from U.S. Military Academy and M.S.

in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/williamsj.html
- Stephanie D. Wilson. Born September 27, 1966. B.S. in Engineering Science from Harvard University and M.S. in Aerospace Engineering from the University of Texas. http://www.jsc.nasa.gov/Bios/htmlbios/wilson.html

The 1995 astronaut candidate rating panel and selection board included the following individuals: Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Robert D. Cabana; Brian Duffy; Michael Foale, Ph.D.; Estella H. Gillette; Linda M. Godwin, Ph.D.; Steven A. Hawley, Ph.D.; Gregory W. Hayes; Susan J. Helms; Robert K. Holkan; Donald R. McMonagle; David H. Mobley; John F. Muratore; Bascom W. Murrah III; Duane L. Ross; John A. Rummel, Ph.D.; James D. Wetherbee; and John W. Young. Mr. Mobley was from NASA Headquarters, and Mr. Murrah was from NASA KSC. The others were from NASA JSC.

Group 17. In 1998, NASA selected 25 astronaut candidates to support the Space Station and Space Shuttle programs. The group of 8 pilots and 17 mission specialists consisted of 21 males and 4 females, including NASA's first Educator Mission Specialist. The astronaut class reported for training at the Johnson Space Center on August 15, 1998. The candidates were:

- Clayton C. Anderson. Born February 23, 1959. B.S. in Physics from Hastings College and M.S. in Aerospace Engineering from Iowa State University. http://www.jsc.nasa.gov/Bios/htmlbios/anderson-c.html
- Lee J. Archambault, Maj., USAF. Born August 25, 1960. B.S. in Aerospace and Astronautical Engineering from the University of Illinois-Urbana and M.S. in Aerospace and Astronautical Engineering from the University of Illinois-Urbana. http://www.jsc.nasa.gov/Bios/htmlbios/archambault.html
- Tracy E. Caldwell. Born August 14, 1969. B.S. in Chemistry from California State University-Fullerton and Ph.D. in Chemistry from the University of California-Davis. http://www.jsc.nasa.gov/Bios/htmlbios/caldwell.html
- Gregory E. Chamitoff. Born August 6, 1962. B.S. in Electrical Engineering from California Polytechnic State University, M.S. in Aerospace Engineering from California Institute of Technology, and Ph.D. in Aeronautics and Astronautics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/chamitoff.html
- Timothy J. Creamer, Maj., U.S. Army. Born November 15, 1959. B.S. in Chemistry from Loyola College and M.S. in Physics from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/creamer.html
- Christopher J. Ferguson, Lt. Comdr., USN. Born September 1, 1961. B.S. in Mechanical Engineering from Drexel University and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/ferguson.html
- Michael J. Foreman, Comdr., USN. Born March 29, 1957. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/foreman.html
- Michael E. Fossum. Born December 19, 1957. B.S. in Mechanical Engineering from Texas A&M University, M.S. in Systems Engineering from the Air Force Institute of Technology, and M.S. in Physical Science from the University of Houston-Clear Lake. http://www.jsc.nasa.gov/Bios/htmlbios/fossum.html
- Kenneth T. Ham, Lt. Comdr., USN. Born December 12, 1964. B.S. in Aerospace Engineering from the U.S. Naval Academy and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/ham.html
- Patricia C. Hilliard. Born March 12, 1963. B.S. in Biology from Indiana University of Pennsylvania and M.D. from the Medical College of Pennsylvania. http://www.jsc.nasa.gov/Bios/htmlbios/hilliard.html
- Gregory C. Johnson. Born July 30, 1954. B.S. in Aerospace Engineering from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/johnson-gc.html
- Gregory H. Johnson, Maj., USAF. Born May 12, 1962. B.S. in Aeronautical Engineering from the U.S. Air Force Academy and M.S. in Civil Engineering from Columbia University. http://www.jsc.nasa.gov/Bios/htmlbios/johnson-gh.html
- Stanley G. Love. Born June 8, 1965. B.S. in Physics from Harvey Mudd College, M.S. in Astronomy from the University of Washington, and Ph.D. in Astronomy from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/love.html
- Leland D. Melvin. Born February 15, 1964. B.S. in Chemistry from the University of Richmond and M.S. in Materials Science from the University of Virginia. http://www.jsc.nasa.gov/Bios/htmlbios/melvin.html
- Barbara R. Morgan. Born November 28, 1951. B.S. in Biology from Stanford University. http://www.jsc.nasa.gov/Bios/htmlbios/morgan.html
- William A. Oefelein, Lt., USN. Born March 29, 1965. B.S. in Electrical and Electronics Engineering from Oregon State University. http://www.jsc.nasa.gov/Bios/htmlbios/oefelein.html
- John D. Olivas. Born May 25, 1966. B.S. in Mechanical Engineering from the University of Texas-El Paso, M.S. in Mechanical Engineering from the University of Houston and Ph.D. in Mechanical Engineering and Materials from Rice University. http://www.jsc.nasa.gov/Bios/htmlbios/olivas.html
- Nicholas J. M. Patrick. Born March 22, 1964. B.A.E. in Engineering from the University of Cambridge, England, M.A. in Engineering from the University of Cambridge (England) M.S. in Mechanical Engineering from Massachusetts Institute of Technology, and Ph.D. in Mechanical Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/patrick.html
- Alan G. Poindexter, Lt. Comdr., USN. Born November 5, 1961. B.A. in Aerospace Engineering from Georgia Institute of Technology and M.S. in Aeronautical Engineering from the U.S. Naval Postgraduate School. http://www.jsc.nasa.gov/Bios/htmlbios/poindexter.html
- Garrett E. Reisman. Born February 10, 1968. B.S. in Economics from the University of Pennsylvania, B.S. in Mechanical Engineering from the University of Pennsylvania, M.S. in Mechanical Engineering from California Institute of Technology, and Ph.D. in Mechanical Engineering from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/reisman.html
- Steven R. Swanson. Born December 3, 1960. B.S. in Engineering Physics from the University of Colorado-Boulder, M.A.S. in Computer Systems from Florida Atlantic University, and Ph.D. in Computer Science from Texas A&M University. http://www.jsc.nasa.gov/Bios/htmlbios/swanson.html
- Douglas H. Wheelock, Maj., U.S. Army. Born May 5, 1960. B.S. in Applied Science from the U.S. Military Academy and M.S. in Aerospace Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/wheelock.html
- Sunita L. Williams, Lt. Comdr., USN. Born September 19, 1965. B.S. in Physical Science from the U.S. Naval Academy and M.S. in Engineering Management from Florida Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/williams-s.html
- Neil W. Woodward III, Lt., USN. Born July 26, 1962. B.S. in Physics from Massachusetts Institute of Technology and M.A. in Physics from the University of Texas-Austin. http://www.jsc.nasa.gov/Bios/htmlbios/woodward.html
- George D. Zamka, Maj., USMC. Born June 29, 1962. B.S. in Mathematics from the U.S. Naval Academy. http://www.jsc.nasa.gov/Bios/htmlbios/zamka.html

The members of the 1998 rating panel and astronaut candidate selection committee were Thomas D. Akers; Joseph D. Atkinson, Jr., Ph.D.; Ellen S. Baker, M.D.; Jeffrey W. Bantle; Robert D. Cabana; Kenneth D. Cockrell; Brian Duffy; Estella H. Gillette; Linda M. Godwin; Ph.D.; James D. Halsell; Steven A. Hawley, Ph.D.; Gregory W. Hayes; Susan J. Helms; James A. Hickmon; Robert K. Holkan; Ellen Ochoa, Ph.D.; Charles J. Precourt; Duane L. Ross; John A. Rummel; Ph.D.; Loren J. Shriver; James D. Wetherbee; and John W. Young. Mr. Shriver was from NASA KSC. The others were from NASA JSC.

Group 18. NASA selected 17 candidates for the astronaut class of 2000. The group consisted of 7 pilots and 10 mission specialists, including the first candidate selected directly from the Navy's submarine community. The following astronaut candidates reported to the Johnson Space Center in August 2000 to begin extensive training in support of the Space Shuttle and Space Station programs:

- Dominic A. Antonelli, Lt., USN. Born August 23, 1967 in Detroit, Michigan. B.S. in Aeronautics and Astronautics from Massachusetts Institute of Technology and M.S. in Aeronautics and Astronautics from the University of Washington. http://www.jsc.nasa.gov/Bios/htmlbios/antonelli-da.html
- Michael R. Barrett. Born April 16, 1959. B.S. in Zoology from the University of Washington and M.D. from Northwestern University. http://www.jsc.nasa.gov/Bios/htmlbios/barratt-mr.html
- Robert Behnken, Capt., USAF. Born July 28, 1970. B.S. in Mechanical Engineering and Physics from Washington University, M.S. in Mechanical Engineering from California Institute of Technology, and Ph.D. in Mechanical Engineering from California Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/behnken-rl.html
- Eric A. Boe, Maj., USAF. Born October 1, 1964. B.S. in Astronautical Engineering from the U.S. Air Force Academy and M.S. in Electrical Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/boe-ea.html
- Stephen G. Bowen, Lt. Comdr., USN. Born February 13, 1964. B.S. in Electrical Engineering from the U.S. Naval Academy and Degree in Ocean Engineering from Massachusetts Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/bowen-sg.html
- B. Alvin Drew, Maj., USAF. Born November 5, 1962. B.S. in Astronautical Engineering and Physics from the U.S. Air Force Academy, and M.S. in Aerospace Science from Embry-Riddle Aeronautical University. http://www.jsc.nasa.gov/Bios/htmlbios/drew-ba.html
- Andrew J. Feustel. Born August 25, 1965. B.S. in Solid Earth Sciences from Purdue University, M.S. in Geophysics from Purdue University, and Ph.D. in Geological Sciences from Queen's University (Canada). http://www.jsc.nasa.gov/Bios/htmlbios/feustel-aj.html
- Kevin A. Ford, Lt. Col., USAF. Born July 7, 1960. B.S. in Aerospace Engineering from the University of Notre Dame, M.S. in International Relations from Troy State University, M.S. in Aerospace Engineering from the University of Florida, and Ph.D. in Astronautical Engineering from the Air Force Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/ford-ka.html
- Ronald J. Garan, Jr., Maj., USAF. Born October 30, 1961. B.S. in Business Economics from SUNY College at Oneonta, M.S. in Aeronautical Science from Embry-Riddle Aeronautical University, and M.S. in Aerospace Engineering from the University of Florida. http://www.jsc.nasa.gov/Bios/htmlbios/garan-rj.html
- Michael T. Good, Maj., USAF. Born October 13, 1962. B.S. in Aerospace Engineering from the University of Notre Dame and M.S. in Aerospace Engineering from the University of Notre Dame. http://www.jsc.nasa.gov/Bios/htmlbios/good-mt.html
- Douglas G. Hurley, Maj., USMC. Born October 21, 1966. B.S. in Civil Engineering from Tulane University. http://www.jsc.nasa.gov/Bios/htmlbios/hurley-dg.html
- Timothy L. Kopra, Maj., U.S. Army. Born April 9, 1963. B.S. in Computer Science from the U.S. Military Academy and M.S. in Aerospace Engineering from Georgia Institute of Technology. http://www.jsc.nasa.gov/Bios/htmlbios/kopra-tl.html
- K. Megan McArthur. Born August 30, 1971. B.S. in Aerospace Engineering from the University of California-Los Angeles. http://www.jsc.nasa.gov/Bios/htmlbios/mcarthur-km.html
- Karen L. Nyberg. Born October 7, 1969. B.S. in Mechanical Engineering from the University of North Dakota, M.S. in Mechanical Engineering from the University of Texas-Austin, and Ph.D. in Mechanical Engineering from the University of Texas-Austin. http://www.jsc.nasa.gov/Bios/htmlbios/nyberg-kl.html
- Nicole P. Stott. Born November 19, 1962. B.S. in Aeronautical Engineering from Embry-Riddle Aeronautical University and M.S. in Engineering Management from the University of Central Florida. http://www.jsc.nasa.gov/Bios/htmlbios/stott-np.html
- Terry W. Virts, Jr., Capt., USAF. Born December 1, 1967. B.S. in Mathematics from the U.S. Air Force Academy, and M.A.S. in Aeronautics from Embry-Riddle Aeronautical University. http://www.jsc.nasa.gov/Bios/htmlbios/virts-tw.html
- Barry E. Wilmore, Lt. Comdr., USN. Born December 29, 1962. B.S. in Electrical Engineering from Tennessee Technological University, M.S. in Electrical Engineering from Tennessee Technological University, and M.S. in Aviation Systems from the University of Tennessee-Knoxville. http://www.jsc.nasa.gov/Bios/htmlbios/wilmore-be.html

The following individuals served on the 2000 rating panel and astronaut candidate selection board: Michael P. Anderson; Ellen S. Baker, M.D.; Jeffrey W. Bantle; Robert D. Cabana; Franklin R. Chang-Diaz, Ph.D.; Kalpana Chawla, Ph.D.; Robert L. Curbeam, Jr.; Nancy J. Currie; Estella H. Gillette; Linda M. Godwin, Ph.D.; Steven A. Hawley, Ph.D.; Tamara E. Jernigan, Ph.D.; Ellen Ochoa, Ph.D.; Scott Parazynski, M.D.; William W. Parsons; Charles J. Precourt; James F. Reilly, Ph.D.; Kent V. Rominger; Duane L. Ross; John A. Rummel, Ph.D.; Loren J. Shriver; James D. Wetherbee; David R. Williams, M.D.; and John W. Young. Mr. Shriver was from NASA KSC. The others were from NASA JSC.

Group 19. NASA selected 11 candidates for the astronaut class of 2004. The group consisted of 2 pilots and 9 mission specialists, including 3 individuals with education backgrounds designated as Educator Astronauts. The following astronaut candidates reported to the Johnson Space Center in August 2004 to begin extensive training in support of the International Space Station and Exploration programs:

- Joseph M. Acaba. Born May 17, 1967. B.S. in Geology from the University of California-Santa Barbara, 1990 and M.S. in Geology from the University of Arizona, 1992. http://www.jsc.nasa.gov/Bios/htmlbios/acaba-jm.html
- Richard R. Arnold II. Born November 26, 1963. B.S. in Accounting from Frostburg State University, MD, and M.S. in Marine, Estuarine & Environmental Science from University of Maryland, 1992. http://www.jsc.nasa.gov/Bios/htmlbios/arnold-rr.html
- Randolph J. Bresnik, Maj., USMC. Born September 11, 1967. B.S., in Mathematics, from The Citadel, 1989 and M. S. in Aviation Systems, University of Tennessee-Knoxville, 2002. http://www.jsc.nasa.gov/Bios/htmlbios/bresnik-rj.html
- Christopher J. Cassidy, Lt. Cmdr., USN. Born January 4, 1970. B.S., in Mathematics, from the U.S. Naval Academy, 1993 and M.S. in Ocean Engineering, from the Massachusetts Institute of Technology, 2000. http://www.jsc.nasa.gov/Bios/htmlbios/cassidy-cj.html
- James P. Dutton, Jr., Maj., USAF. Born November 20, 1968. B.S., in Astronautical Engineering, U.S. Air Force Academy, 1991, M.S. Aeronautics & Astronautics, University of Washington, 1994. http://www.jsc.nasa.gov/Bios/htmlbios/dutton-jp.html
- Satoshi Furukawa, Ph.D., M.D. Born 1964 –Yokohama, Kanagawa, Japan. M.D., University of Tokyo, 1989 and Ph.D., in Medical Science, University of Tokyo, 2000. http://www.jsc.nasa.gov/Bios/htmlbios/furukawa-s.html
- Jose M. Hernandez. Born August 7, 1962. B.S., in Electrical Engineering, from the University of the Pacific, 1984, and M.S., in Electrical & Computer Engineering, University of California-Santa Barbara, 1986. http://www.jsc.nasa.gov/Bios/htmlbios/hernandez-jm.html
- Akihiko, Hoshide. Born in 1968 in Tokyo, Japan. B.S., in Mechanical Engineering, Keio University, 1992 and M.S., in Aerospace Engineering, University of Houston Cullen College of Engineering, 1997. http://www.jsc.nasa.gov/Bios/htmlbios/hoshide-a.html
- Robert S. Kimbrough, Lt. Col., U.S. Army. Born June 4, 1967. B.S., in Aerospace Engineering, U.S. Military Academy, 1989, and M.S., in Operations Research, Georgia Institute of Technology, 1998. http://www.jsc.nasa.gov/Bios/htmlbios/kimbrough-rs.html
- Thomas H. Marshburn, M. D. Born August 29, 1960. B.S., in Physics, Davidson College, NC, 1982, M.S. in Engineering Physics, University of Virginia, 1984, M.D. from Wake Forest University, 1989, and M.S. in Medical Science, University of Texas Medical Branch, 1997. http://www.jsc.nasa.gov/Bios/htmlbios/marshburn-th.htm
- Dorothy M. Metcalf-Lindenburger. Born May 2, 1975. B.A. in Geology, from Whitman College, WA, 1997. http://www.jsc.nasa.gov/Bios/htmlbios/metcalf-lindenburger-dm.html
- Robert L. Satcher, Jr., Ph.D., M.D. Born September 22, 1965. B.S., in Chemical Engineering, Massachusetts Institute of Technology, 1986, Ph.D., in Chemical Engineering, Massachusetts Institute of Technology, 1993, and M.D., from Harvard University, 1994. http://www.jsc.nasa.gov/Bios/htmlbios/satcher-rl.html
- Shannon Walker, Ph.D. Born June 4, 1965. B.S., in Physics, Rice University, 1987, M.S. in Space Physics, Rice University, 1992, and Ph.D.

in Space Physics, from Rice University, 1993. http://www.jsc.nasa.gov/Bios/htmlbios/walker-s.html

- Naoko, Yamazaki. Born 1970 –Matsudo City, Chiba, Japan. B.S., in Aerospace Engineering, University of Tokyo, 1993 and M.S. in Aerospace Engineering, University of Tokyo, 1996. http://www.jsc.nasa.gov/Bios/htmlbios/yamazaki-n.html

The following individuals served on the 2004 rating panel and astronaut candidate selection board: Ellen S. Baker, M.D.; Michael J. Bloomfield; Robert D. Cabana; Jeffrey R. Davis, M.D.; Estella H. Gillette; James M. Heflin; John B. Herrington; Janet L. Kavandi, Ph.D.; Michael Lopez-Alegria; Sandra H. Magnus, Ph.D.; Michael J. Massimino, Ph.D.; Pamela A. Melroy; Leland D. Melvin; Barbara R. Morgan; Lee M. Morin, Ph.D.; Carlos I. Noriega; Kent V. Rominger; Duane L. Ross; Andrew S. W. Thomas, Ph.D.; Rex J. Walheim; Susan M. White; Peggy A. Whitson, Ph.D.; and John W. Young. All were from JSC.

See also **Apollo Lunar Missions; Lunar Exploration; Moon (Earth's); Spaceflight U.S. Manned; Space Shuttle**; and **Space Stations**.

DUANE L. ROSS and TERESA GOMEZ, NASA Johnson Space Center, Houston, TX

ASTRONAVIGATION. The plotting and directing of the movement of a spacecraft from within the craft by means of observations on celestial bodies. Sometimes contracted to *astrogation* or called *celestial navigation*.

ASTRON MACHINE. An experimental thermonuclear device where a magnetic filed is generated by a relativistic ring of electrons and shaped into a magnetic mirror configuration. The hot electrons serve as a heat source to heat the ions.

ASTRONOMICAL CLOCK. A clock that indicates astronomical events as well as time. Historically, these clocks were developed to achieve reliable timekeeping by the mechanical simulation of the observable astronomical relationships of celestial bodies. Probably the first such clock was the great Chinese astronomical clock tower of Su Sung (1020–1101) which incorporated the first solar sideraal gear and used (on the water wheel that drove the clockworks) an escapement mechanism believed to be the world's first. The first recorded astronomical clock in Europe was produced about 1330 by Richard of Wallingford of the Abbey of St. Albans in Hertfordshire, England. Better known as the "Astrarium," completed in 1364 by Giovanni de Dondi of Chioggia, Italy. An exact reproduction of this device is in the Smithsonian Institution's Museum of History and Technology, Washington, DC. This clock indicated the movements of the Sun, Moon and the five then-known planets and displayed mean solar time and a perpetual Julian calendar for the Church's movable feasts. The outstanding modern example of an astronomical clock is Jens Olsen's "World Clock" in Copenhagen's City Hall. Detailed visual simulation of complex astronomical events within and beyond the solar system is now far more accurately achieved by planetarium projectors. See **Planetarium**.

ASTRONOMICAL REFRACTION (Atmospheric Refraction).

1. The difference between the angular positions of the image and object of a celestial object that results from refraction in the earth's atmosphere. Astronomical refraction is greatest near the horizon where it normally exceeds a solar diameter. Consequently, we see the image of the sun above the horizon even though the sun itself is below, and this extends the length of the day measurably at both ends.
2. A variety of phenomena that result from the refraction of celestial light by the earth's atmosphere. It is distinguished from the term terrestrial refraction, which is used when the source is within our atmosphere.

ASTRONOMICAL TWILIGHT. The twilight stage during which the sun's unrefracted center is at elevation angles $-12^\circ f > h_0 > -18^\circ$. During a clear evening's astronomical twilight, horizontal illuminance due to scattered sunlight decreases from $\sim$0.008 lux to $\sim 6 \times 10^{-4}$ lux. At $h_0 = -18^\circ$, 1) no horizon glow is visible at the sun's azimuth (the bright segment's upper boundary is at the observer's astronomical horizon), 2) sixth-magnitude stars can be seen near the zenith, and 3) scattered sunlight's residual illuminance is less than that from starlight and airglow. See also **Atmospheric Optical Phenomena**; and **Aurora and Airglow**.

ASTRONOMICAL UNIT. (AU or **au** or **a.u.** or sometimes **ua**). A unit of distance principally employed in expressing distances within the solar system, but also used to some extent for measuring interstellar distances. Technically defined, one astronomical unit is the mean distance of the earth from the sun. To express this in linear units, it becomes necessary to determine the distance of the earth from the sun in the units chosen or, in other words, to determine the solar parallax. The currently accepted value of the 1 AU is 149,597,870, 691 km (or 92,955,807,267 miles). The value for the length of the astronomical unit is 1.495985×10^8 kilometers (92.956×10^6 miles), and was obtained by radar astronomy. See also **Light-Year**; and **Parsec**.

It is a derived constant and used to indicate distances within the solar system. Its formal definition is the radius of an unperturbed circular orbit a massless body would revolve about the sun in 2*(pi)/k days (i.e., 365.2568983. . . . days), where k is defined as the Gaussian constant exactly equal to 0.01720209895. Since an AU is based on radius of a circular orbit, one AU is actually slightly less than the average distance between the Earth and the Sun (approximately 150 million km or 93 million miles).

The symbol "ua" is recommended by the Bureau International des Poids et Mesures http://www.bipm.fr/, but in the United States and other anglophone countries the reverse usage is more common. The International Astronomical Union http://www.iau.org/, recommends "au," and the international standard ISO 31-1[1] http://www.iso.org/iso/en/ISOOnline.frontpage, uses "AU".

History

Aristarchus (310 BC–c. 230 BC) was a Greek astronomer and mathematician, born on the island of Samos, in ancient Greece. He estimated the distance to the Sun to be about 20 times the distance to the moon, whereas the true ratio is about 390. His estimate was based on the angle between the half moon and the sun, which he estimated as 87°.

According to Eusebius of Caesarea in the *Praeparatio Evangelica*, Eratosthenes found the distance to the sun to be "σΤαδΙωV μΥρΙαδαςΤεΤδαΚΟσΙαςΚαΙ ΟΚΤωΚΙσμΥρΙαςΤ" (literally "of stadia myriads 400 and 80000"). This has been translated either as 4,080,000 stadia (1903 translation by E. H. Gifford), or as 804,000,000 stadia (edition of Edouard des Places, dated 1974-1991). Using the Greek stadium of 185 m, the former translation comes to a far-too-low 755,000 km, whereas the second translation comes to a very accurate 149 million km.

At the time the AU was introduced, its actual value was very poorly known, but planetary distances in terms of AU could be determined from heliocentric geometry and Kepler's laws of planetary motion. The value of the AU was first estimated by Jean Richer and Giovanni Domenico Cassini in 1672. By measuring the parallax of Mars from two locations on the Earth, they arrived at a figure of about 140 million kilometers (87 million miles). See also **Cassini**, **Gian Domenico (1625–1712)**; and **Kepler's Laws of Planetary Motion**.

A somewhat more accurate estimate can be obtained by observing the transit of Venus. This method was devised by Edmond Halley, and applied to the transits of Venus observed in 1761 and 1769, and then again in 1874 and 1882. The Venus transits in 2004 and the upcoming 2012, offer opportunities to witness a phenomenon seen by no living person and not to be repeated until 2117. In 1716 Halley suggested a high-precision measurement of the distance between the Earth and the Sun by timing the transit of Venus. In 1718 he discovered the proper motion of the "fixed" stars by comparing his astrometric measurements with those of the Greeks. Edmond Halley (1656-1742) was an English astronomer, geophysicst, mathematician, meteorologist, and physicist. See also **Halley, Edmond**.

Another method involved determining the constant of aberration, and Simon Newcomb gave great weight to this method when deriving his widely accepted value of 8.80′ for the solar parallax (close to the modern value of 8.794 148″). Simon Newcomb (1835–1909) was an astronomer and mathematician.

[1] The **ISO 31-1** is the part of international standard ISO 31 that defines names and symbols for quantities and units related to *space and time.*

The discovery of the near-Earth asteroid 433 Eros and its passage near the Earth in 1900–1901 allowed a considerable improvement in parallax measurement. More recently very precise measurements have been carried out by radar and by telemetry from space probes.

While the value of the astronomical unit is now known to great precision, the value of the mass of the Sun is not, because of uncertainty in the value of the gravitational constant. Because the gravitational constant is known to only five or six significant digits while the positions of the planets are known to 11 or 12 digits, calculations in celestial mechanics are typically performed in solar masses and astronomical units rather than in kilograms and kilometers. This approach makes all results dependent on the gravitational constant. A conversion to SI units would separate the results from the gravitational constant, at the cost of introducing additional uncertainty by assigning a specific value to that unknown constant.

It is known that the mass of the Sun is very slowly decreasing, and therefore the orbital period of a body at a given distance is increasing. This implies that the AU is getting smaller (by about one centimeter (0.39 in) per year) over time.

Examples

The distances are approximate mean distances. It has to be taken into consideration that the distances between celestial bodies change in time due to their orbits and other factors.

- The Earth is 1.00 ± 0.02 AU from the Sun.
- The Moon is 0.0026 ± 0.0001 AU from the Earth.
- Mars is 1.52 ± 0.14 AU from the Sun.
- Jupiter is 5.20 ± 0.05 AU from the Sun.
- Pluto is 39.5 ± 9.8 AU from the Sun.
- As of November 2005, Voyager 1 (the farthest human-made object) is 97 AU from the Sun.
- The mean diameter of the Solar system, including the Oort cloud, is approximately 10^5 AU.
- Proxima Centauri (the nearest star) is ~268 000 AU away from the Sun.
- The mean diameter of Betelgeuse is 2.57 AU.
- The distance from the Sun to the centre of the Milky Way is approximately 1.7×10^9 AU.

Some conversion factors:

- 1 AU = 149 597 870.691 ± 0.030 km ≈ 92 955 807 miles ≈ 8.317 light minutes ≈ 499 light-seconds
- 1 light-second ≈ 0.002 AU
- 1 light-minute ≈ 0.120 AU
- 1 light-hour ≈ 7.214 AU
- 1 light-day ≈ 173 AU
- 1 light-year ≈ 63 241 AU
- 1 pc ≈ 206 265 AU

ASTROPHYSICS. Astrophysics is the branch of physics that attempts to understand the appearance and behavior of astronomical objects, especially those outside the solar system, including stars and galaxies, assemblages of these, and the material around them. Alternatively, one can describe astrophysics as the portions of astronomy that the physicists of any given generation regard as worthy of their attention.

The word first appears in the late nineteenth century to mean the application of principles of spectroscopy, atomic physics, and thermodynamics to measure the luminosities, temperatures, and chemical compositions of stars and nebulae, while astronomy meant positional measurements and their applications to the solar system, binary stars, and definitions of coordinate systems based on the earth's motions. All of these topics would today be regarded as parts of astronomy and rather old-fashioned ones at that.

Meanwhile, astrophysics has evolved to denote investigations of the internal structure, evolution, and formation of stars and galaxies. Nuclear astrophysics focuses on nuclear reactions as energy sources in stars and as synthesizers of the chemical elements. High energy astrophysics takes as its territory objects and processes where either the energy per particle or photon or the total energy is large (compared to thermal equilibrium or to average objects). Examples include supernovae, pulsars, and x-ray sources; cosmic rays; and quasars and radio galaxies. The study of cosmology is theoretical astrophysics at the largest scales.

History

Although astronomy is as old as recorded history, it was long separated from the study of physics. In the Aristotelian worldview, the celestial pertained to perfection — bodies in the sky being perfect spheres moving in perfectly circular orbits — while the earthly pertained to imperfection; these two realms were seen as unrelated.

Aristarchus of Samos (c.310–c.250 BC) first put forward that the motions of the celestial bodies could be explained by assuming that the Sun and not the Earth was at the center. Aristarchus' heliocentric theory was not accepted in the Ancient Greek world and for centuries, the apparently common-sense view that the Sun and other planets went round the Earth went basically unquestioned, until Nicolaus Copernicus suggested in the 16th century that the Earth and all the other planets in the Solar System orbited the Sun. This idea had been around, though, for nearly 2000 years when Aristarchus first suggested it, but not in such a nice mathematical model. Galileo Galilei made quantitative measurements central to physics, and observed the orbits of Jupiter's moons, contradicting the Earth-Centered dogma of his contemporary Catholic Church.

The availability of accurate observational data led to research into theoretical explanations for the observed behavior. At first, only empirical rules were discovered, such as Kepler's laws of planetary motion, discovered at the start of the 17th century. Later that century, Isaac Newton, bridged the gap between Kepler's laws and Galileo's dynamics, discovering that the same laws that rule the dynamics of objects on earth rules the motion of planets and the moon. Celestial mechanics, the application of Newtonian gravity and Newton's laws to explain Kepler's laws of planetary motion, was the first unification of astronomy and physics.

After Isaac Newton published his *Principia*, maritime navigation was transformed. Starting around 1670, the entire world was measured using essentially modern latitude instruments and the best available clocks. The needs of navigation provided a drive for progressively more accurate astronomical observations and instruments, providing a background for ever more available data for scientists.

At the end of the 19th century, it was discovered that when decomposing the light from the Sun, a multitude of spectral lines were observed (regions where there was less or no light). Experiments with hot gases showed that the same lines could be observed in the spectra of gases, specific lines corresponding to unique chemical elements. In this way it was proved that the chemical elements found in the Sun (chiefly hydrogen) were also found on Earth. Indeed, the element helium was first discovered in the spectrum of the sun and only later on earth, hence its name. During the 20th century, spectroscopy (the study of these spectral lines) advanced, particularly as a result of the advent of quantum physics that was necessary to understand the astronomical and experimental observations.

Observational Astrophysics

Most astrophysical processes cannot be reproduced in laboratories on Earth. However, there is a huge variety of astronomical objects visible all over the electromagnetic spectrum. The study of these objects through passive collection of data is the goal of observational astrophysics.

The equipment and techniques required to study an astrophysical phenomenon can vary widely. Many astrophysical phenomena that are of current interest can only be studied by using very advanced technology and were simply not known until very recently.

The majority of astrophysical observations are made using the electromagnetic spectrum.

- Radio astronomy studies radiation with a wavelength greater than a few millimeters. Radio waves are usually emitted by cold objects, including interstellar gas and dust clouds. The cosmic microwave background

radiation is the redshifted light from the Big Bang. Pulsars were first detected at microwave frequencies. The study of these waves requires very large radio telescopes.

- Infrared astronomy studies radiation with a wavelength that is too long to be visible but shorter than radio waves. Infrared observations are usually made with telescopes similar to the usual optical telescopes. Objects colder than stars (such as planets) are normally studied at infrared frequencies.
- Optical astronomy is the oldest kind of astronomy. Telescopes paired with a charge-coupled device or a spectroscope are the most common instruments used. The Earth's atmosphere interferes somewhat with optical observations, so adaptive optics and space telescopes are used to obtain the highest possible image quality. In this range, stars are highly visible, and many chemical spectra can be observed to study the chemical composition of stars, galaxies and nebulae.
- Ultraviolet, X-ray and gamma ray astronomy study very energetic processes such as binary pulsars, black holes, magnetars, and many others. These kinds of radiation do not penetrate the Earth's atmosphere well, so they are studied with space-based telescopes such as RXTE, the Chandra X-ray Observatory and the Compton Gamma Ray Observatory.

Other than electromagnetic radiation, few things may be observed from the Earth that originate from great distances. A few gravitational wave observatories have been constructed, but gravitational waves are extremely difficult to detect. Neutrino observatories have also been built, primarily to study our Sun. Cosmic rays consisting of very high energy particles can be observed hitting the Earth's atmosphere.

Observations can also vary in their time scale. Most optical observations take minutes to hours, so phenomena that change faster than this cannot readily be observed. However, historical data on some objects is available spanning centuries or millennia. On the other hand, radio observations may look at events on a millisecond timescale (millisecond pulsars) or combine years of data (pulsar deceleration studies). The information obtained from these different timescales is very different.

The study of our own Sun has a special place in observational astrophysics. Due to the tremendous distance of all other stars, the Sun can be observed in a kind of detail unparalleled by any other star. Our understanding of our own sun serves as a guide to our understanding of other stars.

The topic of how stars change, or stellar evolution, is often modelled by placing the varieties of star types in their respective positions on the Hertzsprung-Russell diagram, which can be viewed as representing the state of a stellar object, from birth to destruction. The material composition of the astronomical objects can often be examined using: spectroscopy; radio astronomy; and neutrino astronomy (future prospects).

Theoretical Astrophysics

This discipline seeks to explain the phenomena observed by astronomers in physical terms with a theoretic approach. With this purpose, theoretical astrophysicists create and evaluate models and physical theories to reproduce and predict the observations. In most cases, trying to figure out the implications of physical models is not easy and takes a lot of time and effort.

Theoretical astrophysicists use a wide variety of tools which include analytical models (for example, polytropes to approximate the behaviors of a star) and computational numerical simulations. Each has some advantages. Analytical models of a process are generally better for giving insight into the heart of what is going on. Numerical models can reveal the existence of phenomena and effects that would otherwise not be seen.

Theorists in astrophysics endeavor to create theoretical models and figure out the observational consequences of those models. This helps allow observers to look for data that can refute a model or help in choosing between several alternate or conflicting models.

Theorists also try to generate or modify models to take into account new data. In the case of an inconsistency, the general tendency is to try to make minimal modifications to the model to fit the data. In some cases, a large amount of inconsistent data over time may lead to total abandonment of a model.

Within the astronomical community, theorists are widely caricatured as being mechanically inept and unlucky for observational efforts. Having a theorist at an observatory is considered likely to jinx an observation run and cause machines to break inexplicably or to have the sky cloud over.

Topics studied by theoretical astrophysicists include: stellar dynamics and evolution; galaxy formation; large-scale structure of matter in the Universe; origin of cosmic rays; general relativity and cosmology, including string cosmology. Astrophysical relativity serves as a tool to gauge the properties of large scale structures for which gravitation plays a significant role in physical phenomena investigated and serves as the basis for black hole (*astro*)physics and the study of gravitational waves.

Some widely-accepted theories/models in astrophysics include the Big Bang, Cosmic inflation, dark matter, and fundamental theories of physics. An astrophysical theory which has some supporters but widely seems to be at variance with observations is Plasma cosmology. An example of an astrophysical theory which not widely accepted but is considered viable enough to merit further work is Modified Newtonian Dynamics.

ASYMMETRIC TOP. A model of a molecule which has no three-fold or higher-fold axis of symmetry, so that during rotation all three principal moments of inertia are in general different. Example, the water molecule.

ASYMMETRY. See **Conservation Laws and Symmetry**.

ASYMMETRY (Chemical). Asymmetry involves the presence of four different atoms or substituent groups bonded to an atom. Its existence was discovered in 1815 by the French physicist, J.B. Biot (1774–1867). Biot

found that oil of turpentine and solutions of sugar, camphor, and tartaric acid all rotate the plane of plane-polarized light when placed between two Nicol prisms. This phenomenon is called *optical rotation* and is indicated in symbols, such as: $[\alpha]_D^{20^\circ} = +53.4$ aq., signifying that the substance gives a rotation of 53.4° to the right (clockwise, or plus) in water solution at 20 °C using sodium D line as the light source. Substances in solution that rotate light to the right are designated *d* and are called *dextrorotatory*; substances rotating light to the left are designated *l* and are called *levorotatory*. See also **Isomerism**.

ASYMMETRY FACTOR. The mean cosine of the scattering angle, found by integration over the complete scattering phase function. The asymmetry factor is a fundamental property of a scattering medium that affects the transfer of radiant energy through the medium. Particles that are small compared to the wavelength of the radiation, such as air molecules, have asymmetry factors close to zero. Larger particles, such as cloud droplets, typically have asymmetry factors ~0.85 for visible radiation, consistent with strong forward scattering.

AMS

ASYMPTOTE. The limiting position of a tangent to a curve, where the point of contact is only at an infinite distance from the origin. Where there are no infinite branches, as in the cases of the circle and the ellipse, there is no real asymptote.

Suppose the equation of a given curve can be expanded in a power series

$$y = f(x) = \sum_{k=0}^{n} a_k x^k + \sum_{k=1}^{\infty} b_k / x^k = S_1 + S_2.$$

Then, if $\lim_{x\to\infty} S_2 = 0$, the equation of the asymptote is $y = S_1$. If this equation is linear, the asymptote is a straight line; otherwise, it is a more complicated curve. In the linear case, the equation of the asymptote may be written as

$$y = mx + b;\ m = \lim_{n\to\infty} f'(x)$$

$$b = \lim_{x\to\infty} [f(x) - xf'(x)]$$

ASYMPTOTIC RELATIVE EFFICIENCY (or ARE). The efficiency of an estimator of a statistical parameter (as compared with an optimal estimator) as the sample size on which the estimator is based tends to infinity.

ASYMPTOTIC SERIES. A divergent series of the form

$$A_0 + A_1/x + A_2/x^2 + \cdots + A_n/x^n + \cdots$$

It is an asymptotic representation of a function $f(x)$ if

$$\lim_{x\to\infty} x^n [f(x) - S_n(x)] = 0$$

for any value of n, where S_n is the sum of the first $(n + 1)$ terms of the series.

A familiar example of an asymptotic series is the Euler-Maclaurin formula, which converges for a certain number of terms and then begins to diverge. If one includes a large number of terms in this formula the successive derivatives become increasingly larger in the numerator and they increase much more rapidly than the coefficients, which occur in the denominator. However, if the summation is stopped with the term just before the smallest and not with the smallest term, the error is usually about twice the neglected term. Thus one can obtain satisfactory results in this case and with other such series when they are used with caution. Other examples are the logarithmic integral and the gamma function, both of which can be developed as asymptotic series.

An asymptotic expansion is unique; that is, a given function can be represented by only one such series. It may be integrated, two or more of them can be multiplied together, but in general it should not be differentiated.

ASYNCHRONOUS. This is a term used to designate the property of a device or action whose timing is not a direct function of the clock cycles in the system. In an asynchronous situation, the time of occurrence or duration of an event or operation is unpredictable due to factors such as variable signal propagation delay or a stimulus which is not under control of the computer. See also **Synchronous**.

In terms of a computer channel, an asynchronous channel does not depend upon the computer clock pulses to control the transmission of information to and from the input or output device. Transmission of the information is under the control of interlocked control signals. Thus, when a device has data to send to the channel, the device activates a service request signal. Responding to this signal, the channel activates a "service out" signal. The latter, in turn, activates a "service in" signal in the device and also deactivates the request signal. Information then is transferred to the channel in coincidence with "service in" and the channel acknowledges receipt of the data by deactivating "service out."

Asynchronous operation also occurs in the operation of analog-to-digital subsystems. The system may issue a command to the subsystem to read an analog point and then proceed to the next sequential operation. The analog subsystem carried out the A/D conversion. When the conversion is complete, the subsystem interrupts the system to signal the completion.

Asynchronous also has a broader meaning — specifically unexpected or unpredictable occurrences with respect to a program's instructions.

ASYNCHRONOUS TRANSFER MODE (ATM). See **Transmission Control Protocol (TCP)/Internet Protocol (IP) Suite**.

ATACAMITE. This mineral is a basic chloride of copper corresponding to formula $Cu_2Cl(OH)_3$. Crystallizes in thin, orthorhombic prisms, may occur massive. Hardness, 3–3.5; sp gr, 3.76–3.78; luster, adamantine to vitreous; color, green, streak, green; transparent to translucent.

It is a secondary mineral found associated with malachite and cuprite; originally found at Atacama, Chile, whence its name. Other localities are Bohemia, South Australia, and in the United States in Arizona, Utah, and Wyoming. See also **Cuprite**; and **Malachite**.

ATAVISM. The appearance through heredity of characters not developed in the parents of the organism in question. The strict meaning of the word is the reappearance of grandparental characters, but it has been used also to designate the reappearance of characters from more remote generations.

ATAXIA. Lack of muscular coordination due to disease of the brain and nervous system, particularly the cerebellum or spinal cord. Occurs in cerebral palsy. Degeneration of portions of the spinal cord in later uncontrolled stages of syphilis (*neurosyphilis*) will cause loss of coordination of the limbs (*locomotor ataxia*), much less frequently seen where there is an active public health program directed to the detection, treatment, and prevention of venereal diseases.

Hereditary ataxias may develop in disorders with a known metabolic basis, but the majority of inherited cerebellar and spino-cerebellar degenerations are of unknown causation. Those of early onset are usually of autosomal recessive inheritance, e.g., Frederich's ataxia, while later-onset cases of cerebellar degeneration are most often dominantly inherited.

R. C. V.

ATAXIC. A term applied by Keyes, in 1901, to all unstratified ore deposits in contradistinction to sedimentary, stratified or eutaxic ore deposits.

ATELECTASIS. Collapse of part, or the whole, of a lung. This may be congenital, as in the stillborn infant whose lungs have never been expanded by the act of breathing. More commonly it is acquired, resulting from obstruction to a bronchus by a mucous plug, especially after surgical operations; occasionally by pressure from without as from bony deformity or tumor growth. Atelectasis is a prominent feature of adult respiratory distress syndrome (ARDS).

ATHERMAL TRANSFORMATION. A reaction that occurs without thermal activation. Such a reaction also takes place without diffusion and can occur with great rapidity under the influence of a sufficiently high driving force. The martensite transformation that occurs in steel is primarily athermal, so that the amount of austenite transformed to martensite depends

primarily on the temperature to which the steel is cooled and not upon the rate of cooling or the length of time the metal is held at the quenching temperature. It is necessary to note the difference between an isothermal transformation and an athermal transformation. In the former, the reaction occurs at constant temperature and depends, in general, on both diffusion and thermal activation. The transformation of austenite to pearlite can occur isothermally, with carbon atoms diffusing out of the austenite and into the cementite lamellae. See also **Iron Metals, Alloys, and Steels**.

ATHEROSCLEROSIS. See **Arteries and Veins**; **Ischemic Heart Disease**; and **Cardiovascular Devices**.

ATHODYD. A type of jet engine consisting essentially of a duct or tube of varying diameter and open at both ends, which admits air at one end, compresses it by the forward motion of the engine, adds heat to it by the combustion of fuel, and discharges the resulting gases at the other end to produce thrust. See also **Airplane**.

ATLANTIC SUITE. A term proposed by A. Harker, in 1896, for the chemically and structurally related igneous rocks of the Atlantic Coast line. Chemically the rocks of this suite are described as alkaline and are represented by such types as granite and its magmatic relatives, as compared with the calc-alkali igneous rocks of the Pacific Suite.

ATMOLYSIS. The separation of a mixture of gases by means of their relative diffusibility through a porous partition, as burned clay. The rates of diffusion are inversely proportional to the square roots of the densities of the gases. Hydrogen, thus, is the most diffusible gas.

ATMOMETER. The general name for a scientific instrument that measures the evaporation rate of water into the atmosphere. The atmometer was invented by the Scottish mathematician and engineer Sir John Leslie. Also called *evaporimeter*, *evaporation gauge* or *atmidometer*.

Four main classes of atmometers may be distinguished: 1) large evaporation tanks sunk into the ground or floating in water; 2) small evaporation pans; 3) porous porcelain bodies; and 4) porous paper wick devices. The evaporation from a surface depends greatly upon the nature of the surface and the exposure of the surface to the atmosphere. Measured evaporation rates should be compared only between identical instruments.

See also **Clay Atmometer**; **Evaporation Pan**; **Piché Evaporimeter**; **Precipitation and Hydrometeors**; and **Radio Atmometer**.

ATMOSPHERE (Earth). An envelope (actually a series of envelopes) in the form of imperfect spherical shells of various materials that are bound to the earth by gravitational force. Consisting of gases, vapors, and suspended matter, the total mass of the earth's atmosphere is estimated at approximately 5.1×10^{15} tons, or somewhat less than one-millionth part of the total mass of the earth. One-half of this total mass lies below about 5500 meters (18,000 feet). More than three-fourths of the atmosphere exists below about 10,700 meters (~35,000 feet). The composition of the lower layers of the atmosphere is assumed for purposes of most engineering calculations as 76.8% nitrogen and 23.2% oxygen by weight; 79.1% nitrogen and 20.9% oxygen by volume. A more precise composition of this mixture of gases, including minor constituents, is given in entry on ***Air***.

The earth's atmosphere extends some 600 to 1500 kilometers into space. Two factors are involved in this great extension of the atmosphere. First, above about 100 kilometers, the atmospheric temperature increases rapidly with altitude, causing an outward expansion of the atmosphere far beyond that which would occur were the temperature within the bounds observed at the earth's surface. Second above this distance, the atmosphere is sufficiently rarefied so that the different atmospheric constituents attain diffusive equilibrium distributions in the gravitational field; the lighter constituents then predominate at the higher altitudes and extend farther into space than would an atmosphere of more massive particles. This effect is enhanced by the dissociation of some molecular species into atoms.

The Challenge of Atmospheric Research

The truly scientific study of the earth's atmosphere is a relatively recent phenomenon as compared with most of the fundamental sciences. Although philosopher-scientists like Benjamin Franklin and Thomas Jefferson shed light on weather processes in the 18th Century, and while the invention of the telegraph made possible the first accurate mapping of weather patterns, the theoretical study of the atmosphere did not begin until the late 19th Century, and the rapid development of atmospheric research did not begin until after World War II (late 1940s). Since then, theoretical advances have occurred at a steadily increasing rate, supported by high-speed computers; by vehicles such as instrumented aircraft, high-altitude balloons, rockets, and satellites; and by new sensors, such as radars, lasers, and instruments for measuring the many chemicals present in the atmosphere today.

Atmospheric science presently is recognized as containing some of the most difficult and challenging problems that confront any science. The atmosphere is now viewed as a very complex mixture of chemical and physical processes, linked with the atmosphere of the sun, with the oceans and the earth's plant and animal life, and, of course, with the continually growing effects of human activities (deforestation, pollution, etc.).

A major advancement in atmospheric science in the United States was the establishment, in 1960, of the National Center for Atmospheric Research (Boulder, Colorado), NCAR, http://www.ncar.ucar.edu/ which, in turn, has impacted atmospheric science worldwide. The formation of NCAR dates back to 1956 when the Committee on Meteorology (later renamed the Committee on Atmospheric Sciences) http://dels.nas.edu/basc/ of the National Academy of Sciences recommended an increase of 50 to 100% in support for basic meteorological research and the establishment of NCAR to be operated by a consortium of universities with federal support from the National Science Foundation. As of the late 1980s, scientists and technologists who specialize in atmospheric science from 50 U.S. universities, including the Universities of Alaska and Hawaii; 2 Canadian universities (McGill and the University of Toronto); and 3 other institutions (the Naval Postgraduate School, http://www.nps.edu/, Scripps Institution of Oceanography at the University of California, San Diego, http://sio.ucsd.edu/, and the Woods Hole Oceanographic Institution), http://www.whoi.edu/, constitute the staff of NCAR. The operating entity of NCAR is the University Corporation for Atmospheric Research (UCAR). http://www.ucar.edu/

In commenting on the university consortium and inter-institution concept, Roscoe Braham, who heads the cloud physics research program at the University of Chicago and on the UCAR Board of Trustees stated in 1985, "I think it was clear from the outset that the problems and opportunities in meteorology were so enormous that individual university departments could not cope with their magnitude. In the late 1950s, many of us were dissatisfied with the slow progress that was being made in weather forecasting. Weather modification was viewed as a major opportunity area. The *Thunderstorm Project* (a joint research effort by several U.S. federal agencies based at the University of Chicago) in 1947 had shown how valuable aircraft and radar could be in studying the atmosphere, but the Air Force, which supplied these tools and other equipment for that project, could no longer provide that kind of large-scale support for basic research in the universities. Big computers existed, but nobody had them, practically speaking. There was a general feeling that if we — the universities — had access to resources bigger than ourselves, we could do a much better job of basic research on the atmosphere."

An abridged, but representative list of NCAR targets would include:

1. *Storms* — analyzing and predicting mesoscale weather. An outstanding weather problem is the unanticipated, sometimes destructive, always hazardous occurrence of small-scale weather disturbances. This is exemplified by the demise of Delta Air Lines Flight 191 at Dallas-Fort Worth International Airport on August 2, 1985 when the aircraft encountered a microburst (downdraft). See also article in this encyclopedia on **Fronts and Storms**.
2. *Atmospheric Chemistry* — gaining new insights on the composition of the atmosphere. When one reviews the knowledge of atmospheric chemical composition as it existed two or three decades ago, one is struck by the primitive state of the science at that time. The atmosphere near the earth was viewed as a fluid in motion, transporting moisture and heat. It also transported pollutants arising from cities, factories, and fires. The chemical species in the air were regarded as essentially inert and for good reason — most of the components that were known were inert gases. It is now understood that the atmosphere is a reactive environment. See also **Pollution (Air)**.

3. *Relationship of Sun with Earth*—gaining greater knowledge of the sun, not so much from an astronomical viewpoint, but rather how the earth reacts to changes on the sun. A great deal of research has focused on the solar corona and sunspots. By way of helioseismology, measurements of motions in the interior of the sun have provided a better understanding of the solar activity cycle. As pointed out by Robert Noyes (Harvard University), "This is one of the most important issues in solar physics, especially in terms of solar-terrestrial relationships. Almost every effect of the sun on the earth is magnetically induced through the sunspot cycle, whether it's the influence of solar flares on the upper atmosphere and the aurora or the effect of fluctuations in the ultraviolet flux from the sun on ozone formation in the upper atmosphere." See also **Earth-Sun System Missions; Solar Flares; and Solar Wind.**
4. *Observing and Modeling the Global Atmosphere*—the atmosphere is the prototypical chaotic nonlinear system. This was shown by the simplest atmospheric model, devised by Edward Lorenz in the mid 1960s, the starting point for modern mathematical studies of such systems. Because the atmosphere is chaotic, atmospheric models are sensitive to small variations in initial conditions and possess an inherent growth of error. These properties impose a theoretical limit on the range of deterministic predictions of large-scale flow patterns of about two weeks. As early as 1735, these complications were recognized by George Hadley, an English lawyer and spare-time scientist, who stated, "I think the causes of the General Trade-Winds have not been fully explained by any of those who have wrote on that subject." See also article on **Climate**.
5. *Application of Modern Computer and Instrument Technology*—the first computer was acquired by NCAR in 1964 (CDC 3500) and, over the years, has greatly enhanced its computer capabilities, acquiring a CRAY-1, in 1977 and a second CRAY-1 in 1983. A CRAY X-MP/48 is the latest acquisition and will be used for more realistic climate simulations, thunderstorm and tornado modeling, three-dimensional chemical-dynamical models for studying problems, such as acid precipitation, and models of the solar cycle and the general circulation of the ocean. NCAR also has a generous complement of airborne equipment, radar, and balloons, the oldest yet still valuable tool for reaching up into the atmosphere, measuring it, and bringing samples back or recording them. Huge scientific balloons in current use can carry payloads (in thousands of pounds) to altitudes of 100,000 feet (30 km) and higher. See also article on **Balloon**.

Other subjects in this encyclopedia related to the aforementioned topics are listed at the end of this article.

Atmosphere-Altitude (Pressure-Temperature) Relationships

The composition of the atmosphere does not change much up to 100 kilometers (62.14 miles); there is a region of maximum concentration of ozone (still a very minor constituent) near 20 to 30 kilometers (12 to 19 miles); the relative concentration of water vapor falls markedly from its average sea-level value up to 10 or 15 kilometers (6 or 9 miles), and

TABLE 1. ATMOSPHERIC PRESSURE VERSUS ALTITUDE ABOVE SEA LEVEL

	Altitude Above Sea Level		Pressure

the relative abundance of atomic oxygen begins to become appreciable on approaching 100 kilometers, due to photo dissociation of oxygen by ultraviolet sunlight. Above 200 kilometers (124 miles), atomic oxygen is the principal atmospheric constituent for several hundred kilometers. However, helium is even lighter than atomic oxygen, so its concentration falls less rapidly with altitude, and it finally replaces atomic oxygen as the principal atmospheric constituent above some altitude which varies with the sunspot cycle between 600 and 1,500 kilometers (373 and 932 miles). At still higher altitudes, atomic hydrogen finally displaces helium as the principal constituent. The hydrogen extends many earth radii out into space and constitutes the telluric hydrogen corona, or *geocorona*.

The temperature of the upper atmosphere, and hence its density, varies with the intensity of solar ultraviolet radiation and this, in turn, varies with the sunspot cycle and with solar activity in general. The solar radio-noise flux is a convenient index of solar activity, since it can be monitored at the earth's surface. The minimum nighttime temperature of the upper atmosphere above 300 kilometers (186 miles) has been expressed in terms of the 27-day average of the solar radio-noise flux at 8-centimeter (3-inch) wavelength. This varies from about 600 K (620 °F) near the minimum of the sunspot cycle to about 1,400 K (2,060 °F) near the maximum of the cycle. The maximum daytime temperature is about one-third larger than the nighttime minimum.

Various properties of the earth's atmosphere are described in Tables 1 through 5 and by Figs. 1 and 2. The several layers of the atmosphere are indicated in Table 1, along with the relationship between atmospheric pressure and altitude. Atmospheric density versus altitude are given in Table 2. Geopotential altitude as related with actual altitude and the acceleration due to gravity is given in Table 3. It is interesting to note that the energy required to lift an object 2 million geometric feet is only 1.824 million times that required to lift it 1 foot above sea level — this because of the decrease in the acceleration due to gravity with altitude.

TABLE 2. ATMOSPHERIC DENSITY VERSUS ALTITUDE ABOVE SEA LEVEL

Altitude above Sea Level		Specific Weight	
feet (thousands)	Meters (thousands)	pounds per cubic foot	kilograms per cubic meter
2000	609.60	1.614×10^{-15}	25.856×10^{-13}

Conversion factors used: 1foot = 0.3048 meter
1pound/cubicfoot = 16.03 kilograms/cubic meter.

Reduction of molecular weight, indicating the change in composition of the atmosphere with increasing altitude, is shown in Table 4. The molecular weight of air is assumed essentially constant from sea level up to about 300,000 feet (91,440 meters). At altitudes higher than this, lower molecular weight is largely attributed to the dissociation of oxygen. Above an altitude of about 590,000 feet (179,832 meters), the lower molecular weight is also affected by the diffusive separation and dissociation of nitrogen.

TABLE 3. ACCELERATION DUE TO GRAVITY AND GEOPOTENTIAL ALTITUDE VERSUS ACTUAL ALTITUDE ABOVE SEA LEVEL

Altitude Above Sea Level		Geopotential Altitude		Acceleration Due to Gravity	
Feet (thousands)	meters (thousands)	Feet (thousands)	Meters (thousands)	Feet/second second	meters/second/ second

−40	0.01	0.01	0.02	0.02

The percent water vapor content of air at saturation versus representative temperatures and pressure altitudes is given in Table 5.

The layers of the earth's atmosphere of interest to meteorologists are the *troposphere* and the *stratosphere*. The troposphere is a thermal atmospheric region, extending from the earth's surface to the stratosphere and characterized by decreasing temperature with height, appreciable vertical wind motion, appreciable water vapor content, and containing nearly all clouds, storms, and pollutants. The thickness of the troposphere varies from as little as about 7–8 kilometers (4.4-5 miles) in the cold

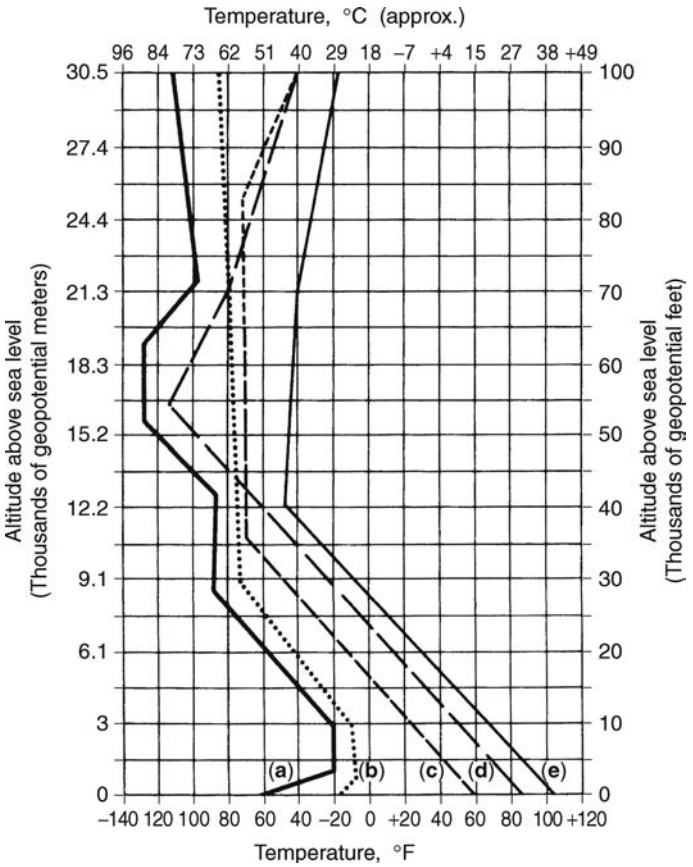

Fig. 1. Relationship between temperature and altitude: (**a**) cold and (**e**) hot are the composities of extremes of cold and hot temperatures; (**b**) arctic and (**d**) tropical are the composities of the arctic and tropical regions: (**e**) is the standard atmosphere upon which altimetry is based.

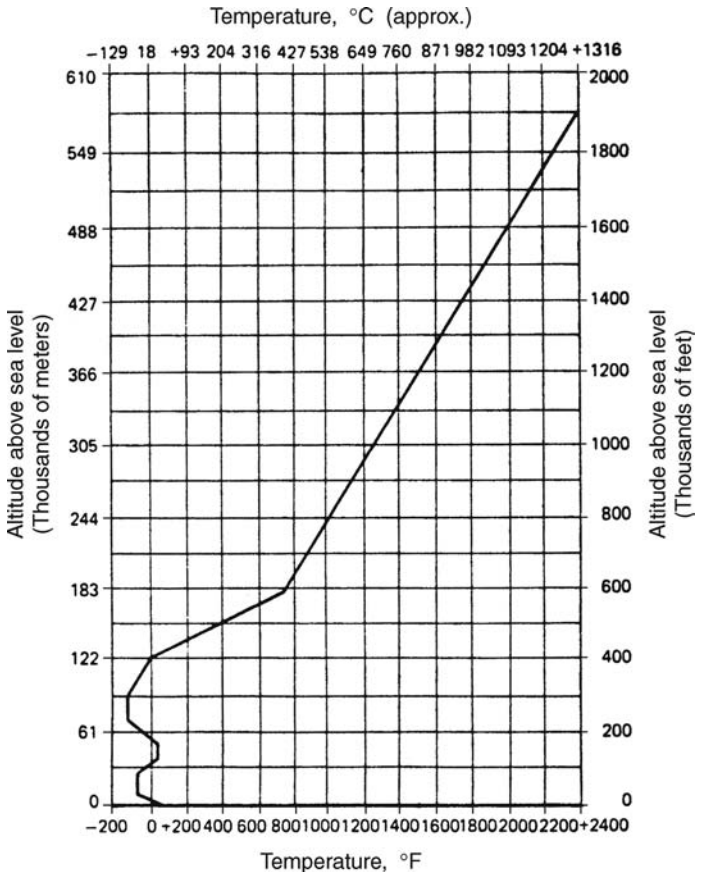

Fig. 2. Real kinetic temperature of the atmosphere, a measure of the kinetic energy of the molecules and atoms constituting the atomsphere is plotted against altitude above sea level here. Numerical values are determined by the assumed molecular weight of the air (see Table 4), as well as assumed values of the temperature lapse rate.

Polar Regions to more than 13 kilometers (8 miles) in the warmer, equatorial regions. Temperatures decrease to the interface between the troposphere and stratosphere. This interface is termed the *tropopause*. At the tropopause, polar temperatures average around −55 °C (−67 °F), in equatorial regions, −80 °C (−112 °F). Above the stratosphere are the *mesosphere* and *ionosphere*, and the outermost layer, the exosphere, gradually fades into the plasma continuum between earth and sun. See also **Tropopause**; **Troposphere**; and **Stratosphere.**

In these higher layers of the atmosphere, complex interactions between the fluxes of electromagnetic radiation of various wavelengths and corpuscular radiation from the sun on one side and the low-density concentrations of atmosphere gases on the other side take place. The particulate radiations are also governed by the earth's magnetic field. Radiations of short wavelength cause a variety of photochemical reactions, the most notable of which is the creation of a layer of ozone acting as an effective absorber of solar ultraviolet and thus causing a warm layer at 30 kilometers (19 miles) in the atmosphere. See **Aerosol**; and **Oxygen**. The upper atmosphere, as an absorber of primary cosmic rays, shows many interesting nuclear reactions and is an important natural source of radioactive substances, including tritium and carbon 14 which are used as tracers of atmospheric motions and as criteria of age. See also **Climate**; and **Cosmic Rays**.

Most manifestations of weather take place in the troposphere. They are governed by the general atmospheric circulation, which is stimulated by the differential heating between tropical and polar zones. The resulting motions in the air are subject to the laws of fluid dynamics on a rotating sphere with friction. They are characterized by turbulence of varying time and space scale. Evaporation of water (see Table 5) from the ocean and its transformation through the vapor state to droplets and ice crystals, forming clouds and precipitation, are important symptoms of the weather-producing forces.

The term *ecosphere* is sometimes used to identify that part of the lower atmosphere where unaided breathing is possible. In meteorology, the term upper atmosphere is sometimes used. That part of the atmosphere above the lower troposphere is called the *upper air*, for which no distinct lower limit is set, but the term is generally applied to the levels above 850 millibars. See also **Ecosphere**; and **Habitable Zone**.

The ionosphere is described in a separate entry, **Ionosphere**.

Heat Balance in the Atmosphere

Total heat received directly from thee sun, at the outer limits of the atmosphere (the amount that would be received at the earth's surface if passage were unaffected by the atmosphere and clouds) is very nearly 1.94 gram-calories per square centimeter per minute. This great quantity of heat is distributed in such a way that the maximum is received directly below the sun, with a decreasing amount received as the distance from the heat equator increases. It is for this reason, of course, that tropical areas are warm; Polar Regions are cold.

Not all the sun's radiation is received at the earth's surface. Clouds and snow reflect about 75% of solar radiation falling upon them; land surfaces reflect an average of 10–30%; water reflects varying percentages, from 70% when the sun is only 5° high, to less than 2% when the sun is over 50° above the horizon. Some solar radiation is absorbed by the atmosphere gases and some by water vapor in the air. Another part is lost to the earth by scattering in the atmosphere. Altogether, solar radiation is distributed as follows: (1) approximately 42% is sent back into space by reflection; (2) 15% is absorbed by the atmosphere and its impurities and cloud particles; and (3) 43% is received and absorbed by the earth's surface. On cloudy days (average cloudiness is about 52%), considerably less solar radiation reaches the earth than on clear days. Loss on a clear day is approximately 17% of the total amount; but on a clouded day, the loss is about 78%. Deserts are conspicuously clear, and therefore receive a much larger percentage of the incoming solar heat than do continental west coasts, which have considerable cloud cover. Snow-covered regions lose a larger percentage of their incoming solar heat than do forest- and vegetation-covered lands. Water surfaces,

averaged the world over, do not reflect a large percentage of solar heat, but water is capable of absorbing large quantities of heat with only a small temperature change. The influence of local terrain on solar radiation plays a considerable role in determining the daily and seasonal temperatures of that area.

The earth receives its heat from a number of sources: (1) about 17% is direct solar radiation; (2) 10% is sky radiation (from scattered solar radiation); (3) 70% is long-wave radiation received from the atmosphere surrounding the earth; and (4) 3% is received by contact with warm surface air currents. It should be realized, however, that all this energy, regardless of its immediate source, originates from the sun.

The fact that there is no accumulation of heat on the earth indicates a radiative heat balance. Radiation received by the earth is dispersed as follows: (1) 7% goes to space by radiation through transparent bands in the atmosphere (transparent to radiation from a black body at 300°K (80°F); (2) 78% goes to the atmosphere by radiation, where it is absorbed and redistributed; and (3) 15% is used in evaporation processes and is carried to the atmosphere, where it adds to the store of atmospheric heat. Water vapor is the principal absorber of earth radiation as it passes through the atmosphere. Carbon dioxide and ozone also have some strong absorption bands.

Those regions between approximately 35°N and 35°S receive more energy than they radiate back to space, whereas the other regions of the earth receive less energy than they radiate. The excess of energy from the subtropical and tropical zones is transferred toward the poles by both the ocean currents and the atmospheric winds. The advection of heat energy balances the differential in direct radiation. Thus, the average temperature at any point on the earth remains sensibly the same from year to year.

Elasser's radiation chart is one of the better known charts for the graphical solution of the radiative transfer problems important in meteorology. Given a radiosonde record of the vertical variation of temperature and water vapor content, such quantities can be found with this chart as the effective terrestrial radiation, net flux of infrared radiation at a cloud base or a cloud top, and radiative cooling rates. A chart of this type used widely in Europe is the Möller chart.

Atmospheric radiation is infrared radiation emitted by or being propagated through the atmosphere. Atmospheric radiation, lying almost entirely within the wavelength interval of from 3 to 80 micrometers, provides one of the most important mechanisms by which the heat balance of the earth-atmosphere system is maintained. Infrared radiation emitted by the earth's surface is partially absorbed by the water vapor of the atmosphere, which, in turn, re-emits it, partly upward, partly downward. This secondarily emitted radiation is then, in general, repeatedly absorbed and re-emitted, as the radiant energy progresses through the atmosphere. The downward flux, or counter-radiation, is of basic importance in the so-called *greenhouse effect*; the upward flux is essential to the radiative balance of the planet. See also **Climate**; and **Global Warming**.

Terrestrial radiation is defined as the total infrared radiation emitted from the earth's surface — to be carefully distinguished from atmospheric radiation, insolation, and effective terrestrial radiation, the latter being the difference between the outgoing infrared terrestrial radiation of the earth's surface and the descending infrared counter-radiation from the atmosphere.

In meteorology, the cooling of the earth's surface and adjacent air, accomplished mainly at night, but whenever the earth's surface suffers a net loss of heat due to terrestrial radiation is known as *radiational cooling*. See also **Solar Energy**.

Thermodynamics of the Atmosphere

In meteorological calculations, the ideal gas law is a satisfactory approximation for the derivation of formulas for the mixture of gases that constitute the atmosphere. The derivation is:

$$PV = RT$$

where

V = Volume
P = Pressure
R = universal gas constant
T = absolute temperature

For one gram, this becomes

$$PV = \frac{RT}{m}$$

where m is the molecular weight of the gas. For G grams, this becomes,

$$PV = \frac{GRT}{m}$$

This equation is valid for each of the constituent gases of the atmosphere. For nitrogen,

$$P_n V = \frac{G_n RT}{M_n}$$

For oxygen,

$$P_0 V = \frac{G_0 RT}{m_0}$$

For argon,

$$P_a V = \frac{G_a RT}{m_a}$$

For water vapor,

$$P_w V = \frac{G_w RT}{m_w}$$

When there is no water vapor present in the atmosphere, these equations can be combined as follows:

$$P_t V = (P_n + P_0 + P_a)V = RT\left[\frac{G_n}{m_n} + \frac{G_0}{m_0} + \frac{G_a}{m_a}\right]$$
$$= RT\left(\frac{G_T}{m_t}\right)$$

In these equations, P_t is the total pressure of the nitrogen, oxygen, and argon. Also, G_t is the total mass of the gases; and m_t is the molecular weight of the mixture, with a numerical value of 28.97.

Because water vapor is always present in varying quantities in the atmosphere, corrections in the equation of state must be made in accordance with the amount of water vapor present. Procedure is as follows:

$$PV = (P_t + P_w)v = RT\left[\frac{GT}{m_t} + \frac{G_w}{m_w}\right]$$
$$= RT\left[\frac{G}{m_t} + \frac{G_w}{m_t} + \frac{G_w}{m_w}\right]$$

In these equations, P is the total pressure of the air gases plus the water vapor, and G is the total mass of the air gases plus the water vapor.

This equation can be rearranged and simplified:

$$PV = RT\frac{G}{m_t}\left[1 - \frac{G_w}{G}\left(1 - \frac{m_t}{m_w}\right)\right]$$

where m_t has a value of 28.97 and m_w has a value of 18.00. This equation is easily reduced to

$$PV = RT\frac{G}{m_t}\left[1 + 0.6\frac{G_w}{G}\right]$$

Virtual temperature of the air is defined as

$$T' = T\left[1 + 0.6\frac{G_w}{G}\right]$$

Virtual temperature is, in effect, the temperature of a mass of dry air having the same density of another mass of air containing water vapor. Virtual temperature is always greater than real temperature, except when G_w is nil.

The equation of state for real air becomes

$$PV = \frac{RT'G}{m_t}$$

If R, the universal gas constant, is made into a specific gas constant for air by letting $R/m_t = R_a$, then for one gram of air, the equation of state becomes $PV = R_a T'$.

The hydrostatic state of equilibrium of the atmosphere varies with the type of atmosphere that is under consideration.

Standard atmosphere is a term used in the following references:

1. A hypothetical vertical distribution of atmosphere temperature, pressure, and density, which, by international agreement, is taken to be representative of atmosphere for purposes of pressure altimeter calibrations, aircraft performance calculations, aircraft and missile design, ballistic tables, etc. The air is assumed to obey the ideal gas law and the hydrostatic equation, which, taken together, relate temperature, pressure, and density variations in the vertical. It is further assumed that the air contains no water vapor, and that the acceleration of gravity does not change with height. The current standard atmosphere was adopted in 1952 by the International Civil Aeronautical Organization (ICAO) http://www.icao.int/index.html, and supplants the U.S. Standard Atmosphere prepared in 1925. The parametric assumptions and physical constants used in preparing the ICAO Standard Atmosphere are as follows:
   a. Zero pressure altitude corresponds to that pressure which will support a column of mercury 760 mm high. This pressure is taken to be 1.013250×106 dynes/cm^2, or 1013.250 mb, or 101.325 kPa (and is known as one standard atmosphere or one atmosphere).
   b. The gas constant for dry air is 2.8704×10^6 erg/gm K.
   c. The ice point at one standard atmosphere pressure is 273.16 K.
   d. The acceleration of gravity is 980.665 cm/sec^2.
   e. The temperature at zero pressure altitude is 15 °C or 288.16 K.
   f. The density at zero pressure altitude is 0.0012250 gm/cm^3.
   g. The lapse rate of temperature in the troposphere is 6.5 °C/km.
   h. The pressure altitude of the tropopause is 11 km.
   i. The temperature at the tropopause is −56.5 °C.
2. A standard unit of atmospheric pressure; the 45° atmosphere, defined as the pressure exerted by a 760 mm column of mercury at 45° latitude at sea level at temperature 0 °C (acceleration of gravity = 980.616 cm/sec^2). One 45° atmosphere equals 760 mm Hg(45°); 29.9213 in. Hg(45°); 1013.200 mb; 101.325 kPa.

Ballistics standard artillery atmosphere is composed of a set of values describing atmospheric conditions on which ballistic computations are based, namely, zero wind, surface pressure of 1000 millibars at the ground, surface temperature of 15 °C (59 °F), a surface relative humidity of 78%, and a lapse rate that yields a prescribed density-altitude relationship.

Adiabatic atmosphere is characterized by a dry-adiabatic lapse rate throughout its vertical extent.

Such a condition is never observed and is also rather poorly designated, since "adiabatic" represents a process, not a condition. The pressure in an adiabatic atmosphere decreases with height according to

$$p = p_0 \left(1 - \frac{gz}{c_{pd} T_0}\right) c_{pd}/R_d,$$

where p_0 and T_0 are the pressure and temperature (K), respectively, at sea level, z the geometric height, R_d the gas constant for dry air, c_{pd} the specific heat of dry air at constant pressure, and g the acceleration of gravity. *See* homogeneous atmosphere.

Model atmosphere is a term used for any theoretical representation of the atmosphere, with particular reference to vertical temperature and pressure distribution.

Isothermal atmosphere (or exponential atmosphere) is an atmosphere in hydrostatic equilibrium, in which the temperature is constant with height, and in which, therefore, the pressure decreases exponentially upward. In such an atmosphere, the thickness between any two levels is given by

$$Z_B - Z_A = \frac{R_d T_v}{g} \ln \frac{P_A}{P_B}$$

where R_d is the gas constant for dry air, T_v the virtual temperature (°K), g the acceleration of gravity, and P_A and P_B the pressures at the heights Z_A and Z_B, respectively. In the isothermal atmosphere, there is no finite level at which the pressure vanishes.

Polytropic atmosphere is characterized by hydrostatic equilibrium with a constant nonzero lapse rate. The vertical distribution of pressure and temperature is given by

$$\frac{P}{P_0} = \left(\frac{T}{T_0}\right)^{9/Ry}$$

where p is the pressure, T the Kelvin temperature, g the acceleration of gravity, R the gas constant for air, and y the environmental lapse rate, the subscript zeros denoting values at the earth's surface.

Homogeneous atmosphere is a hypothetical atmosphere in which the density is constant with height. The lapse rate of temperature in such an atmosphere is known as the autoconvective lapse rate and is equal to g/R (or approximately 3.4 °C/100 meters), where g is the acceleration of gravity and R is the gas constant for air. A homogeneous atmosphere has a finite total thickness given by $R_d T_v/g$, where R_d is the gas constant for dry air and T_v is the virtual temperature (°K) at the surface. For a surface temperature of 273 °K, the vertical extent of the homogeneous atmosphere is approximately 8000 meters. At the top of such an atmosphere, both the pressure and absolute temperature vanish.

With respect to radio propagation, a homogeneous atmosphere is one that has a constant index of refraction, or one in which radio waves travel in straight lines at constant speed. The ideal "homogeneous atmosphere" in this sense is *free space*, which is a perfectly homogeneous medium possessing a dielectric constant of unity, and in which, as in a perfect vacuum, there is nothing to reflect, refract, or absorb energy.

Thermotropic atmosphere, a term used in numerical weather forecasting, is an atmosphere in which the parameters to be forecast are the height of one constant-pressure surface (usually 500 millibars) and one temperature (usually the mean temperature between 1000 and 500 millibars) whereby a surface prognostic chart can also be constructed.

Equivalent barotropic atmosphere is one in which the wind does not change direction with altitude and, therefore, the isotherms and isobars are everywhere parallel.

Barotropic atmosphere is one of a number in which some of the following conditions exist: (1) pressure and temperature surfaces coincide; (2) zero vertical wind shear; (3) zero vertical motion; and (4) zero horizontal velocity divergence.

Baroclinic atmosphere is one in which constant-pressure surfaces intersect constant-density surfaces, thereby creating solenoids, which can cause acceleration.

Adiabatic Processes in the Atmosphere

An adiabatic process is a thermodynamic change of state of a system, in which there is no transfer of heat or mass across the boundaries of the system; where compression always results in warming, and expansion in cooling. When a parcel of air is moved from one position to another in such a manner that energy does not flow across the boundaries of the parcel, the thermal changes taking place within the parcel are said to be adiabatic changes.

Dry-adiabatic processes, during which the air involved remains unsaturated, are relatively simple. The first law of thermodynamics applied to a parcel of unsaturated air of unit mass stipulates:

$$da \times c_v dT + Apdv$$

which, when combined with the gas equation becomes

$$dq = (c_v + AR)dT - \frac{ART}{p}dp$$

For the adiabatic process, this becomes

$$\frac{dT}{T} = \frac{AT}{c_p}\frac{dp}{p}$$

which, upon integration, becomes

$$\frac{T}{T_0} = \left(\frac{p}{p_0}\right)^{AR/c_p}$$

Dry-adiabatic horizontal transfer of a parcel from higher to lower or lower to higher pressure is of only minor consequence because of the comparatively small magnitude of pressure change. Dry-adiabatic vertical transfer of a parcel, however, is one of the important meteorological processes. Temperature decrease in a rising, and increase in a sinking, parcel amounts to very nearly 9.8 °C per km, or 5.4 °F per 1000 feet (304.8 meters). Dew-point changes in a vertically moving unsaturated parcel are considerably less. The dew-point decreases in rising air, and increases in sinking air, at a rate of between 1.3 and 1.8 °C per kilometer (0.7 and 1.0 °F per 1,000 feet), depending upon air temperature.

Pseudo-adiabatic (or *saturation* — or *moist-adiabatic*) processes involve condensation or evaporation, and are by no means constant or simple. In a parcel rising pseudo-adiabatically, the temperature decrease is always less than the dry-adiabatic temperature change by an amount depending upon the weight of the water being condensed and the temperature at which condensation occurs. Condensation releases the latent heat of vaporization within the parcel, which partially counteracts dry-adiabatic cooling. The rate of cooling in rising saturated air varies from about 2.7 °C per kilometer (1.5. °F per 1,000 feet) in warm air at sea level to 9.7 °C per kilometer (5.3 °F per 1000 feet) at high altitudes in cold air, a range that is the direct result of the variance in the amount of water resident in a given mass of air at full saturation. Very cold air can retain only a slight amount of water, whereas very warm air can hold relatively large quantities. Values of resident water vapor at saturation range from 0.01% by weight in arctic air to 3% by weight in tropical air.

Sinking saturated air remains saturated only for a comparatively short distance, during which it is heated pseudo-adiabatically at a rate determined by the amount of evaporation occurring within the parcel. As soon as it becomes unsaturated, the sinking parcel descends dry-adiabatically. Foehn winds are examples of both pseudo-adiabatic and dry-adiabatic changes. Air flowing uphill is cooled pseudo-adiabatically until it reaches the hilltop. On the lee side, the air descends dry-adiabatically. Observable results of the true foehn wind are abundant clouds and rain or snow on the windward side of a mountain range, and clear, warm air on the lee side.

Dew-points in saturated air rising pseudo-adiabatically decrease at the same rate as the temperature. Dew-points in saturated sinking air increase at the same rate as the temperature until the air parcel is no longer saturated; then they rise slowly, as previously described in connection with sinking saturated air.

A large percentage of all clouds and nearly all precipitation result from adiabatic ascent of air.

Assuming increasing positive values with altitude, the following relations hold:

1. Dry-adiabatic temperature change with altitude:

$$\frac{\partial t}{\partial h} = \frac{gK}{R} = -9.8\,^{\circ}\text{C/km}$$

where

t = temperature of parcel
g = gravitational constant
$K = K = \dfrac{c_p - c_v}{c_p} = .288$
R = gas constant

2. Dry-adiabatic dew-point change with altitude:

$$\frac{\partial t_d}{\partial h} = -1.71\left[1 + \frac{2t_d}{237.3} - \frac{t}{273}\right]\,^{\circ}\text{C/km}$$

where

t_d = dew-point temperature in °C
t = air temperature in °C

3. Pseudo-adiabatic temperature change with altitude:

$$\frac{\partial t}{\partial h} = -g\left(\frac{A + .621epLRt}{c_p + 0.21\dfrac{L}{P}\dfrac{de}{dt}}\right)\text{C/km}$$

where

t = temperature of the parcel in °C
g = gravitational constant
A = heat equivalent of work
e = water vapor pressure
p = air pressure
L = heat of condensation
c_p = specific heat at constant pressure for air

Virtual Temperature of Air. In meteorological calculations, it is often convenient to use, instead of the actual air temperature, the temperature that a parcel of air would have if it had the same density and pressure as the sample in question, but was entirely free from water vapor. Since dry air is denser than water vapor under the same conditions, removal of water vapor from moist air will increase its density, so that the temperature will need to be raised to obtain an equivalent density. Therefore, the virtual temperature is higher than the actual, and is given by:

$$T_v = (1 + 0.61q)T$$

where T is the absolute temperature and q the specific humidity.

Atmospheric Stability, Instability, and Equilibrium

Everywhere that air is in motion, some vertical perturbations are present. Isolated parcels and currents of air are started upwards or downwards into new environments. If the density of the environment is different from the density of the parcel after any modification caused by the change of pressure, the parcel experiences a force of buoyancy, which may accelerate or retard the initial displacement. The criterion for static stability of a horizontally stratified compressible fluid is that the gradient of potential density should be negative upwards.

Stability. In meteorology, *static stability* (also called *hydrostatic stability, vertical stability*, or *convectional stability*) is the stability of an atmosphere in hydrostatic equilibrium with respect to vertical displacements, usually considered by the parcel method. The criterion for stability is that the displaced parcel be subjected to a buoyant force opposite to its displacement, e.g., that a parcel displaced upward be colder than its new environment. This is the case if $\gamma < \Gamma$, where γ is the environmental lapse rate and Γ is the process lapse rate, dry-adiabatic for unsaturated air and saturation-adiabatic for saturated air.

Neutral stability. (also called *indifferent stability* or *indifferent equilibrium*) is the state of an unsaturated or saturated column of air in the atmosphere when its environmental lapse rate is equal to the dry-adiabatic lapse rate or the saturation-adiabatic lapse rate, respectively. Under such conditions, a parcel of air displaced vertically will experience no buoyant acceleration.

Hydrostatic Equilibrium. The state of a fluid whose surfaces of constant pressure and constant mass (or density) coincide and are horizontal throughout. Complete balance exists between the force of gravity and the pressure force. The relation between the pressure and the geometric height is given by the hydrostatic equation. The analysis of atmospheric stability has been developed most completely for an atmosphere in hydrostatic equilibrium. The hydrostatic equation is the form assumed by the vertical component of the vector equation of fluid motion when Coriolis, earth curvature, frictional, and vertical acceleration terms are considered negligible compared with those involving the vertical pressure force and the force of gravity. Thus,

$$\frac{\partial p}{\partial z} = -\rho g$$

where p is the pressure, r the density, g the acceleration of gravity, and z the geometric height.

Instability. The concept of instability is employed in many sciences. It is, in general, a property of the steady state of a system such that certain disturbances or perturbations introduced into the steady state will increase in magnitude, the maximum perturbation amplitude always remaining larger than the initial amplitude. The method of small perturbations, assuming permanent waves, is the usual method of testing for instability; unstable perturbations then usually increase exponentially with time. In meteorology, the small perturbations, may

be a wave or a parcel displacement. The parcel method assumes that the environment is unaffected by the displacement of the parcel. The slice method has occasionally been used as a modification of the parcel method to gain a little information about the interaction of parcel and environment.

Absolute instability is the state of a column of air in the atmosphere when it has a super-adiabatic lapse rate, i.e., greater than the dry-adiabatic lapse rate. An air parcel displaced vertically would be accelerated in the direction of the displacement. The kinetic energy of the parcel would consequently increase with the increasing distance from its level of origin.

Baroclinic instability arises from the existence of a meridional temperature gradient (and hence of a thermal wind) in an atmosphere in quasigeostrophic equilibrium and possessing static stability.

Barotropic instability arises from certain distributions of vorticity in a two-dimensional non-divergent flow. This is an inertial instability in that kinetic energy is the only form of energy transferred between current and perturbation. The variation of vortex, i.e., shear, in the basic current may be concentrated in discontinuities of the horizontal wind shear (to be distinguished from *Helmholtz instability*, where the velocity itself is discontinuous) or may be continuously distributed in a curved velocity profile. A well-known necessary condition for barotropic instability is that the vortex must change sign, i.e., vanish, at a point of maximum shear.

Colloidal instability is a property attributed to clouds (regarded in analogy to colloidal systems or aerosols) by virtue of which the particles of the cloud tend to aggregate into masses large enough to precipitate.

Conditional instability is the state of a column of air in the atmosphere when its lapse rate is less than the dry-adiabatic lapse rate but greater than the saturation-adiabatic lapse rate. With reference to the vertical displacement of an air parcel, the air will be unstable if saturated and stable if unsaturated.

Convectional instability (or *potential instability*) is the state of an unsaturated layer or column of air in the atmosphere whose wet-bulb potential temperature, or equivalent potential temperature decreases with elevation.

Gravitational instability occurs in a system in which buoyancy or reduced gravity is the only restoring force on displacements.

Helmholtz instability (also called *shearing instability*) arises from a shear, or discontinuity, in current speed at the interface between two fluids in two-dimensional motion. The perturbation gains kinetic energy at the expense of that of the basic currents.

Hydrodynamic instability (or *dynamic instability*) refers to instability of parcel displacements or, more usually, of waves in a moving fluid system governed by the fundamental equations of hydrodynamics. The space scale of unstable waves is important in meteorology; thus Helmholtz, baroclinic, and barotropic instability give, in general, unstable waves of increasing length. The time scale is also important; a perturbation that grows for two days before dying out is effectively unstable for many meteorological purposes, but this is an initial value problem, and one cannot assume the existence of permanent waves. These meteorological types of hydrodynamic instability must not be confused with the phenomenon often referred to by mathematicians and physicists by the same term. A great deal of study has been devoted to the problem of the onset of turbulence in simple flows under laboratory conditions, and here viscosity is a source of instability. This is not the case in any meteorological motion yet investigated.

Inertial instability (or *dynamic instability*) is, generally, instability in which the only form of energy transferred between the steady state and the disturbance is kinetic energy. More specifically, it is the instability arising in a rotating fluid mass when the velocity distribution is such that the kinetic energy of a disturbance grows at the expense of kinetic energy of the rotation.

Rotational instability is usually synonymous with inertial instability, being, in general, any instability of a rotating fluid system.

Static instability (or *hydrostatic instability*) refers to instability of vertical displacements of a parcel in a fluid in hydrostatic equilibrium.

Thermal instability results in free convection in a fluid heated at a boundary. For the case of heating from below, the onset of convection (as opposed to conduction) is determined by a critical value of the Rayleigh number, and the linear theory admits of various convection-cell forms, including the hexagonal Benard cell. The theories of thermal instability, which are represented by sixth-order convection equations and take into account both viscosity and conductivity, must be distinguished from the theory of static instability, based on the oscillations of a parcel in an atmosphere in hydrostatic equilibrium.

Lapse Rate. This is the rate at which temperature decreases or lapses with altitude; the vertical temperature gradient. Since temperature normally decreases with altitude in the troposphere, it is convenient to assign positive values to the rate of temperature change with altitude: Lapse rate, therefore, is defined as the rate of change of temperature with altitude, and is positive when the temperature decreases. The term applies ambiguously to the environmental lapse rate and the process lapse rate (defined below), and the meaning must often be ascertained from the text.

Autoconvective lapse rate (or autoconvection gradient). The environmental lapse rate of temperature in an atmosphere in which the density is constant with height (homogeneous atmosphere), equal to g/R, where g is the acceleration of gravity and R the gas constant. For dry air, the autoconvective lapse rate is approximately $+3.4 \times 10^{-4}$°C per centimeter.

Undisturbed air will remain stratified even though the lapse rate exceeds the adiabatic rate of 9.8 °C per kilometer (5.5 °F per 1,000 feet). If, however, the lapse rate becomes sufficiently large, density of the air will increase with altitude and will overturn. This critical lapse rate is 34.17 °C per kilometer (or nearly 19 °F per 1000 feet). Dust devils and whirlwinds result from this steep lapse rate, which occurs at ground levels, particularly over concrete roads and the sand and rock of deserts during the heat of day.

Dry-Adiabatic Lapse Rate. A special process lapse rate (defined below) of temperature, being the rate of decrease of temperature with height of a parcel of dry air lifted adiabatically through an atmosphere in hydrostatic equilibrium. This lapse rate is g/C_{pd}, where g is the acceleration of gravity and C_{pd} is the specific heat of dry air at constant pressure; numerically equal to 9.767 °C per kilometer (about 5.4 °F per 1,000 feet). Potential temperature is constant with height in an atmosphere with this lapse rate.

Environmental Lapse Rate. The rate of decrease of temperature with elevation, $-\partial T/\partial z$, or occasionally, $\partial T/\partial p$, where p is pressure. The concept may be applied to other atmospheric variables (e.g., lapse rate of density) if these are specified. The environmental lapse rate is determined by the distribution of temperature in the vertical at a given time and place, and should be carefully distinguished from the process lapse rate (defined below), which applies to an individual air parcel.

Process Lapse Rate. The rate of decrease of the temperature of an air parcel as it is lifted, $-dT/dz$, or occasionally dT/dp, where p is pressure. The concept may be applied to other atmospheric variables, e.g., the process lapse rate of density. The process lapse rate is determined by the character of the fluid processes and should be carefully distinguished from the environmental lapse rate, which is determined by the distribution of temperature in space. In the atmosphere, the process lapse rate is usually assumed to be either the dry-adiabatic lapse rate or the saturation-adiabatic lapse rate (defined below).

Saturation-Adiabatic Lapse Rate(or Moist-Adiabatic Lapse Rate). A special case of process lapse rate, defined as the rate of decrease of temperature with height of an air parcel lifted in a saturation-adiabatic process through an atmosphere in hydrostatic equilibrium. Owing to the release of latent heat, this lapse rate is less than the dry-adiabatic lapse rate, and the differential equation representing the process must be integrated numerically. Wet-bulb potential temperature is constant with height in an atmosphere with this lapse rate.

Superadiabatic Lapse Rate. An environmental lapse rate greater than the dry-adiabatic lapse rate, such that potential temperature decreases with height.

Atmospheric Inversion. This is the abnormal condition in which the temperature of the atmosphere increases with height. The term is also used for a level at which the vertical gradient of temperature changes sign. Dynamically, more importance attaches to the vertical distribution of potential temperature or potential density, and it is common to refer to the boundary between a lower region of negative gradient of potential density and an upper one of positive gradient as an inversion, whether or not the temperature gradient changes sign. An example is the tropopause.

In meteorology, *temperature inversion* refers to an atmospheric condition in which temperature increases with altitude. The temperature below the stratosphere normally decreases with altitude; thus, when it increases, normal conditions are inverted, and an inversion has occurred. Inversions in the troposphere are usually restricted to shallow layers of air, which most frequently occur in the lower 5,000 feet (1,524 meters) above the surface. In low latitudes, the stratosphere has a slight inversion more or less permanently.

The principal characteristic of an inversion layer is its marked static stability, so that very little turbulent exchange can occur within it. Strong wind shears often occur across inversion layers, and abrupt changes in concentrations of atmospheric particulates and atmospheric water vapor may be encountered on ascending through the inversion. When, in meteorological literature and discussion, an "inversion" is mentioned, a temperature inversion is usually meant. The following are particular types of temperature inversion:

Frontal inversion is encountered upon vertical ascent through a sloping front (or frontal zone).

Subsidence inversion is produced by the adiabatic warming of a layer of subsiding air and is enhanced by vertical mixing in the air layer below the inversion.

Surface inversion (or *ground inversion*) is a temperature inversion based at the earth's surface; that is, an increase of temperature with height beginning at the ground level. This condition is due primarily to greater radiative loss of heat at and near the surface than at levels above. Thus, surface inversions are common over land prior to sunrise and, in winter, over high-latitude continental interiors.

Trade-wind inversion (or *trade inversion*) is usually present in the trade-wind streams over the eastern portions of the tropical oceans. It is found in large-scale subsiding flows constituting the descent branches of the Hadley cell and Walker circulation. The subsidence warming in the inversion layer is balanced by radiative cooling and evaporation from the tops of trade cumuli. The height of the base of this inversion varies from about 500 m (1,640 ft) at the eastern extremities of the subtropical highs to about 2,000 m (6,562 ft) at the western and equatorial extremities. In the equatorial trough zone and over the western portions of the trade-wind belt, the inversion does not exist as a mean condition, although it appears in certain weather patterns. The strength of the inversion varies enormously, occasionally being more than 10 °C (50 °F) over 1 km (0.6 mi), but sometimes being absent altogether, especially in the Northern Hemisphere. The inversion is generally strongest when the height of its base is lowest, and vice versa. The thickness of the inversion layer varies from only a few meters (few feet) to more than 1,000 m (3,281 ft). On the average its thickness is about 400 m (1,312 ft). The airflow below the inversion is very moist and filled with cumulus clouds (trade cumuli). Above it, the air is warm and exceedingly dry; this structure is so characteristic of the trade current that tropical analysts think of the tropical troposphere as consisting of a lower moist and an upper dry layer.

Circulation in the Atmosphere

The worldwide pattern of air movement is related to the global pressure belts, the rotation of the earth, the distribution of temperature over the earth, friction between the earth and the atmosphere, and the location of mountains and oceans. The major large-scale patterns of movement of the atmosphere include:

1. *General circulation*, which, in the broadest sense, is a complete description of atmospheric motions over the earth. These statistics are generated from the ensemble of daily data and include not only the temporal and spatial mean flows (e.g. zonal westerlies and easterlies) but also all other mean properties of the atmosphere that are linked to these flows (e.g., semipermanent waves and meridional cells) that together form the general circulation. The general circulation also includes higher-order statistics that measure the spatial and temporal variability of the atmosphere necessary to understand the large-scale temporal and spatial mean state of the atmosphere (e.g., seasonal changes and the effects of transient cyclones).
2. *Planetary Circulation*. Refers specifically to (a) the system of large-scale disturbances in the troposphere when viewed on a hemispheric or world-wide scale, and (b) to the mean or time-averaged hemispheric circulation of the atmosphere; in this sense, almost synonymous with general circulation.
3. *Primary Circulation*. The prevailing fundamental atmospheric circulation on a planetary scale that must exist in response to (a) radiation differences with latitude, (b) the rotation of the earth, (c) the particular distribution of land and ocean; and which is required from the viewpoint of conservation of energy. Primary circulation and general circulation are sometimes taken synonymously. They may be distinguished, however, on the basis of approach. That is, primary circulation is the basic system of winds, of which the secondary and tertiary circulations are perturbations; while general circulation encompasses at least the secondary circulations. The latter dimension of circulation has features of cyclonic scale, while tertiary circulation is represented by such phenomena as local winds, thunderstorms, and tornadoes.
4. *Meridional Cell*. A very large-scale convection circulation in the atmosphere or ocean that takes place in a meridional plane, with northward and southward currents in opposite branches of the cell, and upward and downward motion in the equator-ward and pole-ward ends of the cell. There are three annual mean meridional cells in each hemisphere, the strongest of which is the Hadley cell. A much weaker indirect cell is the Ferrel cell located between 30° and 60° latitude. There is a very weak direct cell in the polar latitudes. These are integral parts of the general circulation.
5. *Zonal Flow* (or *Zonal Circulation*). The flow of air along a latitude circle; more specifically, the latitudinal (east or west) component of existing flow.
6. *Polar Vortex* (or *polar cyclone, polar low, circumpolar whirl*). The planetary large-scale cyclonic circulation, centered generally in the Polar Regions, extending from the middle troposphere to the stratosphere. The westerly airflow is largely a manifestation of the thermal wind above the polar frontal zone of middle and subpolar latitudes. The vortex is strongest in winter when the pole-to-equator temperature gradient is strongest. In the Northern Hemisphere, the vortex has two centers in the mean, one near Baffin Island and the other over northeast Siberia.
7. *Westerlies* (also called *circumpolar westerlies, circumpolar whirl, countertrades, middle-latitude westerlies, polar westerlies, subpolar westerlies, subtropical westerlies, temperate westerlies, zonal westerlies, westerly belt, zonal winds*.) Specifically, the dominant west-to-east motion of the atmosphere, centered over the middle latitudes of both hemispheres. Generally, any winds with components from the west.
8. *Easterlies*. Any winds with components from the east, usually applied to broad currents or patterns of persistent easterly winds, the "easterly belts," such as the equatorial easterlies, the tropical easterlies, and the polar easterlies.

Forces in the Atmosphere

There are two forces that account mainly for driving the horizontal flow of air on a global scale:

1. **Coriolis Force** This is related to the rotation of the earth and is expressed vectorially by

$$C = -2\Omega \times \mathbf{v}$$

and quantitatively by

$$C = -2\Omega v \sin\phi$$

where

C = Coriolis force
Ω = angular velocity of the earth
$\mathbf{v}$ = velocity vector
v = speed of wind
ϕ = the latitude

Coriolis force acts at right angles to the direction of the wind. In the Northern Hemisphere, it acts toward the right; in the Southern Hemisphere, toward the left.

2. **Pressure Gradient Force** This is related to the field of atmospheric pressure at a specified level at or above sea level. It is expressed vectorially by

$$P_f = -\alpha \Delta_p$$

and quantitatively by

$$P_f = -\alpha \frac{\partial p}{\partial t}$$

where

P_f = force resulting from the pressure gradient
α = specific volume
p = pressure gradient
l = rate of pressure change along a direction.

In meteorology, the pressure gradient is regarded as acting from high to low pressure. It is considered to be the component of the force acting at right angles to the isobars. The component parallel to isobars is zero. Basic flow patterns in the atmosphere on the horizontal are indicated in Fig. 3. These patterns are in a steady-state (no acceleration).

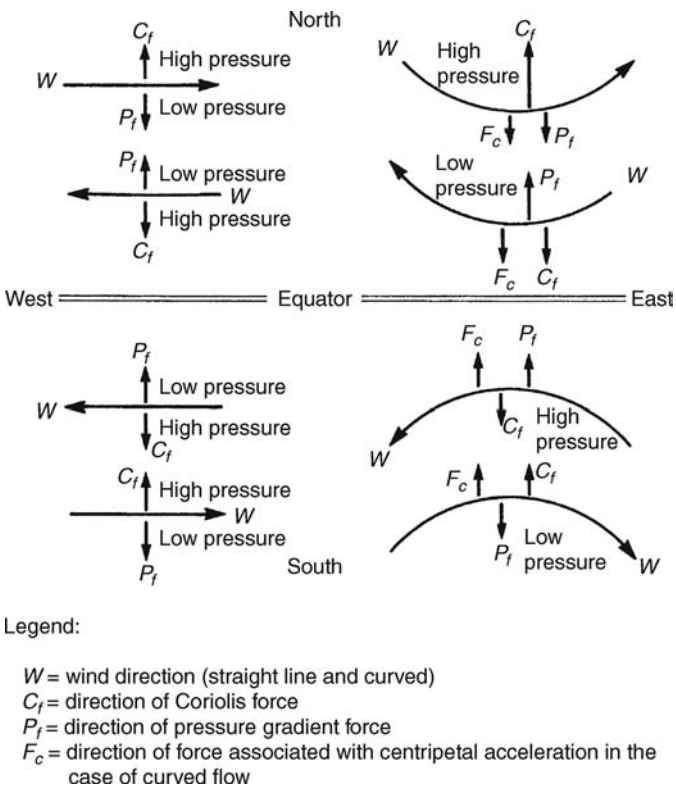

Fig. 3. Basic flow patterns in the atmosphere on the horizontal. These patterns are in a steady state (no acceleration).

3. **Other Forces** Additional forces acting on the atmosphere include:
   a. Centripetal acceleration related forces associated with curved flow.
   b. Frictional drag related forces acting near and at the surface of the earth.
   c. Iso-allobaric forces related to the time rate of change of pressure field.
   d. Divergence and convergence related to vertical flow.

Pressure-Gradient Forces

Pressure Belts. Surrounding the earth at its surface and directly related to the generalized pattern of winds in the atmosphere are four alternating belts of high and low pressure. These belts are formed correspondingly in both the northern and southern hemispheres at roughly 30° intervals from equator to poles. They shift with season, on an average of 5° latitude, reaching the most northerly position in late summer; the most southerly in late winter. See Fig. 4.

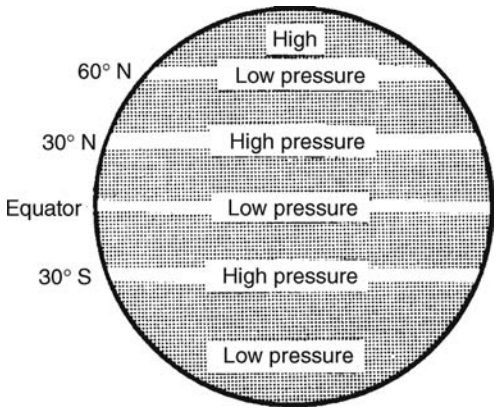

Fig. 4. Pressure belts and gerneral circulation pattern of the air.

1. The *equatorial trough* is a quasi-continuous belt of low pressure extending north and south from the equator; it is commonly called the *doldrums*, or the *equatorial calms*, especially with reference to its light and variable winds. This entire region is one of very homogeneous air, probably the most ideally barotropic region of the atmosphere. Yet, humidity is so high that slight variations in stability cause major variations in weather. The position of the equatorial trough is fairly constant in the eastern portions of the Atlantic and Pacific; but it varies greatly with season in the western portions of those oceans and in southern Asia and the Indian Ocean. It moves into or toward the Southern Hemisphere. It has been suggested that this name be adopted as the one general term for this region of the atmosphere. Thus, the equatorial trough would be said to contain regions of *doldrums*; portions of it could be described as intertropical convergence zones; and within it there might be detected intertropical fronts. However, one weakness of this nomenclature is that it alludes specifically and only to the existence of a trough of low pressure. Perhaps an even more general term might be preferable, for example, atmospheric equator.
2. The *horse latitudes* are narrow high-pressure belts over the oceans at approximately 30°–35° N and S, where winds are predominantly calm or very light, and weather is hot and dry. They are known in the northern and southern hemispheres, respectively, as the *calms of Cancer* and the *calms of Capricorn*. These latitudes mark the normal axis of the subtropical highs, and move north and south by about 5°, following the sun. In the North Atlantic Ocean, these are the latitudes of the Sargasso Sea, where surface waters converge, and which is characterized by clear, warm water, a deep blue color, and large quantities of floating Sargassum or "gulf weed." The name of the Horse Latitudes is believed to have originated in the days of sailing ships. The voyage across the Atlantic in those latitudes was often prolonged by calms or baffling winds, so that water ran short, and ships carrying horses to the West Indies found it necessary to throw the horses overboard.
3. The *subpolar low-pressure belt* is located, in the mean, between 50° and 70° latitude. In the Northern Hemisphere, this "belt" consists of the Aleutian low and the Icelandic low. In the Southern Hemisphere, it is supposed to exist around the periphery of the Antarctic continent.
4. Areas of high pressure, the *polar highs*, form at the 90° poles, where the weather is violent and stormy.

Pressure Areas. These are areas within which the atmospheric pressure is either greater or smaller than other environing regions at the same altitude above sea level. In the case where the pressure is greater than other environing regions, the area of higher pressure is called a *high*. Highs are associated with anticyclonic circulation, clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere. In the case where the pressure is lower than other environing regions, the area of low pressure is called a *low*. Lows are associated with cyclonic circulation, counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere.

Primary and Secondary Highs and Lows. A further classification of pressure areas distinguishes between primary and secondary highs and lows.

Primary (or *semi-permanent*) *highs and lows* cover large areas of the earth's surface for long periods of time (sometimes for the entire year). They are the result of unequal heating of the earth's surface and the consequent movements of air. Where air rises over warmer regions, lows are likely to form; where air sinks over cooler regions, highs are likely to form. The term *center of action* refers to any one of the primary highs or lows. Fluctuations in the nature of these centers are intimately associated with relatively widespread and long-term weather changes.

Secondary highs and lows are, respectively, anticyclonic and cyclonic movements that form within the primary highs and lows. The secondary cyclonic lows are represented, generally, by the inclement weather and by the more-or-less violent phenomena that accompany storms. The secondary highs, unlike lows, represent a single anticyclonic air mass.

The principal semi-permanent pressure areas of the Northern Hemisphere are:

Bermuda High Located over the North Atlantic Ocean, and so named especially when it is located in the western part of the ocean. The same subtropical high, when displaced toward the eastern part of the Atlantic, is known as the *Azores high*. On mean charts of sea level, it is a principal center of action. When it is well-developed and extends westward, warm and humid conditions prevail over the eastern United States, particularly in summer.

North American High (or North American Anticylclone) Located over the North Pacific Ocean and centered, in the mean, at 30–40° N and 140–150°W. On mean charts of sea-level pressure, this subtropical high is a principal center of action. This pressure system is not nearly as well-defined as the analogous Siberian high.

Siberian High (or Siberian Anticyclone) An area of high pressure that forms over Siberia in winter and that is particularly apparent on mean charts of sea level pressure.

Its center is near Lake Baikal, where the average sea level pressure exceeds 1030 mb from late November to early March. This anticyclone is enhanced by the surrounding mountains that prevent the cold air from flowing away readily. In the center of the anticyclone the normal clockwise circulation is replaced by katabatic winds down the river valleys, but to the east along the Pacific Coast there is a belt of very strong northerly winds. The offshore flow is known as the winter monsoon. In summer the Siberian high is replaced by a low pressure area.

Subpolar Highs Located near the Aleutian Islands on mean charts of sea-level pressure, and represents one of the main centers of action in the atmospheric circulation of the northern hemisphere. It is most intense in the winter months; in summer, it is displaced toward the North Pole and is almost nonexistent. The traveling cyclones of subpolar latitudes usually reach maximum intensity in the area of the Aleutian low.

Icelandic Low Located, in the mean, between 50° and 70° latitude. In the Northern hemisphere, this "belt" consists of the Aleutian low and the Icelandic low. In the Southern Hemisphere, it is supposed to exist around the periphery of the Antarctic continent.

In the Southern Hemisphere, there are three semi-permanent high pressure centers, one each in the three oceans, the Pacific, Atlantic, and Indian Ocean. These centers are near 30°S in all cases and they do not migrate much between winter and summer. There is one semi-permanent low pressure center in the southern hemisphere located over the Antarctic region. The main feature in the Southern Hemisphere is a zone of relatively strong westerly winds between the semi-permanent high cells and the semi-permanent low cells. Except for the continent of Australia, these prevailing Westerlies blow uninterrupted over ocean waters.

Types of Pressure Areas. Commonly used general terms for designating various types of pressure areas include:

Center of Action. Any one of several large areas of high and low barometric pressure changing little in location, and persisting through a season or through the whole year. Changes in the intensity and positions of these pressure systems are associated with widespread weather changes. The term is also used to describe any region in which the variation of any meteorological element is related to weather of the following season in other regions.

Col (also Called Saddle Point, Neutral Point). A relatively small area about midway between two cyclones and two anticyclones where the pressure gradient is very weak and winds are usually light and variable. It is the point of intersection between a trough and a ridge in the pressure pattern of a weather map; the point of relatively lowest pressure between the two highs and the point of relatively highest pressure between two lows.

Depression. In meteorology, an area of low pressure; a low or a trough. This is usually applied to a certain stage in the development of a tropical cyclone, to migratory lows and troughs, and to upper-level lows and troughs that are only weakly developed. See also **Cyclones**.

High. An area of high pressure, referring to a maximum of atmospheric pressure in two dimensions (closed isobars) in the synoptic surface chart, or a maximum of height (closed contours) in the constant-pressure chart. Since a high, on the synoptic chart, is always associated with anticyclonic circulation, the term can be used interchangeably with anticyclone.

Low. Also sometimes called depression. A low is an area of low pressure, referring to a minimum of atmospheric pressure in two dimensions (closed isobars) on a constant-height chart, or a minimum of height (closed contours) on a constant-pressure chart. Since a low, on a synoptic chart, is always associated with cyclonic circulation, the term can be used interchangeably with cyclone.

Ridge. 1. Sometimes called *wedge*, an elongated area of relatively high atmospheric pressure, almost always associated with and most clearly identified as an area of maximum anticyclonic curvature of wind flow. The locus of this maximum curvature is called the *ridge line*. Sometimes, particularly in discussions of atmospheric waves embedded in the westerlies, a ridge line is considered to be a line drawn through all points at which the anticyclonically curved isobars or contour lines are tangent to a latitude circle. The most common use of this term is to distinguish it from the closed circulation of a high (or anticyclone); but a ridge may include a high (and an upper-air ridge may be associated with a surface high) and a high may have one or more distinct ridges radiating from its center. The opposite of a ridge is a trough. 2. Also used as reference to other meteorological quantities such as equivalent potential temperature, temperature, and mixing ratio.

That is, an elongated area of relatively high values of any particular field emanating from a maximum. 3. In oceanography, a linear accumulation of broken ice blocks projecting upward, formed by ice deformation, often at the edge of a floe.

A ridge is distinguished from a hummock by being much longer than it is wide. The term ridge is often used to describe an entire ridged ice feature, in which case the portion above the water line is termed the sail and the portion below the water line is termed the keel.

C. The term ridge is used to distinguish it from the closed circulation of a high (or anticyclone); but a ridge may include a high (and an upper-air ridge may be associated with a surface high), and a high may have one or more distinct ridges radiating from its center. The opposite of a ridge is a trough.

Trough. An elongated area of relatively low atmospheric pressure. The axis of a trough is the *trough line*, along which the isobars are symmetrical and curved cyclonically. A V-shaped trough normally contains a front; a U-shaped trough generally contains no front or a very weak one. Usually there is considerable weather associated with a trough line of the V variety. A large-scale trough may include one or more lows; an upper-air trough may be associated with a lower-level low; and a low may have one or more distinct troughs radiating from it. Trough-line movements can be computed and a forecast made of future positions.

Isallobars and Isallobaric Fields. Atmospheric pressure changes at every point in the atmosphere from time to time. It is possible to measure such changes with considerable accuracy. The unit to express pressure change (or pressure tendency) is conventionally the total net change occurring in a 3-hour interval. It is customary to indicate the nature of the change, because the pressure change character may have varied during the selected time interval.

Three-hourly pressure changes are plotted on a synoptic chart (weather map) and lines drawn to join points of equal pressure change. Care is exercised, however, in noting the character of the change in judging the real value of Δp. Lines joining points of equal pressure change are isallobars.

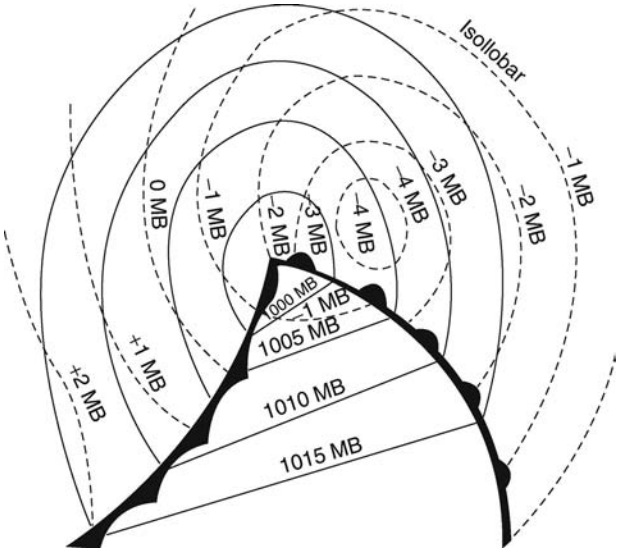

Fig. 5. Isallobars in isallobaric field of the wave cyclone.

See Fig. 5. Isallobars, taken together, constitute an isallobaric field. Where there is present an isallobaric field superimposed on a pressure field, a component of the actual wind blows along the isallobaric gradient, which is directed perpendicular to the isallobars toward regions of greatest pressure fall or least pressure rise, as the case may be. Normally, the isallobaric wind component is small unless the isallobaric field is pronounced. When there is no isallobaric field, the wind is defined approximately by the orientation and spacing of isobars themselves. Isallobaric fields also are used to compute the movement of pressure areas, ridges, troughs, cols, fronts, and isobars. Centers of low pressure will tend to move toward the region of greatest pressure fall, whereas centers of high pressure tend to move toward regions of maximum pressure rise. Both cases have modifying factors, and the direction is not always exactly as would be expected from a casual glance. In all cases of computation of movement, it is necessary to know the isallobaric field, the pressure field, and the orientation of the system whose movement is to be computed.

In establishing an isallobaric field, it is imperative that the diurnal pressure change be accounted for and a correction applied. Diurnal pressure changes do affect movement of pressure systems, but the effect is transient, and, therefore, must be neglected in any study extending more than 6 hours into the future.

In general, isallobars and isallobaric fields are as useful in weather forecasting as the pressure field itself.

Tendency is defined as the local rate of change of a vector or scalar quantity with time at a given point in space. Thus, in symbols, $\partial p/\partial t$ is the pressure tendency, $\partial \xi/\partial t$ the vorticity tendency, etc. Because of the difficulty of measuring instantaneous variations in the atmosphere, variations are usually obtained from the difference in magnitudes over a finite period of time; and the definition of tendency is frequently broadened to include the local time variations so obtained. An example is the familiar three hourly pressure tendency given in surface weather observations.

Terms Associated with Circulation of the Atmosphere

Advection. The process of transport of an atmospheric property solely by the mass motion (velocity field) of the atmosphere; also, the rate of change of the value of the advected property at a given point.

Advection may be expressed in vector notation by

$$-\mathbf{u} \cdot \Delta\phi$$

where $\mathbf{u}$ is the wind vector, ϕ the atmospheric property, and $\square\phi$ the gradient of the property. In three-dimensional Cartesian coordinates, it is

$$-\left(u\frac{\partial\phi}{\partial x} + v\frac{\partial\phi}{\partial y} + w\frac{\partial\phi}{\partial z}\right),$$

where u, v, and w are the wind components in the eastward, northward, and vertically upward directions, respectively. The first two terms compose the horizontal advection and the last term is the vertical advection. Also, it should be noted that the property ϕ may itself be a vector field. Often, particularly in synoptic meteorology, advection refers only to the horizontal or isobaric components of motion, that is, the wind field as shown on a synoptic chart. Regarding the general distinction (in meteorology) between advection and convection, the former describes the predominantly horizontal, large-scale motions of the atmosphere, while convection describes the predominantly vertical, locally induced motions. In oceanography, advection refers to the horizontal or vertical flow of seawater as a current.

Fog drifts from one place to another and cold air moves from polar regions southward by advection. In synoptic meteorology, the term refers only to the horizontal or isobaric components of motion, that is, the wind field as shown on a synoptic chart. The distinction is made between advection and convection, the former describing the predominantly horizontal, large-scale motions of the atmosphere, while the latter describes the predominantly vertical, locally induced motions. Large-scale north-south advection is more prominent in the northern than in the Southern Hemisphere, but west-to-east advection is prominent on both sides of the equator.

Air Parcel. An imaginary body of air to which may be assigned any or all of the basic dynamic and thermodynamic properties of atmospheric air. A parcel is large enough to contain a very great number of molecules, but small enough so that the properties assigned to it are approximately uniform within it and so that its motions with respect to the surrounding atmosphere do not induce marked compensatory movements. It cannot be given precise numerical definition, but a cubic foot of air might fit well into most contexts where air parcels are discussed, particularly those related to static stability. Any fluid parcel may be defined similarly.

Air-Parcel Trajectory. A parcel of air located in a given pressure field will move with the gradient wind of the field (assuming steady flow). At the end of a few hours, the parcel will locate in some new region where it has been carried by the wind. If, however, the pressure field, and therefore the wind, is changing, the parcel will not move into a position indicated by the existing gradient flow. It will follow a trajectory or path dictated by successive gradient directions and velocities as indicated by synoptic charts. An approximation to its trajectory can be had by extrapolating the parcel's indicated movement for as small a time interval as practicable (usually 3 or 6 hours between synoptic charts), using successive synoptic charts. The average of the velocity vectors at the beginning and the end of a given time interval would be taken as the true velocity and direction of the parcel over that time interval. Obviously, the smaller the time interval, the more accurate the trajectory. One of the charts may be a prognostic chart for computing future trajectories. Air trajectories are valuable in estimating the influence the earth has on air as it flows over varied earth surfaces.

Anticyclone. Also termed *high*, an atmospheric circulation having a sense of rotation about the local vertical opposite to that of the earth's rotation, i.e., clockwise in the northern hemisphere; counterclockwise in the southern hemisphere, undefined at the equator; a closed circulation, whose flow is within a closed streamline. With respect to the relative direction of its rotation, it is the opposite of a cyclone.

The barometric pressure within an anticyclone is high relative to its surroundings, and a pressure gradient exists from its center toward its periphery. A well-developed anticyclone is, essentially, an air mass, whose dimensions vary from a few hundred to several thousand miles (kilometers). It is, in general, a region of slowly settling air with a descent rate of from 300–1,500 feet (90–460 meters) per day. Anticyclones are migratory in the region north of 30 to 40°, latitude, and their path usually lies to the east and south. Seasonal semi-permanent anticyclones develop over both North America and Eurasia during winter. A belt of permanent anticyclones, with their centers usually over the oceans, lies between 10° and 40° latitude.

Anticyclones are generally accompanied by bright, clear weather believed to be the result of descending dry air at the anticyclone center; however, rain, drizzle, and cloudy skies may develop in the southwestern and western sectors of the air mass. Anticyclones moving from the north bring cold waves in winter, and cool, clear weather at other seasons. Those moving from the south bring mild weather in winter and hot, dry spells in summer.

Anticyclogenesis is any strengthening or development of anticyclonic circulation in the atmosphere. This applies to the development of anticyclonic circulation where, previously, it was nonexistent, as well as to intensification of existing anticyclonic flow. The most common application of this term is to the formation of a new anticyclone. Care should be taken, however, to distinguish the increase in anticyclonic circulation from the increase in atmospheric pressure (filling), although they usually occur simultaneously.

Convection

1. Atmospheric convection is nearly always turbulent. Convection may be dry, that is, with relative humidities less than 100%, especially in the boundary layer, but is commonly moist, with visible cumuliform clouds. Most convective clouds are driven by positive buoyancy, with virtual temperature greater than the environment, but clouds with precipitation, evaporation, and/or melting can produce negatively buoyant convection.
2. As specialized in atmospheric and ocean science, a class of relatively small-scale, thermally (can be driven by salt concentration in the ocean) direct circulations that result from the action of gravity upon an unstable vertical distribution of mass. (In the case of slantwise convection, though, the motions are larger scale, and are driven by a combination of gravitational and centrifugal forces acting at an angle to the vertical.) Almost all atmospheric and oceanic convection is fully turbulent and is generally composed of a collection of convection cells, usually having widths comparable to the depth of the convecting layer. In the atmosphere, convection is the dominant vertical transport process in convective boundary layers, which are common over tropical oceans and, during sunny days, over continents. In the ocean, convection is prominent in regions of high heat loss to the atmosphere and is the main mechanism of deep water formation. Moist convection in the atmosphere is characterized by deep, saturated updrafts and downdrafts, and unsaturated downdrafts driven largely by the evaporation and melting of precipitation. This form of convection is made visible by cumulus clouds and, in the case of precipitating convection, by cumulonimbus clouds. Moist convection and radiation are the dominant modes of vertical heat transport in the Tropics.
3. In atmospheric electricity, a process of vertical charge transfer by transport of air containing a net space charge, or by motion of other media (e.g., rain) carrying net charge.

Autoconvection is the phenomenon of the spontaneous initiation of convection in an atmospheric layer in which the lapse rate is equal to or greater than the autoconvective lapse rate. The presence of viscosity, turbulence, and radiative heat transfer usually prevents the occurrence of autoconvection until the lapse rate is greater than the theoretical autoconvective lapse rate of approximately $+3.4 \times 10^{-4}$° C per centimeter.

Cyclone. An atmospheric cyclonic circulation, a closed circulation. A cyclone's direction of rotation (counterclockwise in the Northern Hemisphere; clockwise in the southern hemisphere) is opposite to that of an anticyclone. While modern meteorology restricts the use of the term cyclone to the so-called cyclonic-scale circulations (with wavelengths of 1,000 to 2,500 kilometers (621 to 1,553 miles), it is popularly applied to more-or-less violent small-scale circulations such as tornadoes, waterspouts, dust devils, etc. (which may, in fact, exhibit anticyclonic rotation), and even, very loosely, to any strong wind. This term was first used very generally as the generic term for all circular or highly curved wind systems. Because cyclonic circulation and relatively low atmospheric pressure usually coexist, the terms cyclone and low are used interchangeably. Also, because cyclones nearly always are accompanied by inclement, and often destructive, weather, they are frequently referred to simply as storms. See also **Cyclones**.

Equatorial Vortex. A closed cyclonic circulation within the equatorial trough. It develops from an equatorial wave. Some equatorial vortices intensify to become tropical cyclones.

Ferrel Law. When a mass of air starts to move over the earth's surface, it is deflected to the right in the northern hemisphere, and to the left in the southern hemisphere, and tends to move in a circle whose radius depends upon its velocity and its distance from the equator.

Geopotential Height. The height of a given point in the atmosphere in units proportional to the potential energy of unit mass (geopotential) at this height, relative to sea level. The relation, in the centimeter-gram-second (c.g.s.) system, between the geopotential height Z and the geometric height z is

$$Z = \frac{1}{980}\int_0^z g\,\mathrm{d}z$$

where g is the acceleration of gravity, so that the two heights are numerically interchangeable for most meteorological purposes. Also, one geopotential meter is equal to 0.98 dynamic meter. At the present time, the geopotential height unit is used for all aerological reports, by convention of the World Meteorological Organization. See also **Geopotential**.

Geopotential Surface. Also called equigeopotential surface or level surface, this is a surface of constant geopotential, i.e., a surface along which a parcel of air can move without undergoing any changes in its potential energy. Geopotential surfaces also coincide with surfaces of constant geometric height. Because of the poleward increase of the acceleration of gravity along a constant geometric-height surface, a given geopotential surface has a smaller geometric height over the poles than over the equator.

Gradient Flow. Horizontal frictionless flow in which isobars and streamlines coincide; or equivalently, in which the tangential acceleration is everywhere zero. Important special cases of gradient flow, in which two of the normal forces predominate over the third, are: (1) *Cyclostrophic flow*, in which the centripetal acceleration exactly balances the horizontal pressure force; (2) *Geostrophic flow*, where the Coriolis force exactly balances the horizontal pressure force; (3) *Inertial flow*, which is flow in the absence of external forces; (4) in meteorology, frictionless flow in a geopotential surface, in which there is no pressure gradient, so that centripetal and Coriolis accelerations must be equal and opposite.

Inertial Force. A term used specifically in meteorology to designate a force in a given coordinate system arising from the inertia of a parcel moving with respect to another coordinate system. For example, the Coriolis acceleration on a parcel moving with respect to a coordinate system fixed in space becomes an inertial force, the Coriolis force, in a coordinate system rotating with the earth.

Rossby Number. The non-dimensional ratio of the inertial force to the Coriolis force for a given flow of a rotating fluid. It may be given as

$$\mathrm{Ro} = \frac{U}{fL}$$

where U is a characteristic velocity, f the Coriolis parameter (or, if the system is cylindrical rather than spherical, twice the system's rotation rate), and L a characteristic length.

The *thermal Rossby number* is the non-dimensional ratio of the inertial force due to the thermal wind and the Coriolis force in the flow of a fluid that is heated from below.

$$\mathrm{Ro}_T = \frac{U_T}{fL}$$

where f is the Coriolis parameter, L a characteristic length, and U_T a characteristic thermal wind.

Solenoid. In meteorology, a tube formed in space by the intersection of unit-interval isotimic surfaces of two scalar quantities. The number of solenoids enclosed by a space curve is therefore equal to the flux of the vector product of the two gradients through a surface bounded by the curve, or

$$\int_A\int (\Delta\phi_1 \times \Delta\phi_2)\cdot d\mathbf{s} = \oint \phi_1 d\phi_2,$$

where $d\mathbf{s}$ is the vector element of area of a surface bounded by the given curve. Solenoids formed by the intersection of surfaces of equal pressure and density are frequently referred to in meteorology. A barotropic atmosphere implies the absence of solenoids of this type, since surfaces of equal pressure and density coincide.

Tangential Acceleration. The component of the acceleration directed along the velocity vector (streamline), with magnitude equal to the rate of change of speed of the parcel dV/dt, where V is the speed. In horizontal, frictionless atmospheric flow, the tangential acceleration is balanced by the tangential pressure force

$$\frac{dV}{dt} = -\alpha\frac{\partial p}{\partial_s}$$

where α is the specific volume, p the pressure, and s a coordinate along the streamline. Thus, flow without tangential acceleration is along the isobars, and the wind is the gradient wind.

Circulation Theorem

If the atmosphere is baroclinic, that is, if the surfaces of equal pressure and equal density intersect at any angle whatsoever, there is a tendency for a circulation to develop in such a manner that the atmosphere will become barotropic, that is, the surfaces of equal pressure and equal density will coincide. The atmosphere is normally baroclinic. Sea and land breezes, mountain and valley breezes are results of well-defined baroclinic states. Direction of circulation is always such that cold air flows toward warm air at the base of the circulation pattern, and warm flows toward cold at the top of the pattern. Air sinks in the cold air region and rises in the warm air region. Thus, the sea breeze blows along the surface of the earth from cold water to heated land, rises, then returns seaward, and sinks. It is possible to compute the magnitude of the circulation from a given baroclinic state if temperature and pressure are known. Suppose a vertical plane were erected perpendicular to a shore, extending from the cold water to heated land. Lines of equal pressure and temperature drawn in this plane will produce a field of approximate parallelograms, which are known as solenoids. See Fig. 6. A tendency for circulation exists about the perimeter of each solenoid, but, in the field as a whole, this tendency is nullified in adjacent solenoids. There is no nullification along the border solenoids of the whole field, and it is here that a circulation springs up. The number of solenoids in the field is a measure of the expected strength of the resulting circulation.

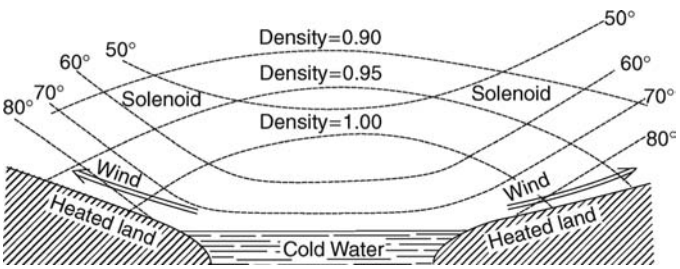

Fig. 6. Circulation theorem and solenoids.

Friction between Wind and the Earth

Even though winds may blow with considerable velocity above the earth's surface, air cannot move rapidly in shallow layers just above the earth where air is caught in the irregularities of the earth's surface. This slowing of a wind at the earth's surface is the result of friction between the moving air and the earth. The effect of friction extends to about 500 meters (>1500 feet). The first effect of reduced velocity is a reduction in the Coriolis force and, therefore, a pressure gradient that is not balanced. Because the pressure gradient force is not balanced. air flows across isobars from high to low pressure. Thus, the unbalancing of the pressure gradient force causes air to converge toward low pressure and diverge from high pressure.

Over land, the average deflection very near the earth is up to 30° and over water it is about 20°. Reduction of wind speed depends upon the nature of the surface. Above the friction layer, the wind speed may be up to twice that at the surface.

Steady-State Wind Equation. In this equation, friction is ignored and the isallobaric and divergence-convergence factors do not come into play.

$$\frac{V}{r} + 2\Omega v \sin\phi = \alpha \frac{\partial p}{\partial r}$$

where

v = wind speed
Ω = angular velocity of the earth
r = radius of curvature of the flow
α = specific volume, and is $1/\rho$, the density
$\frac{\partial p}{\partial r}$ = the pressure gradiant along,
ϕ = the latitude

The wind speed in this relationship is given by:

$$v = \frac{1}{\rho}\frac{\partial p}{\partial r}\frac{1}{2\Omega \sin\phi}$$

where $\alpha = 1/\rho$ and ρ = density.

For straight-line flow,

$$v^2/r = 0,$$

and

$$v = -\Omega r \sin\phi \left[1 - \sqrt{1 - \frac{1}{r\Omega^2 \sin^2\phi}\frac{1}{\rho}\frac{\partial p}{\partial r}}\right]$$

For curved flow about an area of low pressure,

$$v = -\Omega r \sin\phi \left[1 - \sqrt{1 - \frac{1}{r\Omega^2 \sin^2\phi}\left(\frac{1}{\rho}\right)\left(\frac{\partial p}{\partial r}\right)}\right]$$

which is counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere where ϕ is negative.

For curved flow about an area of high pressure,

$$v = -\Omega r \sin\phi \left[1 - \sqrt{1 - \frac{1}{r\Omega^2 \sin^2\phi}\frac{1}{\rho}\frac{\partial p}{\partial r} - 1}\right]$$

which is clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere.

Near the equator, the Coriolis force is approximately zero, and

$$v = \sqrt{\frac{r}{\rho}\frac{\partial p}{\partial r}}$$

Atmospheric Convergence and Divergence

If an imaginary box is erected in the atmosphere near the earth's surface, in such a manner that its base, top, and sides are parallel to the air flow (i.e., the winds), it is possible to illustrate the effects of convergence and divergence. See Fig. 7. When air flows uniformly through this box, there will be no accumulation or diminution of air inside the box. If, for any reason, however, more air flows into one end of the box than flows out the other, there is an accumulation of air, which must seek an outlet. Because the pressure is less at the top of the box than at the bottom, this accumulated air flows upward out of the box. If we followed a cube-shaped unit mass of air through this flow, it would become distorted into a rectangular prism elongated vertically. This process is called *convergence*, and results in a field of rising air. Converging, and therefore rising air can, if the process endures over a sufficient period of time, produce clouds and precipitation. It also tends to destabilize the air. If, in the same box, less air flows into one end than flows out the other, there is an air diminution, and space is available at the top of the box for more air. One unit cube of air will be flattened into a rectangular prism elongated horizontally. This process is called *divergence*, and results in a field of sinking or subsiding air. Divergence, therefore, and subsiding air tend to stabilize the air. Clouds and turbulence diminish in regions of divergence and subsidence.

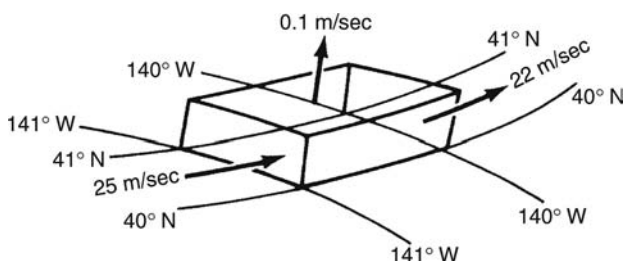

Fig. 7. Principle of convergence and divergence.

Waves in the Atmosphere

In meteorology, any pattern with some roughly identifiable periodicity in time and/or space applies to atmospheric waves in the horizontal flow pattern, i.e., in the wind field, there are wavelike disturbances, such as equatorial, easterly, frontal, Rossby, long, short, cyclone, and

barotropic waves. The study of water-surface waves has bred its own special terminology, such as deep-water, shallow-water, wind, hurricane, and tidal waves. In popular terminology, a surge or influx, is often referred to as a wave, i.e., "heat wave," or "cold wave."

Barometric waves are any waves in the atmospheric pressure field, usually reserved for short-period variations not associated with cyclonic-scale motions or with atmospheric tides.

Barotropic waves occur in a two-dimensional, non-divergent flow, the driving mechanism lying in the variation of vorticity of the basic current and/or in the variation of the vorticity of the earth about the local vertical.

Cyclone waves are (1) disturbances in the lower troposphere, of wavelengths from 1,000 to 2,500 kilometers (621 to 1,553 miles), recognized on synoptic charts as migratory high- and low-pressure systems, and identified with the unstable perturbations connected with baroclinic and shearing instability; and (2) frontal waves at the crests of which are centers of cyclonic circulation; therefore, the frontal waves of wave cyclones.

Easterly waves are migratory wavelike disturbances of the tropical easterlies, which move within the broad easterly current from east to west, generally more slowly than the currents in which they are imbedded. Although best described in terms of wavelike characteristics in the wind field, they also consist of weak troughs of low pressure. Easterly waves do not extend across the equatorial trough.

Equatorial waves are wavelike disturbances of the equatorial easterlies that extend across the equatorial trough.

Frontal waves are horizontal wavelike deformations of fronts in the lower levels, commonly associated with a maximum of cyclonic circulation in the adjacent flow. They may develop into wave cyclones.

Gravity wave disturbances are those in which buoyancy (or reduced gravity) acts as the restoring force on parcels displaced from hydrostatic equilibrium. There is a direct oscillator conversion between potential and kinetic energy in the wave motion.

Long Waves in the Prevailing Westerlies. There develop in the westerlies, particularly during the cold months, certain perturbations, which cause the westerlies to blow alternately northward and southward in a sinusoidal wave pattern, but always with a component of velocity directed from west to east. See Fig. 8. Ridges are associated with anticyclones at ground and near-ground levels, whereas troughs are associated with cyclones. There is, therefore, a definite relation between the sinusoidal perturbations of the westerlies and large-scale surface weather phenomena. Progression eastward, or retrogression westward, of the crests and troughs is usually about the same as surface anticyclones and cyclones. Sinusoidal perturbations can, therefore, be used for prognostic purposes computing their velocities. These velocities are given by the formula:

$$C = U - \frac{bL^2}{4\pi^2}$$

where

C = the velocity of the wave
U = the west to east component of air motion
L = the wavelength of the wave
b = the rate of change in the Coriolis parameter northward

Wave velocities may be positive, zero, or negative; positive indicating easterly movement, negative, westerly movement.

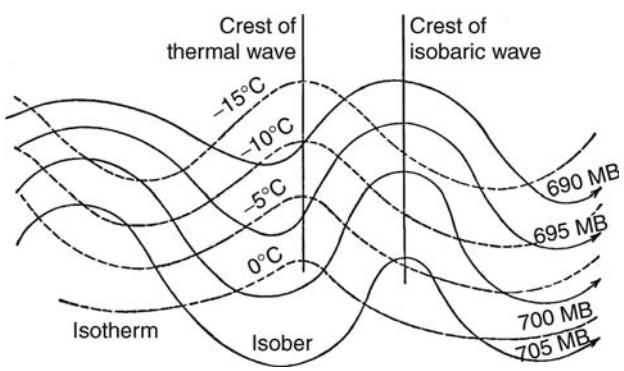

Fig. 8. Long waves in the westerlies.

Isotherms aloft also assume partial or complete sinusoidal form under some conditions. The following relations between amplitudes of the thermal and the streamline wave apply:

$$C = U\left(1 - \frac{A_2}{A_t}\right)$$

where

A_s = streamline amplitude
A_t = thermal amplitude

From this, the following conclusions are possible:

1. If the amplitude of the thermal wave is greater than the streamline wave and the two are in phase, cyclones and anticyclones will have a slow eastward component of movement.
2. If the thermal wave is 180° out of phase with the streamline wave, cyclones and anticyclones move eastward rather rapidly. The smaller the amplitude of the thermal wave in relation to the streamline wave, the more rapid will be the movement of surface systems.
3. If the amplitude of the thermal wave is less than the streamline wave and the two are in phase, cyclones and anticyclones will move with a slow westward component (retrograde motion).
4. If the amplitudes of the thermal and streamline waves are the same and the waves are in phase, the surface systems will have no east-west component of movement.

The first two of these conditions are common: the latter two occur but are not usual.

Mountain Waves in the Atmosphere. These are internal waves located between the earth's surface and the base of the stratosphere. They are created when winds blow across mountainous terrain with a speed of 50 knots or more at the height of the tallest terrain and simultaneously the vertical structure of the atmosphere is favorable for wave development and growth. In North America, the most common locations for development of mountain waves are along the Rocky Mountains, over the Sierra Nevadas, and over the Pacific Coastal Range.

Within the atmosphere when mountain waves are present, the air surges upward and downward; there are vortices and the air movement is chaotic. Evidence of mountain waves is found in the presence of standing lenticular clouds, occasionally a patch of dust kicked up by a gust and, in some select sites, strong gusty winds in mountain passes and canyons.

The most serious impact of mountain waves in the atmosphere is on aircraft that happen to be in the airspace where mountain waves are present. Strong updrafts and downdrafts and moderate-to-severe turbulence are the common experiences.

Conditions under which mountain waves are generated are relatively well known and understood. The wind direction should lie between 90° and not less than 45° to the crest of the terrain. The wind speed should be 50 or more knots at the top of the terrain and should increase with altitude. There should be a stable layer of air or an inversion approximately 10,000 feet (3048 meters) above the level of high terrain. A low tropopause is also favorable.

There are many small local areas where mountain waves occur when the structure of the atmosphere and the winds are favorable. Most prominent locations in the contiguous states of the United States include:

1. Northeastern New Mexico to southeastern Wyoming, including all of central eastern Colorado. Winds are westerly.
2. Nevada-California border and over the western part of Nevada. Winds are west southwesterly.
3. Central northeast Wyoming through central Montana. Winds are southwesterly.

Periodic Changes in the Atmosphere

The atmosphere undergoes periodic recurring changes associated primarily with the relative position of the sun, but to a lesser amount on other factors. The most prominent and obvious periodic changes are the diurnal changes. Less dramatic, but nonetheless obvious are the seasonal changes. Periodic, but recurring changes are associated with the pattern of circulation in both hemispheres, and may also be dependent in part on the changes in ocean

surface temperatures. There are also tides in the atmosphere which can be detected with very sensitive equipment.

Diurnal Changes. Changes completed within and recurring every 24 hours. The diurnal variability of nearly all meteorological elements is one of the most striking and consistent features of the study of weather. The diurnal variations of important elements at the earth's surface can be summarized as follows:

1. Atmospheric pressure varies diurnally or semi-diurnally according to the effects of atmospheric tides. Surface pressure undergoes two definite periods of increase and two of decrease. Mean maximum pressure occurs approximately at ten o'clock local time, in the morning and evening; and mean minimum pressure occurs at four o'clock in the afternoon and morning. In the tropics, this surge and ebb of pressure is very pronounced and highly rhythmic.
2. Temperature tends to reach its maximum about 2–3 hours after local noon, and its minimum at sunrise. Over water, there is a minimum diurnal change as small as a fraction of a degree, and over sandy and rocky desert a maximum that sometimes amounts to 100° or more.
3. Relative humidity tends to become maximum about sunrise, and minimum in the afternoon.
4. Cloudiness and precipitation over a land surface increase by day and decrease at night; over water, the reverse is true but to a lesser extent. Over land, cumulus-type clouds tend to be maximum during afternoons and minimum at night.
5. Fogs tend to be maximum at and shortly after sunrise, and minimum in the afternoon.
6. Evaporation is markedly greater by day; and condensation is much greater at night.
7. Wind generally increases and veers by day, and decreases and backs by night; rough flying air tends to be maximum in midafternoon, and minimum at night.
8. Onshore winds tend to build up during the later morning and afternoon — then die out again in the evening and at night. Offshore winds sometimes set in during nighttime hours. Valley breezes tend to develop — blowing toward higher terrain by day and then reverse to blow downhill by night.

Seasonal Changes. These changes complete their cycle during a year and recur with some variations in intensity during the same months each year. The most prominent and obvious seasonal changes are snow in the winter and thunderstorms in the summer. Some of the more important seasonal changes include:

1. Snow occurs only in winter in most inhabited areas north of 30°N or south of 30°S.
2. The average temperature, mean maximum, and mean minimum temperatures increase to a high value during the second and third months of summer and decrease to a low value during the latter part of winter.
3. Thunderstorms increase in numbers to a maximum occurrence in summer.
4. Fog and low clouds are at a maximum during winter in temperate zone areas.
5. Tornadoes in those areas where they tend to occur are at a maximum in number and intensity during spring months.
6. Severe tropical storms tend to reach a maximum in number during autumn months.
7. Large-scale onshore monsoon circulations are predominantly a summer phenomenon whereas the offshore circulation occurs in winter.
8. Prolonged periods of rainfall (wet season) in the tropics and subtropics are associated with summer; dry periods with winter.

Aperiodic Changes. These appear to be linked to the pattern of circulation of the westerly flow in the atmosphere. There are a number of stable configurations of the west-to-east flow patterns in the atmosphere. Each one of the patterns consists of a discrete number of waves and each wave has a crest and trough. The crests and troughs tend to remain stationary for varying periods of time from weeks to months.

Air movement in the airspace between the trough and the crest of a wave (looking eastward) has a component from the equator toward the poles which tends to carry moisture. Cloud and precipitation-bearing storms predominantly are found in this zone. The airspace between the crest and the trough has an air movement component from the polar region toward the equator that has an associated suppression of cloudiness and precipitation.

A particular stable configuration may remain essentially unchanged for a substantial period of time, causing drought or cold or heat in one area, and opposite conditions in another area. When the pattern breaks down and a different stable configuration is established, the newly established pattern will shift associated conditions to different areas. Shifts from one stable configuration to another are aperiodic (irregular).

Atmospheric Tide

Also known as atmospheric oscillation, the atmospheric tide is an atmospheric motion of the scale of the earth, in which vertical accelerations are neglected (but compressibility is taken into account). Both the sun and moon produce atmospheric tides, which may be thermal or gravitational. A *gravitational tide* is due to gravitational attraction of the sun or moon; the semidiurnal solar atmospheric tide is partly gravitational; the semidiurnal lunar atmospheric tide is fully gravitational. A *thermal tide*, so-called in analogy to the conventional gravitational tide, is a variation in atmospheric pressure due to the diurnal differential heating of the atmosphere by the sun.

The amplitude of the *lunar atmospheric tide* is so small (about 0.06 millibar in the tropics and 0.02 millibar in middle latitudes) that it is detected only by careful statistical analysis of a long record; the only detectable components are the 12-lunar-hour or semidiurnal, as in the oceanic tides, and two others of very nearly the same period. The 12-hour harmonic component of the *solar atmospheric tide* is both gravitational and thermal in origin, and has, by many times, the greatest amplitude of any atmospheric tidal component (about 1.5 millibars at the equator and 0.5 millibar in middle-latitudes); 6- and 8-hour tides of small amplitude have been observed, as well as the 24-hour component, which is a thermal tide with great local variability. The fact that the 12-hour component of the solar atmospheric tide is greater than the corresponding lunar atmospheric tide is ascribed usually to a resonance in the atmosphere with a free period very close to the tidal period.

ATMOSPHERE-OCEAN INTERFACE. Almost 71% of the earth's atmosphere is in contact with oceanic surfaces. The ocean-air interface, therefore, plays a dominant role in determining the water content and temperature of the lower levels of the atmosphere and perhaps of the total atmosphere. The percentage of land and ocean for specified latitude belts and the temperatures in the main oceans in each zone are given in Table 1.

A broad zone lying roughly between 30°N and 30°S is approximately 75% water, with an annual average temperature of near 25°C (77°F) and nowhere below 20°C (68°F). Air in contact with this broad expanse of warm water acquires the properties of the water surface and is permeated by water vapor to considerable depths. This zone is the source region of moist, warm, unstable tropical air masses that move toward the poles as part of the general circulation of large-scale cyclones and anticyclones.

Source of Water Vapor. The air-ocean interface is the primary source of water for the atmosphere and particularly between the latitudes of 40°N and 40°S where the temperature averages 20°C (68°F) or higher. The

average inches of liquid water evaporated each year into each vertical tube of air one-inch square in contact with the ocean surface is given in Table 2. This water vapor is carried aloft and transported laterally within the atmosphere. Secondary sources of water vapor entering the atmosphere include transpiration from plants, evaporation from moist soil and rock, lakes, and rivers.

Thermal Stabilization of the Atmosphere. As provided by the oceans, this is caused primarily by the large-scale uniformity of ocean temperature at the air-ocean interface. From day to day there is no appreciable change in ocean surface temperature except locally in immediate offshore waters. There is a slow seasonal change. Air in contact with the thermally stable ocean surfaces also tends to become thermally stable. Annual seasonal change in average ocean surface temperature for the Pacific, Atlantic, and Indian Oceans is indicated in Table 3. Were it not for the stabilizing influence of the oceans, the annual temperature range would be much greater than it is, i.e., warmer in summer and colder in winter.

TABLE 3. ANNUAL SEASONAL CHANGE IN AVERAGE OCEAN SURFACE TEMPERATURES

Salt Condensation Nuclei. These nuclei required for cloud formation and precipitation originate through the air-ocean interface. Ocean spray from breaking waves creates tremendous numbers of small salt water droplets which are carried up into the atmosphere to evaporate and to leave a very small residue of sea salt. Wherever in the atmosphere the relative humidity approaches saturation values, these nuclei become the core for haze, small cloud droplets, and rain. Constituent chemical elements found in ocean water are also found in the same proportionate ratios in microscopic salt nuclei and in rain water. Over land areas, other nuclei from various sources tend to outnumber the salt nuclei.

Ocean Waves. These are predominately wind-generated. When the wind speed is near calm, the ocean surface is only rippled. As the wind speed increases, air at the ocean-air interface drags the water forward, causing waves to develop. The *fetch* is the stretch or distance over which winds can act upon the ocean surface. Fetch is limited by the distance of open water and by the distance that winds blow in one direction at a sufficient speed. Only rarely does wind direction stay in one orientation for long distances. Likewise, sustained high wind speeds only rarely extend over long distances.

Wave height is empirically related to wind speed by

$$H = 0.025V^2$$

where H is in feet and V is in knots. The maximum wave height is related to the fetch by

$$H_{\max} = 1.5\sqrt{F}$$

where $H_{\max}$ is in feet and F is in nautical miles. See Table 4.

TABLE 4. WAVE HEIGHT VERSUS WIND SPEED AND MINIMUM FETCH

Wave Height (Feet)	Wind Speed (Knots)	Minimum Fetch Required To Attain Height (Nautical Miles)
3	10	3
10	20	48
23	30	240
42	40	760
65	50	1860

Fetches greater than 1000 nautical miles are not common and those as much as 2000 miles probably do not occur. The tallest waves observed are on the order of 60 to 70 feet (18 to 21 meters). Wave heights of 50 feet (15 meters) can be expected in winds of more than 45 knots provided the fetch is sufficient. Very large waves can develop in strong winds within 12 hours when the fetch is sufficiently long. In contrast, strong winds cannot create huge waves on a short fetch.

Swells. These are more or less uniformly spaced, rounded waves that were generated as wind waves, but that have traveled well beyond the ocean areas where they were developed. The orientation of swells changes only slowly, if at all, with time. Therefore, swells can be used to indicate the location of the storm that generated them. Observations of swells is usually part of a weather observation from ships at sea. The height, orientation, and speed of swells observed at a number of points in the open ocean provide meteorologists with useful information in pinpointing storm centers.

The ocean surface most often displays a chaotic mixture of swells and locally generated wind-driven waves. There may be as many as a half-dozen intermingling swells and waves in one spot, causing the sea surface to rise and fall in a most irregular manner.

Superwaves. In 1983, researchers J.G. and G.W. Moore (U.S. Geological Survey) investigated how certain boulders of limestone found on the Hawaiian island of Lanai reached such unusual heights. Limestone-bearing gravel, the newly named *Hulopoe Gravel*, blankets the coastal slopes of Lanai. The deposit, which reaches a maximum altitude of 326 meters (1070 feet), formerly was believed to have been deposited along several different ancient marine strand-lines, but dated submerged coral reefs and tide-gage measurements indicate that the southeastern Hawaiian Islands sink so fast that former worldwide high stands of the sea now lie beneath local sea level. Evidence indicates that the Hulopoe Gravel and similar deposits on nearby islands were deposited during the Pleistocene by a giant wave generated by a submarine landslide on a sea scarp south of Lanai.

Because of the great run-up of the wave, it was probably not a seismic sea wave caused by a subsea earthquake. Either the impact of a meteorite on the sea surface or a shallow submarine volcanic explosion could have generated the Hulopoe wave. The researchers believe, however, that a more likely explanation is a rapid downslope movement of a subsea landslide on the Hawaiian Ridge, which is among the steepest and highest landforms on earth. The occurrence of several major subsea landslides of various ages, possibly triggered by local earthquakes, indicates that the Hawaiian Ridge is a site of repeated slope failure. A landslide in a confined fjord in Alaska in 1958 produced a run-up of 524 meters, the highest on record. The researchers infer that that rapid movement of a submarine slide near Lanai displaced seawater forming a wave that rushed up onto the island, carrying with it rock and reef debris from the near shore shelf and beach.

The El Niño 1982–83 Event

For well over a century, Ecuadorian and Peruvian fishermen have referred to the annual appearance of warm water in the Pacific off their shores at Christmas time as *El Niño* (Spanish for the Christ child). In meteorological terms, El Niño (EN) is an anomalous warming of surface water in the equatorial Pacific, mainly off the coast of Peru. Warming of these waters is a normal event, but periodically and difficult to forecast, the EN in some years is of much greater intensity, covers a larger area of water, and is prolonged. Instead of lasting for just a few months, the warm waters may persist for a year or longer, as in the case of a number of past instances: 1953, 1957–58, 1965, 1972–73, and 1982–83. During the latter event, the sea surface temperature off Peru rose by over 7 degrees Celsius (12.6 °F). A temperature this high seriously affects the Peruvian anchovy fisheries. Traditionally, in a normal year, the catch will exceed 12 million tons. In the 1982–83 EN event, the annual catch dropped to less than one-half million ton. Michael Glantz of the National Center for Atmospheric Research (NCAR) takes exception to the claim that that all of the consequences suffered by the Peruvian fishing industry be charged against the EN event; he believes, rather, that reductions in the catch coincidentally resulted from technological advances, political changes in the national government, and a lack of government-agency supervision of the fishing industry. Be that as it may, the EN was a major factor in the loss.

EN has been linked with a variety of atmospheric anomalies. Some are local — heavy rains in usually arid regions along the Pacific Coast of South America. EN also must be regarded as part of an interrelated set of changes in atmospheric and ocean conditions over much of the Southern Hemisphere, often referred to as the EN-Southern Oscillation, or simply *Southern Oscillation*. The latter may be defined as a massive seesawing of atmospheric pressure between the southeastern and the western tropical Pacific. Southern Oscillation involves a periodic weakening or disappearance of the trade winds, which triggers a complex chain of atmosphere-ocean interactions.

As observed by Michael Wallace (University of Washington), "Most of us feel that (EN) is a coupled phenomenon. The atmosphere itself doesn't have enough of an attention span to know what happened a couple of months ago. The ocean can serve as a memory. It can remember what happened a season or a year ago. But the atmosphere, unlike the ocean, has the large-scale systems that make this phenomenon global."

The apparent coupling between EN and global weather anomalies seemed very convincing in 1982–83 when EN was exceptionally intense. During this period, unusually severe Pacific storms struck the California, Oregon, and Washington coasts. These storms dumped heavy snow on western U.S. mountains, and spring floods followed. Extreme droughts hit many parts of the world, including the western Pacific and Mexico, and torrential rains and flooding drenched parts of South America and the southern United States. A number of scientists have attributed these extreme events to the extraordinary EN.

In an ordinary year, many storm systems form or intensify near the east coast of Asia and move across the Pacific Ocean. Eventually, the storms cross the western United States and continue eastward. However, in some EN years, the Pacific storm track veers northward toward Alaska, altering the usual paths of these winter storms. This happened in the winter of 1976–77, when the western United States had an unusually warm, dry winter, while severe cold and snow swept down over the eastern part of the country as far as Florida.

In 1983, John Geisler (University of Utah) and his colleagues used what is known as the community climate model (CCM) to simulate EN events of three different intensities. Although the model produced the most significant features of northern winter anomalies that accompany intense ENs, it is not clear why one EN winter can differ so much from another. There are indications that the difference may be related to the geographical location of the warm surface water.

Although this experiment may sound simple, it required considerable resources and effort. At the NCAR, its high-speed CRAY-1 computer made it possible. The experiment was nearly five times larger than any prior ones and required more than 100 hours of computer time.

Numerous meteorological and oceanographic scientists throughout the world found the timing right for tackling the challenge of understanding the 1982–83 EN. Much was learned, but scientists are not ready to acknowledge that they can forecast with any degree of reliability when the next EN event may return, or what its consequences may be. Some interesting theories have been proposed, but remain untested. Geoffrey Vallis (Scripps Institution of Oceanography) observed in 1986 that most of the principal qualitative features of the EN-Southern Oscillation phenomenon can be explained by a simple but physically motivated theory. These features are the occurrence of sea-surface warmings in the eastern equatorial Pacific and the associated trade wind reversal; the aperiodicity of these events; the preferred onset time with respect to the seasonal cycle; and the much weaker events in the Atlantic and Indian Oceans. The theory, in its simplest form, is a conceptual model for the interaction of just three variables, namely, (1) near-surface temperatures in the east, and (2) west equatorial ocean, and (3) a wind-driven current advecting the temperature field. For a large range of parameters, the model is naturally chaotic and aperiodically produces EN-like events. For a smaller basin, representing a smaller ocean, the events are proportionately less intense. Vallis summarizes by observing that although the model has many limitations, one being that it cannot describe spatial variations in any detail, it does explain many of the qualitative features of EN. It transparently demonstrates the underlying dynamics and thereby the possibility of a purely internal mechanism for the phenomenon. It shows that external triggering or stochastic forcing is not necessarily essential, although such effects may have a role in the real system.

Cane and Zebiak (Lamont-Doherty Geological Observatory) created a sophisticated model wherein the atmosphere and ocean are coupled to each other, allowing changes in one to affect the other. However, compared with a number of other models, the Cane-Zebiak model is relatively simple, but the designers claim that all essential ingredients are present. One of these is the potential for a feedback between the temperature gradient of the equatorial Pacific, its eastern end normally being colder than its western end, and the east-to-west winds normally blowing along the equator. Inasmuch as the temperature gradient drives these winds that normally keep the warm water at bay in the west, a warming in the east would weaken the gradient and thus the winds. This would lead to further warming. Positive feedback as described has been a part of most EN models since that created by Bjerknes in the 1960s, which related EN and its associated atmospheric phenomenon, the Southern Oscillation. Cane and Zebiak did include one other essential element, i.e., the need for the heat content of the upper tropical Pacific to be higher than normal. Without that precondition, the researchers believe that the feedback needed could not occur. An EN event predicted by the model for 1986–87 did not happen.

Biological Consequences of El Niño 1982–83. The EN event not only provided an excellent opportunity for atmosphere and ocean scientists to exercise new sophisticated and computerized equipment in the laboratory, but also to observe the EN by satellite. As reported by Fiedler (National Oceanic and Atmospheric Administration, La Jolla, California), satellite infrared temperature images illustrated several effects of the EN event. Warm sea-surface temperatures, with the greatest anomalies near the coast, were observed, as were weakened coastal upwelling, and changes in surface circulation patterns. Phytoplankton pigment images from the *Coastal Zone Color Scanner* indicated reduced productivity, apparently related to the weakened coastal upwelling. The satellite images provided direct evidence of mesoscale changes associated with the oceanwide EN event.

In addition to the previously mentioned EN effects of severely lowering the Peruvian anchovy catch, strong winter storms in southern California, attributed by many scientists to the EN event, destroyed most of the canopy of the giant kelp *Macrocystis pyrifera*.

As reported by Michael Glantz in a 1984 paper, some scientists referred to the EN 1982–83 event as the most potent in about a century, because of its alleged linkages to the devastating impacts on the economies of countries that border the Pacific Ocean in the Southern Hemisphere — droughts in Australia, Indonesia, Peru, and Hawaii; an increase in the number of destructive tropical typhoons in the southern Pacific region; the mysterious disappearance and subsequent reappearance of seabirds on Christmas Island; the destruction of Pacific coral reefs; and the decimation of fish stocks that normally inhabit the coastal waters of Peru and Ecuador, (in addition to anchovy).

Just which of the aforementioned effects were directly or indirectly attributable to EN-1982–83 will remain controversial until improved computerized models are developed and tested once again at the occurrence of another intense EN in the indefinite future.

ATMOSPHERE (Planetary). See under **specific planets**.

ATMOSPHERIC ATTENUATION. The reduction with distance from the source of the intensity of an acoustic or an electromagnetic signal propagating through the atmosphere caused by interaction of the signal with gaseous constituents of the atmosphere, aerosols, or hydrometeors. In general, scattering and absorption account for attenuation.

For sound, absorption is usually more important than scattering; it depends on temperature and humidity, and generally increases with increasing acoustic frequency. The main atmospheric constituents that absorb radar energy are oxygen, water vapor, and liquid hydrometeors. Absorption is often neglected at wavelengths of 10 cm and longer, but becomes increasingly important at shorter wavelengths. The contribution of scattering to radar attenuation also increases with decreasing wavelength. For lidar, scattering by molecules, aerosols, and hydrometeors dominates the attenuation, although gaseous absorption is significant at certain spectral bands and is exploited by differential absorption lidar (DIAL) to measure molecular concentrations.

AMS

ATMOSPHERIC BRAKING. The action of slowing down an object entering the atmosphere of the earth or other planet from space, by using the drag exerted by air or other gas particles in the atmosphere; the action of the drag so exerted.

ATMOSPHERIC CHEMISTRY. The study of the composition of and chemical transformations occurring in the Earth's atmosphere and that of other planets. The discipline of atmospheric chemistry includes field

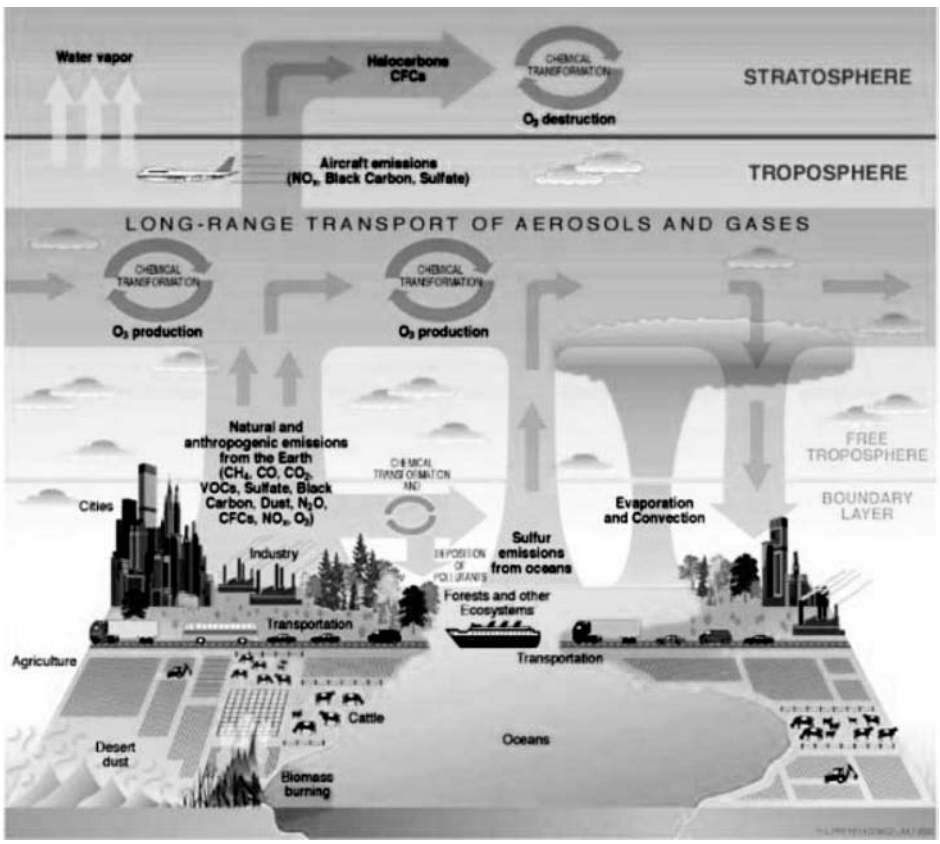

Fig. 1. Schematic of chemical and transport processes related to atmospheric composition. These processes link the atmosphere with other components of the Earth system, including the oceans, land, and terrestrial and marine plants and animals.

measurements, computer modeling, and laboratory measurements, and requires an understanding of the interaction of the atmosphere with the biosphere and anthropogenic influences in order to be able to explain current conditions and to predict future changes.

The composition and chemistry of the atmosphere is of importance for several reasons, but primarily because of the interactions between the atmosphere and living organisms Fig. 1. The composition of the Earth's atmosphere has been changed by human activity and some of these changes are harmful to human health, crops and ecosystems. Examples of problems which have been addressed by atmospheric chemistry include acid rain, photochemical smog, and global warming. Atmospheric chemistry seeks to understand the causes of these problems, and by obtaining a theoretical understanding of them, allow possible solutions to be tested and the effects of changes in government policy evaluated. See also **Acid Rain**; and **Global Warming**.

History

The ancient Greeks regarded air as one of the four elements, but the first scientific studies of atmospheric composition began in the 18th century. Chemists such as Joseph Priestley, Antoine Lavoisier and Henry Cavendish made the first measurements of the composition of the atmosphere. See also **Cavendish, Henry (1731–1810)**; **Lavoisier, Antoine (1743–1794)**; and **Priestley, Joseph (1733–1804)**.

In the late 19th and early 20th century's interest shifted towards trace constituents with very small concentrations. One particularly important discovery for atmospheric chemistry was the discovery of ozone by Christian Friedrich Schoenbein in 1840. See also **Ozone**.

In the 20th century atmospheric science moved on from studying the composition of air to a consideration of how the concentrations of trace gases in the atmosphere have changed over time and the chemical processes which create and destroy compounds in the air. Two particularly important examples of this were the explanation of how the ozone layer is created and maintained by Sydney Chapman and Gordon Dobson, and the explanation of Photochemical smog by Haagen-Smit.

In the 21st century the focus is now shifting again. Atmospheric chemistry is increasingly studied as one part of the Earth system. Instead of concentrating on atmospheric chemistry in isolation the focus is now on seeing it as one part of a single system with the rest of the atmosphere, biosphere and geosphere. An especially important driver for this is the links between chemistry and climate such as the effects of changing climate on the recovery of the ozone hole and vice versa but also interaction of the composition of the atmosphere with the oceans and terrestrial ecosystems. See also **Atmosphere (Earth)**; and **Climate**.

ATMOSPHERIC DUCT. An almost horizontal layer in the troposphere, extending from the level of a local minimum of the modified refractive index as a function of height, down to the level where the minimum value is again encountered, or down to Earth's surface if the minimum value is not encountered again. Atmospheric ducts may act as waveguides for radio and radar waves.

ATMOSPHERIC ELECTRIC FIELD. A quantitative term denoting the electric field strength of the atmosphere at any specified point in space and time. In areas of fair weather, the atmospheric electric field near the earth's surface typically is about 100 volts (V) m^{-1} and is directed vertically in such a sense as to drive positive charges downward to the earth. In areas of fair weather this field decreases in magnitude with increasing altitude, falling, for example, to only about 5 $V\,m^{-1}$ at an altitude of about 10 km (6 miles). Near thunderstorms, and under clouds of vertical development, the surface electric field (the electric field measured at the surface of the earth) varies widely in magnitude and direction, usually reversing its direction immediately beneath active thunderstorms. In areas of minimal local disturbance, a characteristic diurnal variation of electric field strength is observed. This variation is characterized by a maximum that occurs at about 1900 UTC for all points on the earth and is now believed to be produced by thunderstorms that, for geographic regions, are more numerous for the world as a whole at that universal time than at any other. It is now believed that thunderstorms, by replenishing the negative charge to the earth's surface, provide the supply current to maintain the fair- weather electric field in spite of the continued flow of the air–earth current that tends to neutralize that field. The range of the electric field in fair weather varies considerably with geographical area, from one part of the globe to another. If, however, there are no local sources of pollution, the surface electric field has its maximum amplitude around 1900 UTC.

ATMOSPHERIC ELECTRICITY. 1. Electrical phenomena, regarded collectively, that occur in the earth's atmosphere. These phenomena include not only such striking manifestations as lightning and St. Elmo's fire, but also less noticeable but more ubiquitous effects such as atmospheric ionization, the air–earth current, and other quiescent electrical processes. The existence of separated electric charges in the atmosphere is a consequence of many minor processes (spray electrification, dust electrification, etc.) and a few major processes (cosmic-ray ionization, radioactive-particle ionization, and thunderstorm electrification). The details of thunderstorm charge separation are poorly understood. The maintenance of the prevailing atmospheric electric field is now widely believed to be due to thunderstorm effects.

2. The study of electrical processes occurring within the atmosphere.

ATMOSPHERIC INTERFERENCE (or Spherics). The interference of radio reception caused by natural electric disturbances in the atmosphere.

ATMOSPHERIC OPTICAL PHENOMENA. Because of varying conditions present in the atmosphere from time to time and notably the presence of ice crystals, dust particles, and other particulate matter, several interesting optical effects are the result.

Sky Color

The characteristic blue color of clear skies is due to preferential scattering of the short-wavelength components of visible sunlight by air molecules. Presence of foreign particles in the atmosphere alters the scattering processes in such a way as to reduce the blueness. Hence, spectral analysis of diffuse sky radiation provides useful information concerning the scattering particles. The study and measurement of the blueness of the sky is called *cyanometry*. Sometimes the Linke scale (or blue-sky scale) is used. The Linke scale is simply a set of eight cards of different standardized shades of blue. They are numbered 2 to 16, the odd numbers to be used by the observer when the sky color appears to lie between any of the given shades.

Halos and Coronas

A halo is any one of a large class of atmospheric phenomena appearing as colored or whitish rings and arcs about the sun or moon when seen through an ice crystal cloud, or in a sky filled with falling ice crystals. The halos exhibiting prismatic coloration are produced by refraction of light by the crystals and those exhibiting only whitish luminosity are produced by reflection from the crystal faces. The minute spicules of ice, in falling, take some definite attitude determined by their shape. Some are needlelike and assume a horizontal position; some are flat disks or stars and fall with their planes horizontal; while others, made up of both disks and rods, behave like a parachute. The sunlight is refracted by each type in a characteristic manner and dispersed into colors; it is also reflected from their external surfaces without dispersion.

Halos differ from coronas in that the former are produced by refraction and reflection due to ice crystals, whereas the latter are produced by diffraction and reflection due to water drops. A colored halo may often

be distinguished from a corona in that it has the red nearest the sun or moon, whereas the corona has red in the exterior rings.

Halo Phenomena. With regards to type, orientation, motion, and solar elevation angle of ice crystals, a large variety of halos is possible, theoretically. Many varieties have been observed. Some halos theoretically predicted have not yet been reported; some that have been reported have not yet been theoretically explained, such as the Hevelian halo (described below). On rare occasions, an observer's sky will be filled with a display of four or five halo phenomena at one time, usually persisting for only a few minutes. Much supernatural lore about such displays was built up by the ancients.

By far the most common halo phenomenon is the *halo of* 22°, in the form of a prismatically colored circle of 22° angular radius around the sun or moon, exhibiting coloration from red on the inside to blue on the outside. It is produced by refraction of light that enters one prism face and leaves by the second prism face beyond, thus being refracted by an effective prism of 60° angle. In order to have a full 22° halo, the sky must be filled with hexagonal ice crystals falling with random orientations, a condition that apparently is frequently satisfied. This halo exhibits a distinct spectral pattern out to blue, due to the tipping of the crystals and consequent overlap of spectra in all but the red end. A reddish inner edge is usually all that one can discern.

Closely allied to the 22° halo are the *parhelia* ("mock suns" or "sun dogs") and *paraselenae* ("mock moons"). The parhelia are two colored (reddish) luminous spots that appear at points 22° (or somewhat more) on both sides of the sun and at the same elevation as the sun. Their lunar counterpart is the weakly colored paraselenae, which are observed less frequently than the parhelia because of the moon's comparatively weak luminosity. These phenomena are produced by refraction in hexagonal crystals falling with principal axes vertical, the effective prism angle being 60°, as in the halo of 22°.

The parhelic circle ("mock sun ring") and the paraselenic circle ("mock moon ring") are halos consisting of a faint white circle passing through the sun or moon, respectively, and running parallel to the horizon for as much as 360° of azimuth. These circles are often seen in the sky along with parhelia or paraselenae, and are produced in the same manner. Parhelia and paraselenae occur at several positions along the parhelic circle other than the common 22° position, i.e., at 46°, 90°, 120°.

The *Hevelian halo* is the halo of 90°; it appears, only occasionally, as a faint, white halo on the sun or moon, and is a member of the class of halos reported but not yet fully explained.

A *sun pillar* (or a "light pillar") is a luminous streak of light, white or slightly reddened, extending above and below the sun, most frequently observed near sunrise or sunset. It may extend to about 20° above the sun, and generally ends in a point. The luminosity is thought to be produced simply as a result of reflection of sunlight from the tops and bottoms of tabular hexagonal ice crystals falling with principal axes vertical. See also **Sun Pillar**.

A *sun cross* is a rare halo phenomenon in which bands of white light intersect over the sun at right angles. It appears probable that most of such observed crosses appear merely as a result of the superposition of a parhelic circle and a sun pillar.

The *arcs of Lowitz* is a type of halo, rarely seen, in which the luminous arcs extend obliquely downward from the 22° parhelia on either side of the sun (or moon); it is concave towards the sun, with reddish inner edges; and is produced by refraction in hexagonal ice crystals that are oscillating as they descend.

The *circumhorizontal arc* is produced by refraction of light entering snow crystals, and consists of a colored arc, red on its upper margin, which extends for about 90° parallel to the horizon and lies about 46° below the sun. The *circumzenithal arc* is produced by refraction of light entering the tops of tabular ice crystals; it consists of a brightly colored arc about 90° in arc length, and is found about 46° above the sun, with its center at the zenith. It is typically very short-lived, but also very brilliant. In addition to these arcs, several types of halo arcs known generically as *tangent arcs* are occasionally formed as loci tangent to other halos, especially to the halo of 22°.

Corona. The corona consists of one or more rings located symmetrically about the sun or moon caused by diffraction of light passing through liquid water droplets. Coronas are of varied radii about the sun or moon, dependent upon the size of the water droplets. The radius of any corona is inversely related to the diameter of the water droplets causing it:

$$\sin\theta = \frac{(N + 0.22)L}{D}$$

where

θ = angular radius of the corona ring
N = order of the corona ring (1st, 2nd, etc.)
L = wavelength of the light
D = diameter of the water droplets

The order of coloration in a corona ring is from blue on the inside to red on the outside (opposite to the coloration of halo rings).

Bishop rings are corona rings of faint reddish-brown seen in dust clouds.

Glory or Anticorona. A glory ring is observed on a cloud top of edge opposite to the position of the sun, i.e., the antisolar point. Glories are most frequently observed from aircraft flying above clouds. The shadow of the plane is in the center of the glory ring. See Fig. 1. These anticorona rings are complementary to the corona rings.

Bouguer's halo is a ring of faint white light usually about 39 feet (12 meters) in radius observed on some occasions outside the glory ring.

Rainbow

A rainbow is an optical and meteorological phenomenon that causes a nearly continuous spectrum of light to appear in the sky when the Sun shines onto droplets of moisture in the Earth's atmosphere. It takes the form of a multicoloured arc, with red on the outside and violet on the inside. Traditionally, the full sequence of colours is most commonly cited as red, orange, yellow, green, blue, indigo, and violet. It is important to note that this is an inconsistent list: all primary and secondary colours are present in some form, but only one tertiary colour. It is commonly thought that indigo was included due to the different religious connotations of the numbers six and seven at the time of Isaac Newton's work on light, despite its lack of scientific significance and the poor ability of humans to distinguish colours in the blue portion of the visual spectrum.

A traditional way of recalling each of the seven colours of the rainbow in sequence is by using the mnemonic "Richard Of York Gave Battle In Vain", where the first letter of each word corresponds to the first letter of each colour. The mnemonic alludes to the defeat of Richard III by Henry Tudor at the Battle of Bosworth Field. In York, an alternative version is taught that goes "Rowntrees Of York Gave Best In Value", referring to the confectionery Rowntrees. Another, less obvious, though more common way is the use of the meaningless name Roy G. Biv or ROYGBIV. This method is purely phonetic. Some humorous examples also exist, including "Ring Out Your Granny's Boots In Vinegar".

A drawback to all these methods is that they include the colour of indigo between blue and violet, though most modern rainbow definitions do not include that as a distinct colour, partly due to the poor ability of humans to distinguish colours in the blue portion of the visual spectrum. Since rainbows are composed of a nearly continuous spectrum, different people, most notably across different cultures, identify different numbers of colours in rainbows.

Looking into a "sheet" of water drops (rain, fog, spray) that is illuminated by strong white light from behind, an observer sees one, and sometimes two, concentric, spectrally colored rings, called a rainbow. If two are visible, the inner ring, called the "primary bow," is brighter and narrower than the outer ring or "secondary bow." In the primary bow, red is on the outside edge and violet on the inside edge; the order in the secondary bow is reversed. In Fig. 2 is shown the dispersion composing the primary and secondary bow. The colors are not so pure as in a spectrum because each wavelength extends over a wide radial range, the rainbow itself being made up of the fairly pronounced intensity maxima.

The colors of the rainbow are caused by dispersion of sunlight as it is refracted by (approximately spherical) raindrops. The light is first refracted as it enters the surface of the raindrop, reflected off the back of the drop, and again refracted as it leaves the drop. The overall effect is that the incoming light is reflected back over a wide range of angles, with the most intense light at an angle of about 40°–42°, regardless of the size of the drop. Since the water of the raindrops is dispersive, the amount that the sunlight is bent depends upon the wavelength, and hence colour, of the light's constituent parts. Blue light is refracted at a greater angle than red

Fig. 1. Photograph of a glory ring made by a crew member of an American airliner. Note that center of glory ring is at exact position of cockpit in shadow of aircraft.

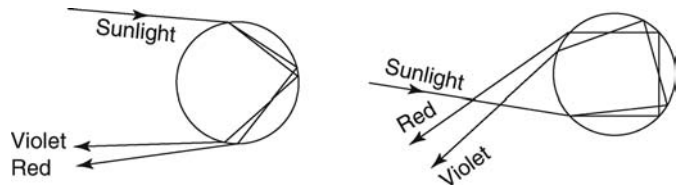

Fig. 2. Formation of primary bow (left) and secondary bow (right). Circles represent a raindrop

light, but because the area of the back of the droplet has a focal point inside the droplet, the spectrum crosses itself, and therefore the red light appears higher in the sky, and forms the outer colour of the rainbow. Contrary to popular belief, the light at the back of the raindrop does not undergo total internal reflection; however, light that emerges from the back of the raindrop does not create a rainbow between the observer and the Sun. The spectra emitted from the back of the raindrop do not have a maximum of intensity, as the other visible rainbows do, and thus the colours blend together and do not form a rainbow.

Occasionally, a second, dimmer secondary rainbow is seen outside the primary bow. Secondary rainbows are caused by a double reflection of sunlight inside the raindrops, and appear at an angle of 50°–53°. As a result of the second reflection, the colours of a secondary rainbow are inverted compared to the primary bow, with blue on the outside and red on the inside. The dark area of unlit sky lying between the primary and secondary bows is called Alexander's band (Fig. 3), after Alexander of Aphrodisias who first described it.

A third, or triple, rainbow can be seen on rare occasions, and a few observers have reported seeing quadruple rainbows in which a dim outermost arc had a rippling and pulsating appearance. These rainbows would appear on the same side of the sky as the Sun, making them hard to spot.

Occasionally, another beautiful and striking rainbow phenomenon can be observed, consisting of several faint rainbows on the inner side of the primary rainbow, and very rarely also outside the secondary rainbow. They are slightly detached and have pastel colour bands that do not fit the usual pattern. They are known as supernumerary rainbows, and it is not possible to explain their existence using classical geometric optics. The alternating faint rainbows are caused by interference between rays of light following slightly different paths with slightly varying lengths within the raindrops. Some rays are in phase, reinforcing each other through constructive interference, creating a bright band; others are out of phase by up to half a wavelength, cancelling each other out through destructive interference, and creating a gap. Given the different angles of refraction for rays of different colours, the patterns of interference are slightly different for rays of different colours, so each bright band is differentiated in colour, creating a miniature rainbow. Supernumary rainbows are clearest when raindrops are small and of similar size. The very existence of supernumary rainbows was historically a first indication of the wave nature of light, and the first explanation was provided by Thomas Young in 1804.

Other rainbow variants are produced when sunlight reflects off a body of water. Where sunlight reflects off water before reaching the raindrops, it produces a *reflection* rainbow. These rainbows share the same endpoints as a normal rainbow but encompass a far greater arc when all of it is visible. Both primary and secondary reflection rainbows can be observed.

A *reflected* rainbow, by contrast, is produced when light that has first been reflected inside raindrops then reflects off a body of water before reaching the observer. A reflected rainbow is not a mirror image of the primary bow, but is displaced from it to a degree dependent on the Sun's altitude. Both types can be seen in the image to the right.

A *fog bow* is a type of rainbow, faintly colored, seen on fog layers whose droplets are small.

In a very few cases, a moonbow, or night-time rainbow, can be seen on strongly moonlit nights. Moonbows are relatively faint, due to the

Fig. 3. A double rainbow features reversed colours in the outer (secondary) bow, with the dark Alexander's band between the bows. **(courtesy of NASA).**

smaller amount of light from the Moon. As with rainbows, they are in the opposite part of the sky from the moon. It is difficult to discern the rainbow colors due to the faint nature of a moonbow, so it often appears as a pale, white arc.

History. The Persian astronomer Qutb al-Din al-Shirazi is thought to have first given a fairly accurate explanation for the rainbow phenomenon. The work of Robert Grosseteste on light was continued by Roger Bacon, who wrote in his *Opus Majus* of 1268 (http://www.fordham.edu/halsall/source/bacon2.html) about experiments with light shining through crystals and water droplets showing the colours of the rainbow. Theodoric of Freiberg is also known to have given an accurate theoretical explanation of the rainbow in 1307: he postulated that when sunlight falls on individual drops of moisture, the rays undergo two refractions (upon ingress and egress) and one reflection (at the back of the drop) before transmission into the eye of the observer" (quoted from David C, Lindberg, *Roger Bacon's Theory of the Rainbow: Progress or Regress?*, Isis, Vol. 57, no. 2, p. 236.).

Descartes, in 1637, further advanced this explanation. Knowing that the size of raindrops didn't appear to affect the observed rainbow, he experimented with passing rays of light through a large glass sphere filled with water. By measuring the angles that the rays emerged, he concluded that the primary bow was caused by a single internal reflection inside the raindrop and that a secondary bow could be caused by two internal reflections. He was able to back this up with a derivation of the law of refraction (subsequently, but independently of, Snell) and correctly calculated the angles for both bows. However, he was unable to explain the colours.

Isaac Newton was the first to demonstrate that white light was composed of the light of all the colours of the rainbow, which a glass prism could split into the full spectrum of colours. He also showed that red light gets refracted less than blue light, which led to the first scientific explanation of the major features of the rainbow. Newton's corpuscular theory of light was unable to explain supernumary rainbows, and a satisfactory explanation was not found until Thomas Young realised that light behaves as a wave under certain conditions, and can interfere with itself.

Young's work was refined in the 1820s by George Biddell Airy, who explained the dependence of the strength of the colours of the rainbow on the size of the water droplets. Modern physical descriptions of the rainbow are based on Mie scattering, work published by Gustav Mie in 1908. Advances in computational methods and optical theory continue to lead to a fuller understanding of rainbows. For example, Nussenzveig provides a modern overview. Nussenzveig, H. Moyses: "The Theory of the Rainbow," *Scientific American* 236: 116, 1977.

Mirage

A mirage, derived from the Latin mirari, meaning "to be astonished", is a curious atmospheric phenomenon caused by the total reflection of light at a layer of rarefied air. The most familiar manifestation is observed in warm weather on paved highways. The air next to the pavement becomes heated and rarefied in comparison with that above it, so that, at a sufficient angle of incidence, objects beyond the area are mirrored as if by polished silver, giving the almost irresistible impression that one is looking at a layer of water. Travelers in hot desert regions are sometimes thus deceived. Much more rarely the phenomenon appears in the air at a higher level than the observer. In either case, the images are inverted; and because of the irregular contour of the air layer, they are usually distorted. A somewhat different effect, known as *looming*, is produced by the refraction of light passing from rarefied air to a lower and denser layer. This results either in distortion, making distant objects appear grotesquely elongated vertically, or in lifting into view objects beyond the horizon. Looming effects are most frequently observed at sea.

Twilight and Afterglows

Twilight is that period between sunset and night and between night and sunrise. Civil Twilight is the period when the sun is between 0° and 6° below the horizon. Nautical Twilight is that period when the sun is between 0° and 12° below the horizon. Astronomical Twilight is that period when the sun is 0° and 18° below the horizon. Night is the period when the sun is more than 18° below the horizon.

The curtain of night is a relatively sharp slightly curved line across the sky that rises in the east in the evening. The night recedes in the east before the line of dawn, which is also a slightly curved line, appears. Both the curtain of night and the line of dawn are best observed from an aircraft flying at a high altitude from which position both lines can be sharply delineated.

Afterglow. A broad, high arch of radiance seen occasionally in the western sky above the highest clouds in deepening twilight. It is caused by the scattering effect exerted upon the components of white light by very fine particles of material suspended in the upper atmosphere. When used in this rather broad sense, the term embraces all the complex luminosity observed in the western twilight sky, but chiefly the purple light and the bright segment.

The purple light is the faint purple glow observed on clear days over a large region of the western sky after sunset, and over the eastern sky before sunrise. The purple light first appears, in the sunset case, for example, at a solar depression of 2°; at that time, it extends from about 35° to about 50° elevation above the solar point, and has an azimuthal extent of between 40° and 80°. Maximum intensity of the glow typically occurs at the time the sun is about 4° below the horizon. Increasing depression of the sun causes the top of the purple light to descend steadily toward the western horizon. The effect disappears at solar depression angles near 7°, being replaced in the western sky by the bright segment.

Whiteout. Also termed milky weather, whiteout is an atmospheric optical phenomenon of the polar regions in which the observer appears to be engulfed in a uniformly white glow. Neither shadows, horizon, nor clouds are discernible; senses of depth and orientation are lost; only very dark, nearby objects can be seen.

For a description of aurora and air glow, see **Aurora and Airglow**.

Fig. 4. Primary and secondary rainbows are visible, as well as a reflected primary and a faintly visible reflection primary. (*image courtesy of David Sinson, NOAA, Office of Coast Survey*).

Polarization of Sky Radiation

There are three commonly detectable points of zero polarization of diffuse sky radiation, neutral points, lying along the vertical circle through the sun:

Arago Point. Named for its discoverer, the Arago point is customarily located at about 20° above the antisolar point; but it lies at higher altitudes in turbid air. The latter property makes the Arago distance a useful measure of atmospheric turbidity.

Babinet Point. This point typically lies only 15° to 20° above the sun, and hence is difficult to observe because of solar glare. The existence of this neutral point was discovered by Babinet in 1840.

Brewster Point. Discovered by Brewster in 1840, this neutral point is located about 15° to 20° directly below the sun; hence, it is difficult to observe because of the glare of the sun.

Zodiacal light is not an atmospheric phenomenon. See **Zodiacal Light**.

ATMOSPHERIC OZONE. A minor but important constituent (chemical symbol O_3) of the earth's atmosphere. While it is essential for life as we know it today, it is also a toxic gas that can result in significant physiological and ecological damage if exposures exceed critical limits. In both the stratosphere and troposphere, ozone concentration levels depend on many linked chemical and meteorological mechanisms, which vary significantly with space and time. Human pollutant emissions often perturb these linkages, resulting in significant increases or decreases in ozone concentration. While many facets of ozone's atmospheric behavior are well understood, a large number of important uncertainties remain, the resolution of which will require substantial combined efforts by the meteorological and chemical communities. See also **Ozone**; **Stratospheric Ozone**; and **Tropospheric Ozone**.

ATMOSPHERIC PHYSICS. Atmospheric physics deals with the application of physical laws to the study of the structure, composition, and motion of the atmosphere. Most importantly Earth's with the aim of understanding the complex interactions between different components of the atmosphere such as aerosols, clouds, turbulence, and electromagnetic radiation. It forms the basis for, but is not limited to, the study of weather and climate, for this reason, a major goal of the discipline is to develop an understanding of atmospheric behavior that is good enough to allow predictions of the evolution of the atmosphere over time scales from days to decades, on spatial scales from a few kilometers to the whole globe.

Attempts, to understand the effects of the atmosphere on man's environment date back to the origin of science itself. At the present time, considerable attention is being focused by the public, politicians, and media

on fears that the habitability of the Earth is being altered as an inadvertent side-effect of increasing industrialization. As a result, atmospheric physics is one of the most rapidly growing and widely discussed areas of applied physics at the present time.

In the simplest physical terms, atmospheric science is basically the study of a relatively thin, radioactively heated and cooled layer of mixed gases on a large, rapidly rotating sphere with an uneven surface and with chemical activity and all three phases of water present. Because it deals with basic processes, atmospheric physics as a field is not restricted to the single example of the Earth. Eight bodies in the solar system are known to have substantial atmospheres and exhibit structure and behavior analogous to that on the Earth. Information about these derived from astronomical observations and space experiments can be used to make powerful tests of theories and models of atmospheric systems.

The three main cornerstones of the discipline are the subfields of atmospheric radiation (that is, electromagnetic radiation from the sun and terrestrial infrared radiation, and their quantum interactions with atmospheric molecules), geophysical thermodynamics, and gas-phase chemistry, especially photo-chemistry. The coupling between the various processes in these categories is extensive and important, and progress with a theoretical understanding of atmospheric processes, as well as attempts at prediction (weather and climate forecasting), depends to an increasing extent on vast computer models. The experimental side of the field is now dominated by the development of increasingly large and complex optical instruments, radiometers and spectrometers, deployed in space on satellites. Such experiments produce formidable quantities of raw data, and processing and analyzing the information from satellites also call for a very high level of computing power and sophistication.

Thus the field of atmospheric physics unites many areas of basic physics and engineering to address a topic of great complexity and relevance to society.

See also **Atmosphere (Earth)**; **Climate**; **Meteorology**; and **Weather Technology**.

ATMOSPHERIC POLARIZATION. Polarization in the clear daytime sky can be quantified by the degree of linear polarization P and by the vibration ellipse orientation for skylight's polarized component.

For Stokes's parameters, I (the scattered irradiance), Q, U, and V, skylight's linear polarization P is

$$P = \frac{(Q^2 + U^2)^{1/2}}{I},$$

thus ignoring its minimal degree of circular polarization, $\frac{V}{I}$. P is zero at neutral points and has local maxima along a celestial great circle that is 90° from the sun. At sunrise and sunset, this great circle is a sky meridian perpendicular to the clear sky's principal plane.

ATMOSPHERIC PRESSURE. Also termed *barometric pressure*, atmospheric pressure is the pressure exerted by the atmosphere as a consequence of gravitational attraction on the vertical column of air lying directly above the surface of the earth upon which the pressure is effective. As with any gas, atmospheric pressure is ultimately explainable in terms of the kinetic energy of impacting constituent atmospheric gases upon the surface that experiences the pressure.

Atmospheric pressure is one of several basic meteorological parameters. It is measured fundamentally by the height of a column of mercury (or other heavy fluids) in a sealed and evacuated tube, one end of which is exposed to the air. Atmospheric pressure forces the mercury to rise in the sealed and evacuated portion of the tube to a height at which the weight of the mercury exactly balances the weight of the air column resting on the open end of the tube. Such an instrument is called a barometer.

Air pressure is expressed in several ways. The most commonly used unit in meteorology is the *millibar* in which one millibar equals 1000 dynes per square centimeter. Atmospheric pressure averages about 1013.2 millibars at sea level. The kilopascal (kPa) is also a measure of atmospheric pressure. One kPa = 10 millibars. In the kPa system, average atmospheric pressure is 101.325 kPa. The height of the mercury column in a barometer is also used, either as millimeters or inches of mercury. Average sea level pressure in this system is 760 millimeters or 29.92 inches of mercury. Pounds per square inch is used in engineering. The term atmosphere is also used, one atmosphere being average sea level air pressure.

Hydrostatic Equation. Pressure-altitude relations in the atmosphere are mathematically precise and can be determined from the hydrostatic equation:

$$\frac{\partial p}{\partial h} = -\rho g$$

and the equation of state for air,

$$p = \rho RT$$

which leads to the relation

$$p = p_0 \left[\frac{T_0 - \lambda h}{T_0} \right]^{g/R\lambda}$$

where p = pressure
p_0 = pressure at height zero
h = altitude
ρ = density
g = acceleration of gravity
T = temperature (absolute)
T_0 = temperature at height zero (also absolute)
R = universal gas constant
λ = lapse rate and is constant

In the real atmosphere, many layers of air, each having its own approximately constant lapse rate of temperature, press down on each other to create the total air pressure at the base of the bottom layer. Air pressure results from

$$p_0 = p_1 + p_2 + p_3 \cdots + p_n = \sum_1^n p_i$$

where the p's are valid at the base of their respective layers. A fictitious lapse rate can be used that will yield nearly the same results as the combined pressures of the several uniform layers.

When the atmosphere is isothermal, as it very nearly is in the stratosphere, the pressure-height relationship becomes

$$p = p_0 e^{-gh/RT}$$

These relations state that (1) pressure decreases more rapidly with altitude when the temperature is low than when temperature is high; and (2) pressure decreases more rapidly with altitude when the lapse rate is large than when it is small.

The standard atmosphere is used for calibration of altimeters. It is not very often that the real atmosphere assumes the arbitrarily assigned values of the standard atmosphere; therefore, altimeters do not often indicate exact altitude.

Total mass of air per cubic centimeter is the *density of air*.

Air density at standard conditions of 0°C and 760 millimeters of mercury is 0.0012930 gram per cubic centimeter of air free from water vapor. The standard density of air at 32°F and 14.7 pounds pressure is 0.081 pound per cubic foot (1.3 kilograms per cubic meter) and its composite molecular weight is 28.84.

The variation of air pressure with altitude is given in Table 1. See also **Atmosphere (Earth)**.

TABLE 1. VARIATION OF AIR PRESSURE WITH ALTITUDE IN STANDARD ATMOSPHERE AS USED IN ALTIMETRY

ALTITUDE		PRESSURE		
Feet	Meters	Inches of Mercury	Millibars	Pounds per Square Inch
Sea Level	Sea Level	29.92	1013.2	14.7
1000	304.8	28.86	977.3	14.2
5000	1524	24.89	842.9	12.2
10,000	3048	20.58	696.9	10.1
15,000	4572	16.88	571.6	8.3
20,000	6096	13.75	465.6	6.8
25,000	7620	11.10	375.9	5.4
30,000	9144	8.88	300.7	4.4
40,000	12,192	5.54	187.6	2.7
50,000	15,240	3.44	116.5	1.7

Scale Height. This is a measure of the relationship between density and temperature at any point in an atmosphere; the thickness of a homogeneous atmosphere which would give the observed temperature:

$$h = kT/mg = RT/Mg$$

where k is the Boltzmann constant; T is the absolute temperature; m and M are the mean molecular mass and the molar mass of the layer; g is the acceleration of gravity; and R is the universal gas constant.

See also **Barometer**. For references see entries on **Climate**; and **Meteorology**.

PETER E. KRAGHT, Consulting Meteorologist, Mabank, TX

ATMOSPHERICS. The radio frequency electromagnetic radiation originating, principally, in the irregular surges of charge in thunderstorm lightning discharges. Also called *atmospheric interference, strays, and sferics.*

Atmospherics are heard as a quasi-steady background of crackling noise (static) on certain radio frequencies, such as those used to broadcast AM radio signals. Since any acceleration of electric charge leads to emission of electromagnetic radiation, and since the several processes involved in propagation of lightning lead to very large charge accelerations, the lightning channel acts like a huge transmitter, sending out radiation with frequencies of the order of 10 kHz. Atmospherics may occasionally be detected at distances in excess of 3500 km (2000 mi) from their source. Advantage has been taken of this characteristic by using radio direction-finding equipment to plot cloud-to-ground lightning locations, and to locate active thunderstorm areas in remote regions and in-between weather reporting stations. See also **Lightning**.

ATMOSPHERIC SCIENTISTS. Atmospheric science is the study of the atmosphere — the blanket of air covering the Earth. *Atmospheric scientists*, commonly called *meteorologists*, study the atmosphere's physical characteristics, motions, and processes, and the way in which it affects the rest of our environment. The best known application of this knowledge is in forecasting the weather. Aside from predicting the weather, scientists also attempt to identify and interpret climate trends, understand past weather, and analyze today's weather. However, weather information and meteorological research also are applied in air-pollution control, agriculture, forestry, air and sea transportation, defense, and the study of possible trends in the Earth's climate, such as global warming, droughts, or ozone depletion.

Atmospheric scientists who forecast the weather, known professionally as *operational meteorologists*, are the largest group of specialists. They study information on air pressure, temperature, humidity, and wind velocity; and apply physical and mathematical relationships to make short-range and long-range weather forecasts. Their data come from weather satellites, weather radars, sensors, and weather stations in many parts of the world. Meteorologists use sophisticated computer models of the world's atmosphere to make long-term, short-term, and local-area forecasts. More accurate instruments for measuring and observing weather conditions, as well as high-speed computers to process and analyze weather data, have revolutionized weather forecasting. Using satellite data, climate theory, and sophisticated computer models of the world's atmosphere, meteorologists can more effectively interpret the results of these models to make local-area weather predictions. These forecasts inform not only the general public, but also those who need accurate weather information for both economic and safety reasons, such as the shipping, air transportation, agriculture, fishing, forestry, and utilities industries. See also **Geostationary Operational Environmental Satellite (GOES)**; **Polar-Orbiting Environmental Satellite (POES)**; **Nimbus Satellite Program**; and **Weather Satellites**.

The use of weather balloons, launched a few times a day to measure wind, temperature, and humidity in the upper atmosphere, is currently supplemented by sophisticated atmospheric monitoring equipment that transmits data as frequently as every few minutes. Doppler radar, for example, can detect airflow patterns in violent storm systems — allowing forecasters to better predict tornadoes and other hazardous winds, and to monitor the storms' direction and intensity. Combined radar and satellite observations allow meteorologists to predict flash floods. See also **Balloon**; and **Weather Technology**.

Some atmospheric scientists work in research. *Physical meteorologists*, for example, study the atmosphere's chemical and physical properties; the transmission of light, sound, and radio waves; and the transfer of energy in the atmosphere. They also study factors affecting the formation of clouds, rain, and snow; the dispersal of air pollutants over urban areas; and other weather phenomena, such as the mechanics of severe storms. *Synoptic meteorologists* develop new tools for weather forecasting using computers and sophisticated mathematical models of atmospheric activity. *Climatologists* study climactic variations spanning hundreds or even millions of years. They also may collect, analyze, and interpret past records of wind, rainfall, sunshine, and temperature in specific areas or regions. Their studies are used to design buildings, plan heating and cooling systems, and aid in effective land use and agricultural production. Environmental problems, such as pollution and shortages of fresh water, have widened the scope of the meteorological profession. *Environmental meteorologists* study these problems and may evaluate and report on air quality for environmental impact statements. Other research meteorologists examine the most effective ways to control or diminish air pollution.

Training, Other Qualifications, and Advancement

A bachelor's degree in meteorology or atmospheric science, or in a closely related field with courses in meteorology, usually is the minimum educational requirement for an entry-level position as an atmospheric scientist.

The preferred educational requirement for entry-level meteorologists in the Federal Government is a bachelor's degree — not necessarily in meteorology — with at least 24 semester hours of meteorology courses, including 6 hours in the analysis and prediction of weather systems, 6 hours of atmospheric dynamics and thermodynamics, 3 hours of physical meteorology, and 2 hours of remote sensing of the atmosphere or instrumentation. Other required courses include 3 semester hours of ordinary differential equations, 6 hours of college physics, and at least 9 hours of courses appropriate for a physical science major — such as statistics, chemistry, physical oceanography, physical climatology, physical hydrology, radiative transfer, aeronomy, advanced thermodynamics, advanced electricity and magnetism, light and optics, and computer science. Sometimes, a combination of education and appropriate experience may be substituted for a degree.

Although positions in operational meteorology are available for those with only a bachelor's degree, obtaining a second bachelor's degree or a master's degree enhances employment opportunities and advancement potential. A master's degree usually is necessary for conducting applied research and development, and a Ph.D. is required for most basic research positions. Students planning on a career in research and development need not necessarily major in atmospheric science or meteorology as an undergraduate. In fact, a bachelor's degree in mathematics, physics, or engineering provides excellent preparation for graduate study in atmospheric science.

Because atmospheric science is a small field, relatively few colleges and universities offer degrees in meteorology or atmospheric science, although many departments of physics, earth science, geography, and geophysics offer atmospheric science and related courses. Prospective students should make certain that courses required by the National Weather Service and other employers are offered at the college they are considering. Computer science courses, additional meteorology courses, a strong background in mathematics and physics, and good communication skills are important to prospective employers. Many programs combine the study of meteorology with another field, such as agriculture, oceanography, engineering, or physics. For example, hydrometeorology is the blending of hydrology (the science of Earth's water) and meteorology, and is the field concerned with the effect of precipitation on the hydrologic cycle and the environment. Students who wish to become broadcast meteorologists for radio or television stations should develop excellent communication skills through courses in speech, journalism, and related fields. Those interested in air quality work should take courses in chemistry and supplement their technical training with coursework in policy or government affairs. Prospective meteorologists seeking opportunities at weather consulting firms should possess knowledge of business, statistics, and economics, as an increasing emphasis is being placed on long-range seasonal forecasting to assist businesses.

Beginning atmospheric scientists often do routine data collection, computation, or analysis, and some basic forecasting. Entry-level operational meteorologists in the Federal Government usually are placed in intern positions for training and experience. During this period, they learn about the Weather Service's forecasting equipment and procedures, and rotate to different offices to learn about various weather systems. After completing the training period, they are assigned a permanent duty station. Experienced meteorologists may advance to supervisory or administrative jobs, or may handle more complex forecasting jobs. After several years of experience, some meteorologists establish their own weather consulting services.

The American Meteorological Society http://www.ametsoc.org/, offers professional certification of consulting meteorologists, administered by a Board of Certified Consulting Meteorologists. Applicants must meet formal education requirements (though not necessarily have a college degree), pass an examination to demonstrate thorough meteorological knowledge, have a minimum of 5 years of experience or a combination of experience plus an advanced degree, and provide character references from fellow professionals.

Employment of atmospheric scientists is projected to increase about as fast as the average for all occupations through 2014. The National Weather Service has completed an extensive modernization of its weather forecasting equipment and finished all hiring of meteorologists needed to staff the upgraded stations. The Service has no plans to increase the number of weather stations or the number of meteorologists in existing stations. Employment of meteorologists in other Federal agencies is expected to remain stable.

On the other hand, job opportunities for atmospheric scientists in private industry are expected to be better than for those in the Federal Government over the 2004-14 period. As research leads to continuing improvements in weather forecasting, demand should grow for private weather consulting firms to provide more detailed information than has formerly been available, especially to weather-sensitive industries. Farmers, commodity investors, radio and television stations, and utilities, transportation, and construction firms can greatly benefit from additional weather information more closely targeted to their needs than the general information provided by the National Weather Service. Additionally, research on seasonal and other long-range forecasting is yielding positive results, which should spur demand for more atmospheric scientists to interpret these forecasts and advise weather-sensitive industries. However, because many customers for private weather services are in industries sensitive to fluctuations in the economy, the sales and growth of private weather services depend on the health of the economy.

There will continue to be demand for atmospheric scientists to analyze and monitor the dispersion of pollutants into the air to ensure compliance with Federal environmental regulations outlined in the Clean Air Act of 1990, but related employment increases are expected to be small. Opportunities in broadcasting are rare and highly competitive, making for very few job openings.

U.S. Department of Labor, Bureau of Labor Statistics

ATMOSPHERIC SHELL. (Also called atmospheric layer, atmospheric region). Any one of a number of strata or "layers" of the earth's atmosphere. See also **Atmosphere (Earth)**.

Temperature distribution is the most common criterion used for denoting the various shells. The troposphere (the "region of change") is the lowest 10 or 20 km (6 or 12 miles) of the atmosphere, characterized by decreasing temperature with height. The term stratosphere is used to denote both 1) the relatively isothermal region immediately above the tropopause, and 2) the shell extending upward from the tropopause to the minimum temperature level at 70–80 km (43.5–50 miles); the mesosphere is the shell between about 20 (12 miles) and 70 or 80 km (43.5 or 50 miles) that has a broad maximum temperature at about 40 or 50 km (25 or 31 miles); and the thermosphere is the shell above the mesosphere with a more or less steadily increasing temperature with height. The distribution of various physicochemical processes is another criterion. The ozonosphere, lying roughly between 10 and 50 km (6 and 31 miles), is the general region of the upper atmosphere in which there is an appreciable ozone concentration and in which ozone plays an important part in the radiative balance of the atmosphere. The ionosphere, starting at about 70 or 80 km (43.5 or 50 miles), is the region in which ionization of one or more of the atmospheric constituents is significant. The neutrosphere, the shell below this, is, by contrast, relatively un-ionized. The chemosphere, with no very definite height limits, is the region in which photochemical reactions take place. Dynamic and kinetic processes are a third criterion. The exosphere is the region at the "top" of the atmosphere, above the critical level of escape, in which atmospheric particles can move in free orbits, subject only to the earth's gravitation. Composition is a fourth criterion. The homosphere is the shell in which there is so little photo-dissociation or gravitational separation that the mean molecular weight of the atmosphere is sensibly constant; the heterosphere is the region above this, where the atmospheric composition and mean molecular weight is not constant. The boundary between the two is probably at the level at which molecular oxygen begins to be dissociated, and this occurs in the vicinity of 80 or 90 km (50 or 56 miles). For further subdivisions, see **Ionosphere**; and **Troposphere**.

See also **Mesosphere**; **Ozonosphere**; **Tropopause**; **Stratosphere**

ATMOSPHERIC TURBULENCE. Air usually flows from one point to another in a turbulent manner, that is, the flow is infested with a multitude of small deviations of speed in all directions. This phenomenon has been observed for hundreds of years in the spreading and dissipation of smoke plumes. This can be demonstrated by inserting a pencil-sized smoke source into a wind stream. The thread of visible smoke does not extend downwind in a straight, thin line, but rather follows a zigzag path, spreading out and expanding downwind. This behavior demonstrates the presence of turbulence in the atmosphere.

When specific instantaneous speeds of the wind are measured at a point for a relatively large number of observations over a comparatively brief period, and this ensemble of data is averaged, the small deviations in speed all cancel each other with the mean speed remaining.

Moving air behaves as if embedded eddies of varying sizes roll and migrate, eventually to be absorbed into another part of the main airstream, merge with other eddies, or dissipate some distance from their origin. The result of turbulent flow is the transport of atmospheric pollutants, particulates, water vapor, heat, and momentum.

The *mixing length* is a rather imprecisely defined distance over which eddies of a certain size are able to transport their own embedded properties. Thus, during its life span, an eddy rolls and migrates from one point in the airstream to another, carrying its implanted pollutants, particulates, water vapor, heat, and momentum but shedding these as it travels to become totally lost at the end of its mixing length. The concept is similar to that of the mean free path in molecular theory.

Turbulent flow in the atmosphere has many significant meteorological consequences. Among others, the shape of the wind-speed profile just above the earth in the lower 500 meters depends in large part on the turbulent mixing in that layer. The speed profile is nearly always one in which there is a rapid increase just above the ground, but increasing less

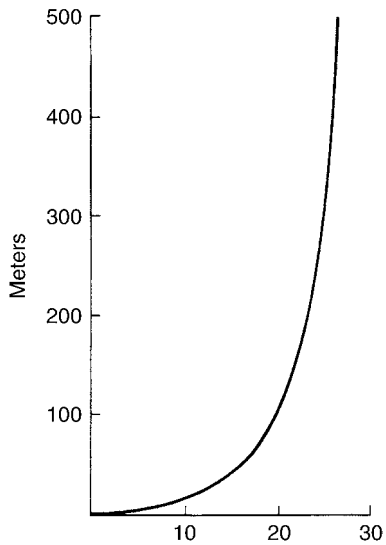

Fig. 1. Wind speed profile based on the model: $V = 10 \log h$, where V is in knots and h is in meters.

rapidly at higher levels. Exponential and logarithmic models describe the profile theoretically. See Fig. 1.

Industrial pollutants are distributed upward and laterally by atmospheric turbulence as they are carried downwind in the large-scale airflow. Acid rain and snow fall hundreds of miles from the pollutant source region. A specialized field of industrial meteorology has emerged in the past 35 years to deal with the problems of industrial pollutants in the atmosphere.

Water vapor in the atmosphere originates primarily from the oceans, rivers, and lakes, as well as from transpiration from vegetation. These sources are all at the earth's surface. Eddies in the turbulent flow of the atmosphere distribute the water vapor and thus rain and snow fall far from the source of moisture.

Condensation and sublimation nuclei are dispersed extensively throughout the tropopause by turbulent flow. Salt particles from sea spray are among the nuclei that are distributed everywhere by atmospheric turbulence. These nuclei join other factors in causing rain and snow.

Heat is transported upward by eddies in turbulent flow, thus "cooling" the earth's surface and "warning" the higher atmospheric layers.

Eddies in turbulent flow of sufficiently large dimensions can alter the longitudinal air flow past aircraft in flight, thus causing rough-flying air. Most such rough air is simply an annoyance to travelers, but in some instances, may jolt the aircraft and toss items in the cabin around.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

ATOLL. A coral reef of ring-shape and appearing as a low, essentially circular, but sometimes elliptical or horseshoe shaped island. An atoll also may be a ring of closely spaced coral islets which encircle or nearly encircle a shallow lagoon where there is evidence of preexisting land of non-coral origin, and surrounded by deep water in the open sea. Atolls are common in the western and central Pacific Ocean.

ATOM. An atom is a basic structural unit of matter, being the smallest particle of an element that can enter into chemical combination. Each atomic species has characteristic physical and chemical properties that are determined by the number of constituent particles (protons, neutrons, and electrons) of which it is composed; especially important are the number Z of protons in the nucleus of each atom. To be electrically neutral the number of electrons in an atom must also be Z. The arrangement of these electrons in the internal structure of an atom determines its chemical properties. All atoms having the same atomic number Z have the same chemical properties, but differ in greater or lesser degree from atoms having any other value of Z. Thus, for example, all atoms of sodium ($Z = 11$) exhibit the same characteristic properties and undergo those reactions which chemists have found for the element sodium. Although these reactions are similar in some degree to those reactions characteristics of certain other elements, such as potassium and lithium, they are not exactly the same and hence can be distinguished chemically (see **Chemical Elements**), so sodium has properties distinctly different from those of all other elements. Individual atoms can usually combine with other atoms of either the same or another species to form molecules.

As explained in the entry on atomic structure, atoms having the same atomic number may differ in their neutron numbers or in their nuclear excitation energies.

The term *atom* has a long history, which goes back as far as the Greek philosopher Democritus. The concept of the atomic nature of matter was revived near the beginning of the nineteenth century. It was used to explain and correlate advancing knowledge of chemistry and to establish many of the basic principles of chemistry, even though conclusive experimental verification for the existence of atoms was not forthcoming until late in the nineteenth century. It was on the basis of this concept that Mendeleev first prepared a periodic table. See **Periodic Table of the Elements**.

Several qualifying terms are used commonly to refer to specific types of atoms. Examples of some of the terms are given in the following paragraphs.

An *excited atom* is an atom that possesses more energy than a normal atom of that species. The additional energy commonly affects the electrons surrounding the atomic nucleus, raising them to higher energy levels.

An *ionized atom* is an ion, which is an atom that has acquired an electric charge by gain or loss of electrons surrounding its nucleus.

A *labeled atom* is a tracer which can be detected easily, and which is introduced into a system to study a process or structure. The use of those labeled atoms is discussed at length in the entry **Isotope**.

A *neutral atom* is an atom that has no overall, or resultant, electric charge.

A *normal atom* is an atom which has no overall electric charge, and in which all the electrons surrounding the nucleus are at their lowest energy levels.

A *radiating atom* is an atom that is emitting radiation during the transition of one or more of its electrons from higher to lower energy states.

A *recoil atom* is an atom that undergoes a sudden change or reversal of its direction of motion as the result of the emission by it of a particle or radiation in a nuclear reaction.

A *stripped atom* is an atomic nucleus without surrounding electrons; also called a nuclear atom. It has, of course, a positive electric charge equal to the charge on its nucleus.

Subatomic particles and organization of the atom are discussed in the entry **Particles (Subatomic)**.

ATOMIC CLOCKS. These devices make use of a property that is generally found only in systems of atomic dimensions. Such systems cannot contain arbitrary amounts of energy, but are restricted to an array of allowed energy values $E_0, E_1, \ldots, E_n$. If an atomic system is to change its energy between two allowed values, it must emit (or absorb) the energy difference — as by emission (or absorption) of a quantum of electromagnetic radiation. The frequency f_{ij} of this radiation is determined by the relation

$$|E_i - E_j| = \Delta E = hf_{ij}$$

where h is Planck's constant. The rate of an atomic clock is controlled by the frequency f_{ij} association with the transition from the state of energy E_i to the state of energy E_j of a specified atomic system, such as a cesium atom or an ammonia molecule. A high-frequency electromagnetic signal is stabilized in the atomic frequency f_{ij} and a frequency converter relates the frequency f_{ij} to a set of lower frequencies which then may be used to run a conventional electric clock.

The atomic frequency f_{ij} is, according to present knowledge, free of inherent errors. It is, in particular, not subject to "aging" since any transition that the system makes puts it in a state of completely different energy, where it cannot falsify the measurement. Herein lies the principal advantage over other methods of time measurement. Two atomic clocks have exactly the same calibration so long as they are calibrated against the same atomic transition. Atomic readings made in Boulder, Colorado and Neufchâtel, Switzerland between 1960 and 1963 differed on the average by less than 3 msec, whereas the deviation of the astronomically measured time TU_2 from atomic time is of the order of 50 msec. For this reason, the atomic second was adopted as the new time unit, by the Twelfth General Conference on Weights and Measures, in October 1964. This was initially defined as the time interval spanned by 9,192,631,770 cycles of the transition frequency between two hyperfine levels of the atom of cesium 133 undisturbed by external fields. See also "Atomic Clock" in entry on **Clock**.

The accuracy of present atomic clocks is limited by the thermal noises inherent at room temperatures. Theoretically, this limitation could be removed if the clocks were maintained in an atmosphere approaching absolute zero. However, some atomic clocks, like hydrogen maser clocks, stop oscillating when they are supercooled. In 1979, scientists at the Harvard-Smithsonian Center for Astrophysics overcame this problem by coating a supercooled maser cavity with carbon tetrafluoride. With the CF_4 frozen on the interior surfaces of the cavity, the oscillating hydrogen atoms could be reflected off the walls without becoming perturbed, thus preserving the phase of the oscillations. The researchers were able to keep a hydrogen maser clock operating at temperatures somewhat above 25 K. It has been estimated that a hydrogen maser clock cooled to about 25 K could

run for 300 million years before losing one second of time, a factor some six times better than present hydrogen masers. The Center for Astrophysics is interested in improved maser clocks in connection with long-baseline interferometry and satellite tracking systems. It is also envisioned that a supercooled clock put on a space probe could be helpful in research on gravity waves and possibly provide clues toward better understanding the sun's mass distribution and angular momentum.

Refer to article on **Relativity and Relativity Theory** for description of the Sagnac effect. An atomic clock moved once around the Earth's equator in an easterly direction will *lag* a master clock at rest on the Earth by about 207.4 nanoseconds; a clock similarly moved in a westerly direction will *lead* the clock at rest by about 207.4 nanosceconds.

ATOMIC DISINTEGRATION. The name sometimes given to radioactive decay of an atomic nucleus and occasionally to the breakup of a compound nucleus formed during a nuclear reaction (see **Radioactivity**).

ATOMIC ENERGY. 1. The constitutive internal energy of the atom, which would be released when the atom is formed from its constituent particles, and absorbed when it is broken up into them. This is identical in magnitude with the total binding energy and is proportional to the mass defect. 2. Sometimes this term is used to denote the energy released as the result of the disintegration of atomic nuclei, particularly in large-scale processes, but such energy is more commonly called nuclear energy. See **Nuclear Power Technology**.

ATOMIC ENERGY LEVELS. 1. The values of the energy corresponding to the stationary states of an isolated atom. 2. The set of stationary states in which an atom of a particular species may be found, including the ground state, or normal state, and the excited states.

ATOMIC FREQUENCY. The vibrational frequency of an atom, used particularly with respect to the solid state.

ATOMIC HEAT. The product of the gram-atomic weight of an element and its specific heat. The result is the atomic heat capacity per gram-atom. For many solid elements, the atomic heat capacity is very nearly the same, especially at higher temperatures and is approximately equal to $3R$, where R is the gas constant (Law of Dulong and Petit).

ATOMIC HEAT OF FORMATION. Of a substance, the difference between the enthalpy of one mole of that substance and the sum of the enthalpies of its constituent atoms at the same temperature; the reference state for the atoms is chosen as the gaseous state. The atomic heat of formation at 0 K is equal to the sum of all the bond energies of the molecule, or to the sum of all the dissociation energies involved in any scheme of step-by-step complete dissociation of the molecule.

ATOMIC MASS (Atomic Weight). As of the late 1980s, the current and internationally accepted unit for atomic mass is *1/12th of the mass of an atom of the ^{12}C nuclide and the official symbol is u*. The SI symbol *u* was selected so that it would indicate measurements made on the unified scale.[1]

It is interesting to note that prior to 1961, *two* atomic mass scales were used. Chemists preferred a scale based on the assignment of *exactly* 16, which experience had shown as the *average* mass of oxygen atoms as they are found in nature. On the other hand, physicists preferred to base the scale on a single isotope of oxygen, namely, ^{16}O (oxygen-16). The two scales differed because oxygen has three stable isotopes, ^{16}O, ^{17}O, and ^{18}O (as well as three identifiable radioactive isotopes, ^{14}O, ^{15}O, and ^{19}O).

Long before an understanding of the structure of the atom had been established and before the existence of isotopes was evidenced, several pioneers proposed what have become known as the concepts (laws) of:

Combining Volumes — under comparable conditions of pressure and temperature, the volume ratios of gases involved in chemical reactions are simple whole numbers

Combining Weights — if the weights of elements that combine with each other be called their 'combining weights,' then elements always combine either in the ratio of their combining weights or of simple multiples of these weights.

This then led to the establishment of the basic principle that the *combining weight of an element or radical is its atomic weight divided by its volume*.

Although the tables of atomic weights published today embrace all of the known chemical elements, it should be pointed out that the concept of combining weights stemmed exclusively from very early experiments strictly with *gases*. The kinetic theory of gases, which was developed from a line of logic that did not require the innermost understanding of the atom as we know it today, served as the early basis of how atoms react in quantitative proportions with each other to form compounds.

Boyle (1662) observed that at constant temperature the volume of a sample of gas varies inversely with pressure, but Boyle did not explain why this was so. Somewhat later, Charles (1787) refined the observation to the effect that the volume of any sample of a gas varies directly with the *absolute temperature* provided that the pressure is held constant. A few years later, Gay-Lussac (1808), in reporting the results of his experiments with reacting gases, observed that volumes of gases that are used or produced in a chemical reaction can be expressed in ratios of small whole numbers — a concept to become known as Gay-Lussac's law of combining volumes. It should be noted that the foregoing concepts proposed by Boyle, Charles, and Gay-Lussac were based upon experimental observations, not on theory.

An explanation for the law of combining volumes was given by Avogadro (1811) in which he proposed that equal volumes of all gases at the same pressure and temperature contain the same number of molecules. This, obviously, was an extension of Bernoulli's earlier thinking.[2] Avogadro's observations were essentially ignored and it remained for Cannizzaro (1858–1864) to develop, in a practical way, a method for computing the combining weights for gaseous compounds. This work led to the universal acceptance of Avogadro's principle. Cannizzaro used gas densities to assign atomic and molecular weights, basing his atomic weight scale on hydrogen. The hydrogen atom was assigned a value of 1 (approximately its assigned value today). The molecular weight of hydrogen was 2.

Much further research and careful experimentation was required to convey the principle to solid compounds. See entries on **Chemical Composition**; and **Chemical Formula**.

In returning to the attractive simplicity of combining weights in terms of ratios of small whole numbers, why then is it necessary, considering the standard for comparison ($^{12}C = 12$), to extend the atomic weight values to four and more decimal places? The principal answer is the presence of isotopes. Isotopes were unknown in the days of Boyle and other early pioneers. In essence, the atomic weight of an element is a *weighted average* of the atomic masses of the natural isotopes. The weighted average is determined by multiplying the atomic mass of each isotope by its fractional abundance and adding the values thus obtained. A fractional abundance is the decimal equivalent of the percent abundance. However, for the standard of comparison, obviously a specific isotope was selected rather than a weighted average for that element.

[1] It should be stressed that *u*, as the standard for comparing the masses (weights) of all chemical elements in all kinds of chemical compounds, refers not simply to the carbon atom, but rather to one very specific isotope, carbon-12. There are two stable isotopes of carbon, ^{12}C and ^{13}C, and four known radioactive isotopes, ^{10}C, ^{11}C, ^{14}C, and ^{15}C.

[2] An attempt was made by Daniel Bernoulli (1738) to explain Boyle's law on the basis of what later became known as the *kinetic theory of gases*. Bernoulli introduced the concept that the pressure of a gas results from the collisions of gas molecules within the walls of the gas container. This established a connection between the *numbers* of gas molecules present and their kinetic energy present at any given temperature.

One might also query — since we know so much today about the masses of the protons, neutrons, and electrons comprising an atom,[3] why not simply add up these specific values for a given atom? This, of course, still would not relieve the isotope problem, but it is not accurate to do so mainly because of Einstein's equation $E = mc^2$. As pointed out by Mortimer, with the exception of $^1_1$H, the sum of the masses of the particles that make up a nucleus will always differ from the actual mass of the nucleus. If the required nucleons were brought together to form a nucleus, some of their mass would be converted into energy. Called the *binding energy*, this is also the amount of energy required to pull the nucleus apart.

For practical purposes, a majority of elements have a constant mixture of natural isotopes. For example, mass spectrometric studies of chlorine show that the element consists of 75.53% $^{35}_{17}$Cl atoms (mass = 34.97 *u*) and 24.47% $^{37}_{17}$Cl atoms (mass = 36.95 *u*). Experience has shown that any sample of chlorine from a natural source will consist of these two isotopes in this proportion.

ATOMIC MASS UNIT. See **Units and Standards**.

ATOMIC NUMBER. The number of protons (positively charged mass units) in the nucleus of an atom, upon which its structure and properties depend. This number represents the location of an element in the periodic table. It is normally the same as the number of negatively charged electrons in the shells. Thus, an atom is electrically neutral except in an ionized state, when one or more electrons have been gained or lost. Atomic numbers range from 1, for hydrogen, to 110 for darmstadtium.

See also **Atomic Mass (Atomic Weight)**; **Chemical Elements**; and **Periodic Table**.

ATOMIC ORBITALS. See **Orbitals**.

ATOMIC PERCENT. The percent by atom fraction of a given element in a mixture of two or more elements.

ATOMIC PLANE. A plane passed through the atoms of a crystal space lattice, in accordance with certain rules relating its position to the crystallographic axes. See **Mineralogy**.

ATOMIC RADIUS. See **Chemical Elements**.

ATOMIC SPECIES. A distinctive type of atom. The basis of differentiation between atoms is (1) mass, (2) atomic number, or number of positive nuclear charges, (3) nuclear excitation energy. The reason for recognizing this third class is because certain atoms are known, chiefly among those obtained by artificial transmutation, which have the same atomic (isotopic) mass and atomic number, but differ in energetics.

ATOMIC SPECTRA. An atomic spectrum is the spectrum of radiation emitted by an excited atom, due to changes within the atom; in contrast to radiation arising from changes in the condition of a molecule. Such spectra are characterized by more or less sharply defined "lines," corresponding to pronounced maxima at certain frequencies or wavelengths, and representing radiation quanta of definite energy.

The lines are not spaced at random. In the spectrum of hydrogen, for example, there is a prominent red line (H_α) and, far from it, another (H_β) in the greenish-blue, then after a shorter wavelength interval a blue-violet line (H_γ), and after a still shorter interval another violet line (H_δ), etc. One has only to plot the frequencies of these lines as a function of their ordinal number in the sequence to get a smooth curve, which shows that they are spaced in accordance with some law. In 1885, Balmer studied these lines, now called the Balmer series, and arrived at an empirical formula which in modern notation reads

$$\nu = Rc\left(\frac{1}{n_1^2} - \frac{1}{n_2^2}\right)$$

It gives the frequency of successive lines in the Balmer series if R is the Rydberg constant, c the velocity of light, $n_1 = 2$, $n_2 = 3, 4, 5, \ldots$. As n_2 becomes large, the lines become closer together and eventually reach the series limit of $\nu = Rc/4$. Ritz, as well as Rydberg, suggested that other series might occur where n_1 has other integral values. These, with their discoverers and the spectral region in which they occur are as follows:

Lyman series, far ultraviolet, $n_2 = 2, 3, 4, \ldots, n_1 = 1$
Paschen series, far infrared, $n_2 = 4, 5, 6, \ldots, n_1 = 3$
Brackett series, far infrared, $n_2 = 5, 6, 7, \ldots, n_1 = 4$
Pfund series, far infrared, $n_2 = 6, 7, 8, \ldots, n_1 = 5$

See also **Energy Level**.

ATOMIC SPECTROSCOPY. Chemical analysis by atomic absorption spectrometry involves converting the sample, at least partially, into an atomic vapor and measuring the absorbance of this atomic vapor at a selected wavelength which is characteristic for each element. The measured absorbance is proportional to concentration, and analyses are made by comparing this absorbance with that given under the same experimental conditions by reference samples of known composition. Several methods of vaporizing solids directly can be used in analytical applications. One of the first methods used was spraying a solution of the sample into a flame, giving rise to the term "absorption flame photometry." When a flame is used, the atomic absorption lines are usually so narrow (less than 0.05 Å) that a simple monochromator is not sufficient to obtain the desired resolution. Commercial atomic absorption spectrophotometers overcome this difficulty by using light sources which emit atomic spectral lines of the element to be determined under conditions which ensure that the lines in the spectrum are narrow, compared with the absorption line to be measured. With this arrangement, peak absorption can be measured, and the monochromator functions only to isolate the line to be measured from all other lines in the spectrum of the light source. See Fig. 1.

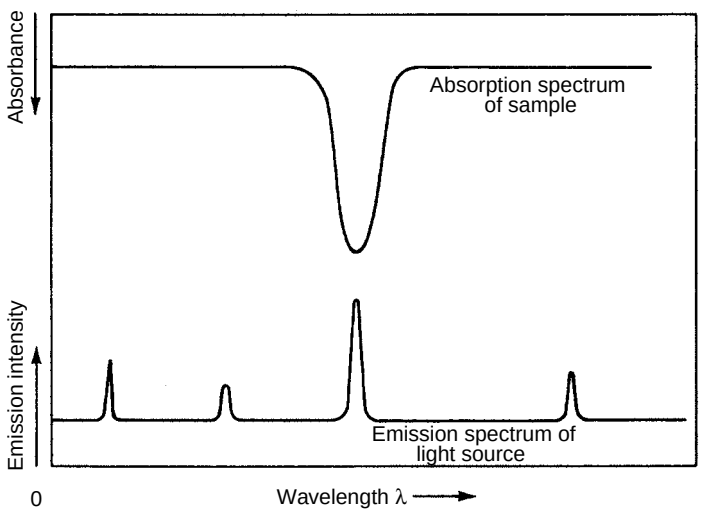

Fig. 1. Lines emitted by the light source are much narrower than the absorption line to be measured.

Atomic spectra, which historically contributed extensively to the development of the theory of the structure of the atom and led to the discovery of the electron and nuclear spin, provide a method of measuring ionization potentials, a method for rapid and sensitive qualitative and quantitative

[3] Mass of proton is 1.007277 *u*; of neutron is 1.008665 *u*; mass of electron is 0.0006486 *u*.

analysis, and data for the determination of the dissociation energy of a diatomic molecule. Information about the type of coupling of electron spin and orbital momenta in the atom can be obtained with an applied magnetic field. Atomic spectra may be used to obtain information about certain regions of interstellar space from the microwave frequency emission by hydrogen and to examine discharges in thermonuclear reactions.

ATOMIZATION. The breaking up of a liquid into small droplets, usually in a high-speed jet or film.

ATRIUM. Literally, an entrance chamber, and so applied to various organs. 1. The main part of the cavity of the middle ear. 2. The vestibule of the female genital passages. 3. A chamber into which the genital organs open in the flatworms. 4. A cavity formed of folds of the body wall in *Amphioxus* and the tunicates, which partially surrounds the pharynx and opens to the exterior by an atriopore. 5. The chamber at the end of an air tube in the lungs, with which the ultimate air sacs or alveoli communicate. 6. The chamber of the heart in vertebrates which empties into the ventricle. In this sense the term atrium is frequently replaced by auricle, although in strict terminology the auricle refers only to a small appendage of the atrium. See also **Heart and Circulatory System (Physiology)**.

ATROPHY. Physiologic or pathologic reduction in size of a mature cell or organ, usually with some degree of degeneration. Following certain diseases, types of accidents and surgery where nerves may be damaged or cut, atrophy may be temporary or permanent. Where there is traumatic injury of the nerves that cannot be repaired, atrophy is progressive. Atrophy or degeneration of the anterior lobe of the pituitary gland in adults results in Simmonds-Sheehan disease, a disorder characterized by an extreme appearance of aging. The metabolic functions of the body are affected and eventually mental functions decline as well. Pituitary atrophy is believed to result from anoxia, a lack of oxygen reaching the gland after a condition, such as postpartum hemorrhage, where excessive blood is lost. Simmonds-Sheehan disease sometimes is confused with *anorexia nervosa*, a serious nervous condition in which the patient eats little food and is greatly emaciated. A metabolic test (Metapirone test) can distinguish the two conditions. Further, in females, amenorrhea (absence of menstruation) is a constant feature of Simmonds-Sheehan disease.

ATTENUATION. 1. In its most general sense, attenuation is reduction in concentration, density or effectiveness. 2. In psychological statistics, the weakening of the correlation between two variables due to errors of measurement on them. 3. In radiation theory, attenuation is used to express the reduction in flux density, or power per unit area, with distance from the source; the reduction being due to absorption and/or scattering. In this usage, attenuation does not include the inverse-square decrease of intensity of radiation with distance from the source. 4. The same restriction applies to the use of the term in nuclear physics, where attenuation is the reduction in the intensity of radiation on passage through matter where the effect is usually due to absorption and scattering. 5. In an electric network or line, attenuation is loss, usually of current. See **Attenuation Factor**; and **Attenuator**.

In terms of scientific instruments, the Scientific Apparatus Makers Association defines attenuation as: (1) A decrease in signal magnitude between two points, or between two frequencies; and (2) The reciprocal of gain, when the gain is less than one. Attenuation may be expressed as a dimensionless ratio, scalar ratio, or in decibels as 20 times the $\log_{10}$ of that ratio.

ATTENUATION COEFFICIENT (symbol α). A measure of the space rate of attenuation of any transmitted electromagnetic radiation. The attenuation coefficient is defined by

$$dI = -aI_0 dx$$

or

$$I = I_0 e^{-ax}$$

where I is the flux density at the selected point in space; I_0 is the flux density at the source; x is the distance from the source; and a is the attenuation coefficient.

In general, the attenuation coefficient is specified only when the attenuation is known to be due to both absorption and scattering, or when it is impossible to determine which is the cause. See **Absorption Coefficient**; **Electromagnetic Radiation**; and **Scattering**.

ATTENUATION CONSTANT. 1. A measure of the rate of attenuation per unit length; the rate of flux-density (or power) reduction as energy (visual, electromagnetic, acoustic) propagates from its source. Also called attenuation factor, decay constant. For free-space transmission of radar frequency energy, the attenuation constant is usually expressed in decibels per mile or kilometer (db/mi or db/km).

2. Specifically, of a traveling plane wave at a given frequency, the relative rate of decrease of amplitude of a field component (or of voltage or current) in direction of propagation in nepers per unit length.

See also **Attenuation Coefficient (symbol α)**; and **Attenuation Factor**.

ATTENUATION FACTOR. 1. A measure of the opacity of a layer of material for radiation traversing it. It is equal to I_0/I, in which I_0 and I are the intensities of the incident and emergent radiation, respectively. In the usual sense of exponential absorption

$$I = I_0 e^{-\mu x}$$

where x is the thickness of the material and μ is the absorption coefficient. 2. A meaning similar to that in (1) is current in electrical circuit applications, where the attenuation factor is the ratio of the input current to the output current of a line or network.

ATTENUATION (Sideband). That form of attenuation in which the transmitted relative amplitude of some component(s) of a modulated signal (excluding the carrier) is smaller than that produced by the modulation process.

ATTENUATOR. The attenuator, often called a pad, is a network designed to introduce a definite loss in a circuit. It is designed so the impedance of the attenuator will match the impedance of the circuit to which it is connected, often being connected between two circuits of different impedance and serving as a matching network as well as an attenuator. It is distinguished from a simple resistance in that the impedance of an attenuator does not change for various values of its attenuation. It is a valuable unit in making many laboratory tests on communications equipment, where it is used to adjust the outputs of two pieces of apparatus or for two different conditions so the relative merits may be determined from the attenuator setting. In much communication work it is desirable to transmit power at a higher level than will be used in order to overcome circuit noises, and then to reduce it to the proper value at the receiving end by a pad. It is usually calibrated in decibels and thus indicates the attenuation introduced by it.

Among the types of attenuators, there is the *coaxial line attenuator*, which, as its name indicates, is designed for use in a coaxial line. It may be fixed or variable. One of its special types is the *chimney attenuator*, which received its name from the appearance of the stub lines. The *flap or fin attenuator* is a waveguide attenuator in which a flap or fin of conducting materials is moved into the guide in such a manner as to cause power absorption. The *transverse film attenuator* consists of a conducting film placed transverse to the axis of a waveguide.

ATTITUDE. The position or orientation of an aircraft or spacecraft, either in motion or at rest, as determined by the relationship between its axes and some reference line or plane or some fixed system of reference axes.

ATTRACTOR. A stable equilibrium state having the property that small departures from the equilibrium continually diminish. An attractor may be represented in a coordinate system as a single point (the usual case) or as a bounded set of infinitely many points (as in the case of a limit cycle). A strange attractor is an attractor containing an infinite number of points and having the property that small changes in neighboring states give rise to large and apparently unpredictable changes in the evolution of the system. The best-known example of a strange attractor in meteorology is that discovered by E. N. Lorenz 1963 in solutions to a simplified set of

equations describing the motion of air in a horizontal layer heated from below.

Lorenz, E.N.: "Deterministic Nonperiodic Flow," *J. Atmos. Sci.*, **20**, 130–141 (1963).

ATTRITION (Geology). From the Latin *attritio*, meaning a grinding or rubbing down, and used in the terminology of geological science to refer to the grinding of particles through the transporting power of wind, running water, or by the movement of glaciers.

ATTRITION MILLS. Equipment of this type is used in the process industries to reduce the size of various feeds. Attrition connotes a rubbing action, although this action usually is combined with other forces, including shear and impact. Attrition mills also are referred to as disk mills and normally comprise two vertical disks mounted on horizontal shafts, with adjustable clearance between the vertical disks. In some designs, one vertical disk may be stationary. In other designs, the two vertical disks rotate at differential speeds or in opposite directions. Material is fed to the mill so that it is subjected to a tearing or shredding action. Because of the frictional nature of the operation, temperatures build up and heat-sensitive materials cannot be size-reduced in this type of equipment. Attrition mills sometimes are used principally as mixers to provide an intimate blending of powders. Special plates are used to permit intensive blending with a minimum of grinding action. Throughput rates per horsepower required are high.

ATWATER, WILBUR OLIN (1844–1907). Wilbur Atwater was an American chemist who pioneered human nutrition research in the USA. The son of a Methodist clergyman, Atwater was born in Johnsburg, New York. He studied at the University of Vermont and Wesleyan University in Connecticut and then, as a graduate student, at Yale under Professor Samuel Johnson, receiving the PhD degree in 1869. In 1874 he became Professor of Chemistry at Wesleyan University and began work in agricultural chemistry, but soon concentrated on the chemical analysis of foods. He visited Carl Voit's laboratory in Munich to learn the techniques of respiration calorimetry and nitrogen balance trials.

In that period food purchases could cost a working family 50% of their income and Atwater endeavored to find ways of reducing this cost with cheaper sources of protein and fat. His articles in the *Century Magazine* attracted wide attention. In 1887 he was invited to take the new position of Director of the Office of Experimental Stations for the U.S. Department of Agriculture, and was on leave for three years from Wesleyan University. He established the *Experiment Station Record*, and laid down the principle that each State Experiment Station should concentrate on a few investigations and "conduct them on such a scale ... and accuracy as to secure results of permanent value."

Back at Wesleyan, he organized the construction of the first direct-and-respiration calorimeter in the USA that could house human subjects at rest and doing physical work. Studies with it demonstrated that calories from fat and carbohydrate were of equal value in supporting work.

K. J. CARPENTER, University of California, Berkeley, CA

AUDIBILITY. The wide loudness range of the human ear is exemplified by the fact that the most intense sound that can be tolerated is a million million times greater in intensity than a sound that is just audible. This is a range of approximately 120 decibels. The decibel scale is a logarithmic ratio scale. The frequency range (*audio frequency*) of hearing is usually stated as 16 Hz to 20,000 Hz. The ear is most sensitive in the middle-frequency range of 1,000 to 6,000 Hz. Few individuals can hear above 20,000 Hz. Below 15 Hz, if detected, the sound normally is perceived not as a note, but as individual pulses.

In terms of discrimination of frequency and intensity, it is possible for about 1,400 pitches and 280 intensity levels to be distinguished. The rather phenomenal aspects of hearing can be observed in such behavior as localization of sounds (*auditory localization*), speech perception and, in particular, the understanding of one voice in the noisy environments of many. Acoustic events that last only a few milliseconds also can usually be detected.

The instrument for measuring hearing acuity is termed an *audiometer*. See also **Auditory Organs**; and **Hearing and the Ear**.

AUDIBILITY ZONE. A region surrounding a sound source, such as an explosion, in which the sound can be detected, usually by a human without special aids. The concept of an audibility zone may be applied to frequencies outside the range of human hearing and to detectors far more sensitive than the human ear. The existence and geometry of audibility zones depend on temperature and wind component profiles along the the path between the source and the receiver. Audibility zones close to a source depend on the wind and temperature profiles in the boundary layer. At greater distances, temperature profiles in the stratosphere and mesosphere and the location of the tropospheric jet stream are the primary determinants of the location and extent of audibility zones.

AUDIO FILES. See **File Types**.

AUDIOGRAM. A graph showing the hearing loss, the percent of hearing loss, or the percent of hearing as a function of frequency. See also **Hearing and the Ear**.

AUDIO/VIDEO REMOTE CONTROL PROFILE (AVRCP). See **Bluetooth™ Wireless Technology**.

AUDITORY ORGANS. Organs sensitive to stimulation by sound waves. True auditory organs occur in arthropods and vertebrates. In the former they vary considerably but in the latter they are the ears and can be traced through their variations to a common structural foundation.

The simplest arthropod auditory organ is known as a chordotonal organ. It consists of a nerve ending with accessory cells connected with the body wall, which is apparently the immediate source of the vibrations to which the organ responds. More elaborate auditory organs are found in grasshoppers, katydids, mosquitoes, and related species. In the grasshoppers they are located on the sides of the first abdominal segment, in the katydids in the front tibiae, and in the mosquitoes at the base of the antennae. In all forms the scolophore is the essential sensory ending; accessory structures vary to a greater degree but usually include a modification of the cuticula which serves as a resonating membrane, or tympanum.

The essential auditory portion of the vertebrate ear is the cochlea, a spiral organ of elaborate structure containing terminations of the auditory nerve. This organ is part of the inner ear. In the mammals the outer ear includes the pinna, usually called the ear, and the external auditory canal leading inward to the tympanum or ear drum which vibrates in response to sound waves. Between these two regions lies the cavity of the middle ear, derived from the pharynx and connected with it by the Eustachian tube. The middle ear is bridged by a series of small bones, the hammer, anvil, and stirrup, which convey the vibrations of the tympanum mechanically to the liquid in the inner ear. These parts are variably developed in vertebrates below the mammals, all of which have simpler ears than described. The ears of bats play a unique part in the avoidance of obstacles during flight.

See also **Hearing and the Ear**; and **Sensory Organs**.

AUGEN-GNEISS. A gneissoid rock that contains lenticular crystals or mineral aggregates resembling "eyes." Derived from the German *augen*, eyes.

AUGER EFFECT. A process, discovered by P. Auger, in which the energy released in the deexcitation of an excited electronic energy state of an atom is given to another one of the bound electrons rather than being released as a photon. This type of transition is usually described as radiationless. The process usually occurs only for transitions in the x-ray region of energy states. The final state corresponds to one higher degree of ionization than does the initial state. The ejected electron has kinetic energy equal to the difference between the energy of the x-ray photon of the corresponding radiative transition and the binding energy of the ejected electron.

AUGITE. This mineral is a common monoclinic variety of pyroxene whose name is derived from the Greek word meaning "luster," in reference to its shining cleavage faces. Chemically it is a complex metasilicate of calcium, magnesium, iron and aluminum. Color, dark green to black, may be brown or even white; hardness, 5–6; specific gravity, 3.23–3.52. Augite is important as a primary mineral in the igneous rocks and also as secondary mineral. The white augite is called leucaugite from the Greek word meaning "white." Chemical analysis reveals this variety as containing little or no iron. Augite is of widespread occurrence.

See also **Pyroxene**.

AUGMENTATION. A term used by astronomers to indicate the increase in apparent diameter of the moon, or of any other object close enough to the earth to be observed as a disk, as the altitude of the object increases.

In Fig. 1(a), we have a representation of conditions for the object, M, on the horizon for an observer, O; in Fig. 1(b), the object, M, is at the zenith on the meridian for the observer, O'. In both figures, C represents the center of the earth. The distance, CM, of the object from the center of the earth is assumed to be a constant. Examination of the figures will show at once that (a) gives the maximum distance of the object from the observer, whereas (b) gives the minimum value of this distance. Since apparent angular diameter of an object increases with decrease of distance, and since apparent size is defined as the apparent angular diameter, the object is seemingly larger under conditions (b) than (a), i.e., larger on the meridian than when rising.

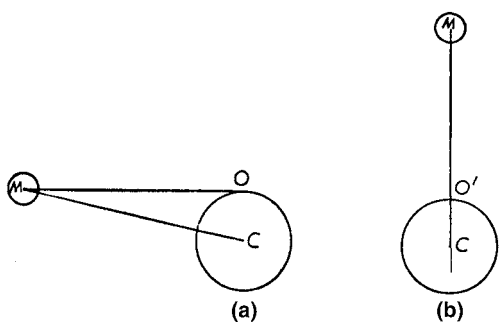

Fig. 1. Demonstration of augmentation.

For the sun and planets, augmentation is too small to be considered except in the most refined observations of the altitude of a limb. However, in the case of the moon, augmentation may amount to as much as 37″. Failure to properly correct for this effect, when a limb of the moon is observed for determination of a line of position in navigation, might introduce an error as great as 0.3 mile in the position of a ship.

AURA MISSION. NASA's Aura is a mission to understand and protect the air we breathe. With the launch of Aura NASA has begun to make the most comprehensive measurements of the Earth's atmosphere. It also caps off a 15-year international effort to establish the world's most comprehensive Earth Observing System, whose overarching goal is to determine the extent, causes, and regional consequences of global change. Aura's objective is to study the chemistry and dynamics of the Earth's atmosphere with emphasis on the upper troposphere and lower stratosphere (0–30km (0–18.6 miles) by employing multiple instruments on a single satellite. The satellite's measurements enable scientists to investigate questions about ozone trends, air quality changes and their linkages to climate change. These observations provide accurate data for predictive models and provide useful information for local and national government agencies.

Aura (Latin for breeze) was launched successfully on July 15, 2004, aboard a Delta II 7920-10L, a two stage expendable rocket, from the Western Test Range at Vandenberg Air Force Base, California. The design life is five years with an operational goal of six years. Aura is the third in a series of major Earth observing satellites to study the environment and climate change. The first and second missions, Terra (launched December, 1999) and Aqua (launched May, 2002), are designed to study the land, oceans, and the Earth's radiation budget. Aura's chemistry measurements also follow up on measurements which began with NASA'S Upper Atmospheric Research Satellite and continues the record of satellite ozone data collected from the TOMS missions. The United Kingdom and the Netherlands are providing instruments for this mission. Aura flies in formation about 15 minutes behind Aqua. See also **Aqua Mission**; and **Terra Satellite (EOS AM-1)**.

The Aura spacecraft was launched into a near polar, sun-synchronous orbit with a period of approximately 100 minutes. The spacecraft repeats its ground track every 16 days to provide atmospheric measurements over virtually every point on the Earth in a repeatable pattern, permitting assessment of atmospheric phenomena changes in the same geographic locations throughout the life of the mission.

The spacecraft orbits at 705 km in a sun-synchronous orbit (98o inclination) with a 1:45 PM ± 15 minute equator crossing time. Aura limb instruments are all designed to observe roughly along the orbit plane. MLS is on the front of the spacecraft (the forward velocity direction) while HIRDLS, TES and OMI are mounted on the nadir side.

Aura Spacecraft Subsystems

The spacecraft structure is a lightweight "eggcrate" compartment construction made of graphite epoxy composite over honeycomb core, providing a strong but light base for the science instruments. See Figs. 1 and 2. The weight of the structure is approximately 700 kilograms (1,543pounds), significantly lighter than a comparable aluminium structure, leaving more of the launcher weight-lift capability for science measurements.

A deployable flat-panel solar array with over 20,000 silicon solar cells provides 4600 watts of power in sunlight. While in sunlight, a portion of the solar array power, driven to always face the sun, charges a 24 cell nickel-hydrogen battery which powers the spacecraft and the instruments when the spacecraft is in night phase of the orbit.

The data system can handle over 100 gigabits of scientific data stored onboard. All spacecraft data are then relayed via an X-band communication system to one of two polar region ground stations each orbit. The spacecraft can also broadcast scientific data directly to ground stations over which it is passing. The ground stations also have an S-band uplink capability for spacecraft and science instrument operations.

The S-band communication subsystem also can communicate through NASA's TDRSS synchronous satellites in order to periodically track the spacecraft, calculate the orbit precisely, and issue commands to adjust the orbit to maintain it within defined limits.

Spacecraft attitude is maintained by stellar-inertial, and momentum wheel-based attitude controls with magnetic momentum unloading, through interaction with the magnetic field of the Earth that provide accurate pointing for the instruments. Typical pointing knowledge of the line of sight of the instruments to the Earth is on the order of one arc minute (about 0.02 degrees)

Electronic components are housed on panels internally, leaving the spacecraft "deck" available for the four science instruments, and providing them a wide field of view. The side of the spacecraft away from the Sun is devoted to thermal radiators, which radiate excess heat to space and provide the proper thermal balance for the entire spacecraft.

A propulsion system of four small one-pound thrust hydrazine monopropellant rockets gives the spacecraft a capability to adjust its orbit periodically to compensate for the effects of atmospheric drag, so that the orbit can be precisely controlled to maintain altitude and the assigned ground track.

Aura's Instruments

EOS Aura's Instruments, HIRDLS, MLS, OMI, and TES (Fig. 3) contain advanced technologies that have been developed for use on environmental satellites. Each instrument provides unique and complementary capabilities that will enable daily global observations of Earth's atmospheric ozone layer, air quality, and key climate parameters.

HIRDLS: High Resolution Dynamics Limb Sounder. HIRDLS is an infrared limb-scanning radiometer measuring trace gases, temperature, and aerosols in the upper troposphere, stratosphere, and mesosphere. The instrument provides critical information on atmospheric chemistry and climate. Using vertical and horizontal limb scanning technology, HIRDLS provides accurate measurements with daily global coverage at high vertical and horizontal resolution. The University of Colorado, the

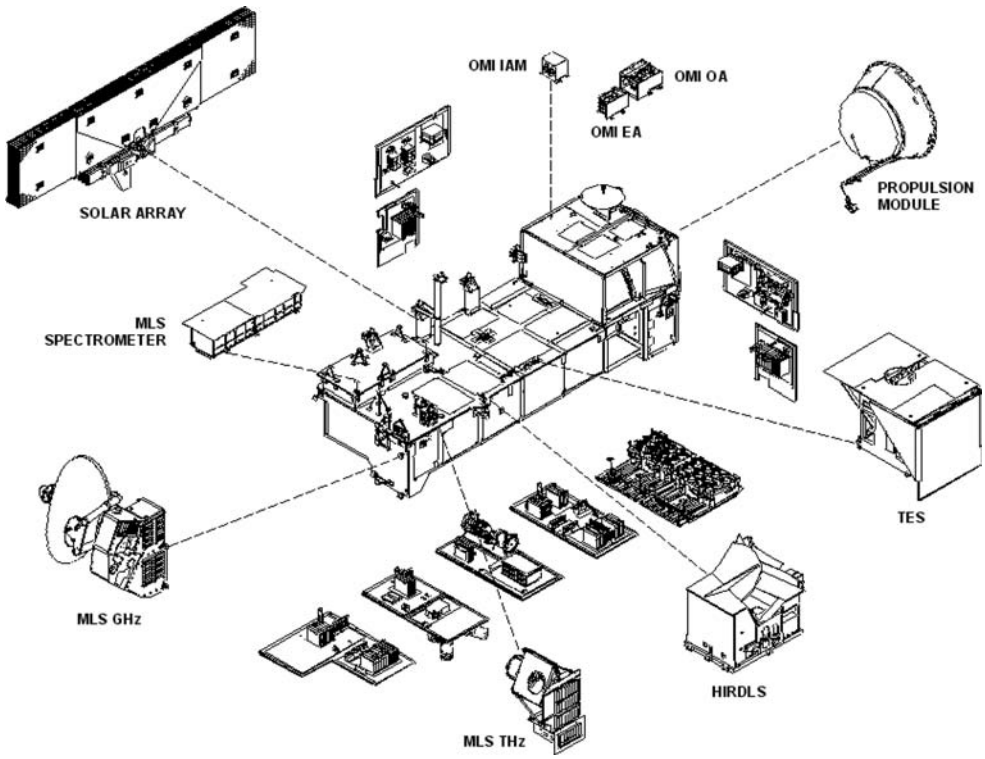

Fig. 1. Spacecraft configuration.

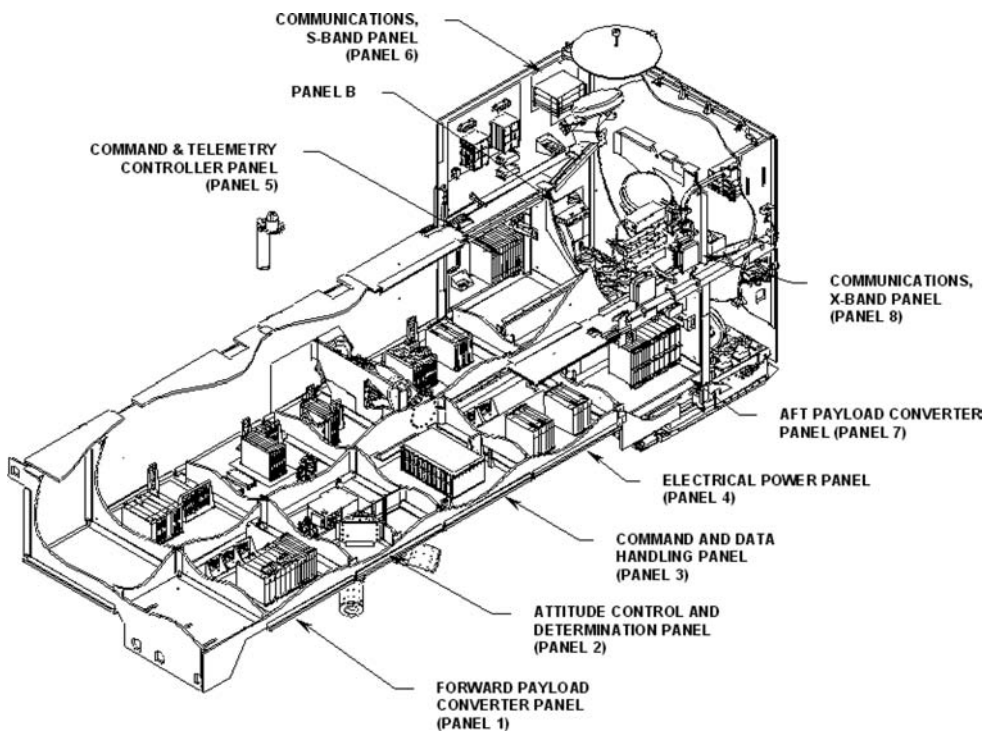

Fig. 2. Spacecraft equipment configuration.

National Center for Atmospheric Research (NCAR), Oxford University (UK) and Rutherford Appleton Laboratory (UK) designed the HIRDLS instrument. Lockheed Martin built and integrated the instrument subsystems. The National Environmental Research Council funded the United Kingdom participation. See http://aura.gsfc.nasa.gov/instruments/hirdls/hirdls_instteam.html.

The HIRDLS instrument will obtain profiles over most of the globe, both day and night. Complete Earth coverage can be obtained in twelve hours. Observations of the lower stratosphere and upper troposphere are possible through the use of special narrow and more-transparent spectral channels.

After launch, activation of the HIRDLS instrument revealed that the optical path was blocked so that 20% of the aperture could view the earth's atmosphere. Engineering studies suggest that a piece of thermal blanketing material ruptured from the back of the instrument during the explosive decompression of launch. Attempts to remove this material mirror failed. However, even with the 80% blockage, measurements at high vertical resolution can be made at one scan angle.

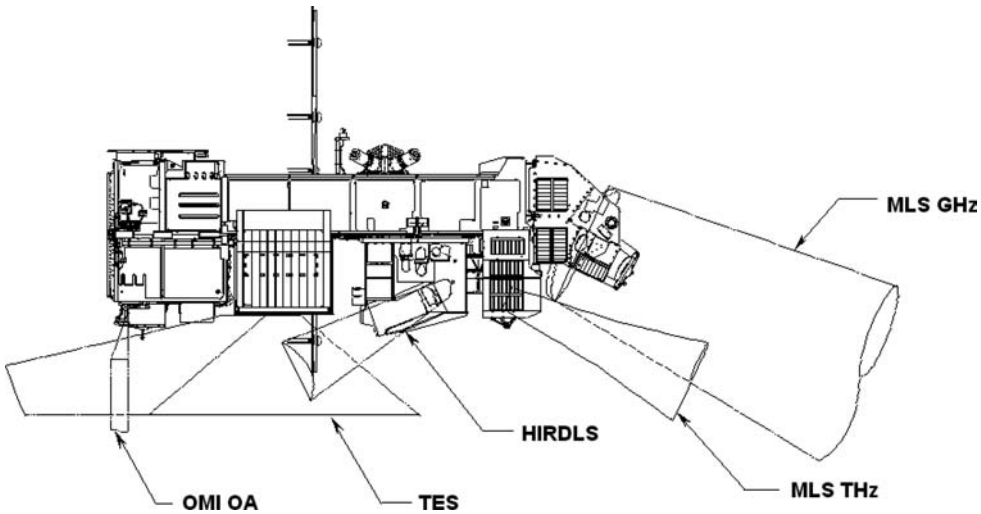

Fig. 3. Aura instrument field of view accommodation.

The overall science goals of HIRDLS are to observe the global distributions of temperature and several trace species in the stratosphere and upper troposphere at high vertical and horizontal resolution. Specific issues to be investigated include:

- Fluxes of mass and chemical constituents between the troposphere and stratosphere [stratosphere-troposphere exchange (STE)];
- chemical processes, transport, and mixing [particularly in the upper troposphere/lower stratosphere (UT/LS)];
- momentum, energy, heat, and potential vorticity balances of the upper troposphere and middle atmosphere;
- geographically and seasonally unbiased long-term climatologies and interannual variability of middle-atmosphere temperature, constituents, dynamical fields, and gravity waves;
- global distributions and interannual variations of aerosols, cirrus, and PSCs;
- tropospheric cloud-top heights;
- tropospheric temperature and water vapor retrievals (by providing high-resolution limb data for joint retrieval with EOS nadir sounders); and
- diagnostic studies of atmospheric dynamics, chemistry, and transport processes, down to small spatial scales, to test and improve models of these processes.

Although HIRDLS lost is azimuth scanning capability, much of the science can be retained through the use of chemical transport and data assimilation models.

MLS: Microwave Limb Sounder. MLS is a limb scanning emission microwave radiometer. MLS measures radiation in the Gigahertz (GHz) and Terahertz (THz) frequency ranges (millimeter and submillimeter wavelengths). Aura's MLS is a major technological advance over the MLS flown on UARS (Upper Atmosphere Research Satellite), http://umpgal.gsfc.nasa.gov/. MLS measures important ozone-destroying chemical species in the upper troposphere and stratosphere. In addition, MLS has a unique ability to measure trace gases in the presence of ice clouds and volcanic aerosols. NASA's Jet Propulsion Laboratory (JPL) developed, built, tested, and operates MLS, http://mls.jpl.nasa.gov/.

MLS uses microwave emission to measure stratospheric temperature and upper tropospheric constituents. MLS also has unique capability to measure upper tropospheric water vapor in the presence of tropical cirrus, and also the cirrus ice content. These measurements are valuable for diagnosing the potential for severe loss of Arctic ozone when abundances of stratospheric chlorine will still be high, and slight cooling of the stratosphere could exacerbate ozone loss due to chlorine chemistry.

MLS is providing the first global measurements of OH, HO2 and BrO, constituents that play an important role in stratospheric chemistry. MLS is unique in its ability to provide these measurements in the presence of tropical cirrus, where important processes affecting climate variability occur. MLS also provides unique measurements of cirrus ice content.

The simultaneous MLS measurements of upper tropospheric water vapor, ice content, and temperature, under all conditions and with good vertical resolution, will be of great value for improving our understanding of processes affecting the distribution of atmospheric water, climate variability, and tropospheric-stratospheric exchange. The simultaneous measurements of dynamical tracers CO and N2O enhance the value of this data set by helping identify source regions of the air masses being observed.

The overall scientific objectives of EOS MLS are to help improve understanding and assessment of:

Ozone Depletion

+ emphasis on the lower stratosphere, but
+ perform critical monitoring of the *entire* stratosphere
+ during the period when ozone is most vulnerable to destruction by chlorine

Climate Change

+ emphasis on processes in the upper troposphere and lower stratosphere
+ for both seasonal-to-interannual and long-term climate variability

Tropospheric Ozone

+ distribution of *upper* tropospheric ozone measured directly
+ important for understanding effects of aviation and radiative forcing of climate
+ distribution of total tropospheric ozone from TOMS-MLS, OMI-MLS

Volcanic Effects

+ on ozone depletion and climate change

OMI: Ozone Monitoring Instrument. OMI is a nadir viewing spectrometer that measures solar reflected and backscattered light in a selected range of the ultraviolet and visible spectrum. The instrument's 2,600 km (1,616 mile) viewing swath is perpendicular to the orbit track, providing complete daily coverage of the sunlit portion of the atmosphere. OMI is Aura's primary instrument for tracking global ozone change and continues the high quality column ozone record begun in 1970 by Nimbus-4. OMI has a broader wavelength range and better spectral resolution and also measures column amounts of trace gases important to ozone chemistry and air quality. OMI maps aerosols and estimate ultraviolet radiation reaching the Earth's surface. OMI's horizontal resolution is about four times greater than TOMS (Total Ozone Mapping Spectrometer). The Netherlands Agency for Aerospace Programs (NIVR) and the Finnish Meteorological Institute (FMI) contributed the OMI instrument to the Aura mission. The Netherlands companies, Dutch Space and TNO-TPD, together with Finnish companies, Patria, VTT and SSF, built the instrument. See also http://aura.gsfc.nasa.gov/instruments/omi/omi_instteam.html.

OMI Instrument Science includes:

- OMI derives its heritage from NASA's TOMS instrument, and ESA's GOME (Global Ozone Monitoring Experiment) instrument (currently flying on the European Remote Sensing Satellite ERS-2 satellite). However, it can measure many more atmospheric constituents than TOMS, and provides much better ground resolution than GOME (13 km × 25 km (8 miles × 15.5 miles) for OMI vs. 40 km × 320 km (25 miles × 199 miles) for GOME), and unlike GOME, which provides 3 day global coverage, OMI will provide daily global coverage.
- OMI is the key instrument on EOS Aura for monitoring the recovery of the ozone layer in response to the phase out of chemicals, such as CFCs, agreed to by the nations of the world in the Montreal protocol and later modifications to it at Copenhagen, and London.
- OMI will measure, together with its companion instruments MLS, HIRDLS, Criteria Pollutants such as O_3, NO_2, SO_2 and aerosols. The US Environmental Protection Agency (EPA) has designated these atmospheric constituents as posing serious threats to human health and agricultural productivity. These measurements will be made at near urban scale resolution and track industrial pollution and biomass burning.
- OMI will detect volcanic ash and sulfur dioxide produced in volcanic eruptions with up to 40 times more sensitivity than TOMS and GOME. These measurements are important for aircraft safety.
- OMI will measure ozone profiles (in the UV) complimentary to those measured by TES and HIRDLS (in the IR) and MLS (in the microwave).
- OMI will measure BrO, Formaldehyde, and OClO which all play a major role in stratospheric chemistry in the stratosphere and troposphere.
- OMI will measure the total amount of atmospheric ozone, NO_2 as well as lower atmospheric dust, smoke and other aerosols.

TES: Tropospheric Emission Spectrometer. TES is an imaging Fourier Transform Spectrometer observing the thermal emission of the Earth's surface and atmosphere, night and day. TES measures tropospheric ozone directly and other gases important to tropospheric pollution with very high horizontal resolution. TES has a higher resolution than OMI, but with less coverage. Satellite tropospheric chemical observations are difficult to make due to the presence of clouds. To overcome this problem, TES was designed to observe both downward (in the nadir) and horizontally (across the limb). This observation capability provides measurements of the entire lower atmosphere, from the surface to the stratosphere. NASA's JPL developed, built, tested, and operates TES, http://tes.jpl.nasa.gov/. The TES primary objective is to measure trace gases associated with air quality.

TES Instrument Science includes: TES measurements will help determine local atmospheric temperature and humidity profiles, local surface temperatures, and local surface reflectance and emittance. TES observations will also be used to study volcanic emissions for hazard mitigation, indications of the chemical state of the magma, eruption prediction, and quantification of the role of volcanoes as sources of atmospheric aerosols.

The aforementioned database will calibrate models of the present and future state of the Earth's lower atmosphere. These models will investigate topics such as:

- Biogeochemical cycles between the lower atmosphere and biosphere (primarily carbon monoxide and methane);
- global climate modification caused by an increase in radiative active gases;
- distribution and lifetimes of chlorofluorocarbons (CFCs) and halons, which contribute substantially to the depletion of stratospheric ozone;
- changes in the oxidizing power of the troposphere and the distribution of tropospheric ozone caused by urban and regional pollution sources, particularly carbon monoxide, nitrogen oxides, methane, and other hydrocarbons;
- acid deposition precursors;
- sources and sinks of species important to the generation of tropospheric and stratospheric aerosols; and
- natural sources of trace gases such as methane from organic decay, nitrogen oxides from lightning, and sulfur compounds from volcanoes.

Aura Top 10 Discoveries. Approaching its second anniversary since launching in July 2004, Aura has been retrieving information and producing valuable data of the Earth and its atmospheric properties. Each instrument working individually and alongside its counterparts to bring us ozone measurements, tropospheric maps of carbon monoxide and cloud ice, as well as measurements in the stratosphere.

Below are the selected top 10 discoveries that Aura's instruments have brought us so far.

SO_2 Emissions from Smelters. Aura Instrument : OMI. The Peruvian copper smelters are among the world's largest industrial point sources of sulfur dioxide (SO_2), and are among the most polluting in the world. OMI is sensitive enough to identify copper being emitted from the La Oroya and Ilo smelters even though these produce less SO_2 than the volcanoes. See also http://aura.gsfc.nasa.gov/science/top10_smelters.html.

First Global Tropospheric Maps Show Streams of Tropospheric Ozone Crossing the Oceans. Aura Instruments : OMI & MLS. OMI & MLS can estimate the tropospheric ozone residual by subtracting the MLS stratospheric ozone from OMI column ozone. See also http://aura.gsfc.nasa.gov/science/top10_omi-mls-maps.html.

First Maps of Tropospheric Ozone & Carbon Monoxide. Aura Instrument : TES. Coincident measurements of tropospheric ozone and carbon monoxide are critical for understanding chemical and dynamical processes, which can be very complex in the troposphere. See also http://aura.gsfc.nasa.gov/science/top10_tes-maps.html.

First Global Measurement of Cloud Ice in Upper Troposphere. Aura Instrument : MLS. Cloud ice measurement will improve global circulation models used for weather and climate forecasts.

The measurements will also help quantify the upper tropospheric hydrological cycle, including water vapor feedbacks on climate change. http://aura.gsfc.nasa.gov/science/top10_cloudice.html.

First Maps of Sub-Visual Cirrus in the Upper Tropical Troposphere. Aura Instrument : HIRDLS. MLS sees cloud ice, but HIRDLS sees the clouds themselves, even clouds that are so thin that people cannot see them. Just as in the MLS cloud ice map we see large amounts of this cirrus in regions of significant cloud ice. See also http://aura.gsfc.nasa.gov/science/top10_cirrus.html.

First Global Observations of HDO/H_2O Ratio—A Tracer of Global Hydrological Processes. Aura Instrument : TES. The hydrological cycle acts differently in different location. The TES measurements show that in the tropics, re-evaporation of precipitation is an important process controlling cloud formation. Up to 70% of precipitation is re-evaporated into the cloud. See also http://aura.gsfc.nasa.gov/science/top10_HDO-H2O.html.

Measurement of CO in Upper Troposphere. Aura Instrument : MLS. CO is a signature of pollution and can be transported a long way from its source. Not surprisingly, that transport can be vertical as well as horizontal. These images show how CO detected in the lower stratosphere can tell us something about where convection is occurring. See also http://aura.gsfc.nasa.gov/science/top10_CO.html.

Continuous Measurement of HCl in Stratosphere. Aura Instrument : MLS. The continuous measurement of HCl in the stratosphere shows the rapid recovery of this major chlorine reservoir after polar ozone loss, and continues the long-term measurements from UARS HALOE. Monitoring HCl tells us about ozone loss processes and the recovery of the ozone layer. See also http://aura.gsfc.nasa.gov/science/top10_HCI.html.

First Measurement of OH in the Middle Stratosphere. Aura Instrument : MLS. The MLS measurements of OH and HO2 have provided the first tests of global stratospheric hydrogen chemistry and resolved the disagreement between model estimates of OH and earlier observations—these data suggest earlier observations are suspect. See also http://aura.gsfc.nasa.gov/science/top10_OH.html.

First Global Measurement of Small Scale Gravity Waves in the Stratosphere. Aura Instrument : HIRDLS. HIRDLS high resolution temperature measurements show short vertical wavelength gravity waves, permitting assessment of gravity wave forcing in the stratospheric circulation. See also http://aura.gsfc.nasa.gov/science/top10_gravitywaves.html.

AUREOLE (Geology). The contact metamorphic zone of varying width that often surrounds an igneous intrusion. Such areas of contact metamorphism often contain valuable ore deposits, especially when they surround batholiths which have intruded sedimentary formations.

AURIC AND AUROUS. Prefixes often used in the naming of gold salts of valence +3 (ic) and +1 (ous). Thus, auric chloride, aurous nitrate, and so on.

AURIGA (the charioteer). This constellation is best known because it contains the bright star Capella (the she-goat) (α Aurigae) and her kids. The kids are three fainter stars, forming, to the naked eye, a small triangle, which always serves to distinguish Capella from other bright stars on a clear night. Capella is a bright star, yellowish in appearance, and of the same spectral type as our sun. The star, however, is so much larger than our sun that, in spite of its great distance (49 light-years), it appears as first magnitude, whereas the sun at the same distance would be sixth magnitude, or barely visible to the naked eye on a clear moonless night. Capella A is a spectroscopic binary with a period of 104 days. More distant are two additional M dwarf components, making Capella a four-star system, or small cluster. See map accompanying the entry **Constellations**.

AURORA AND AIRGLOW. The visual aurora consists of luminous forms (arcs, rays, bands) in the night sky, usually confined to high latitudes and based in the ionospheric E region. See also **Ionosphere**. The airglow consists of a faint relatively uniform luminosity, which is worldwide in occurrence and, except under exceptional conditions, can only be observed instrumentally. The distinction between faint aurora and bright airglow in auroral regions is not clear.

The luminosity arises from emissions of the atmospheric constituents in the atomic, molecular or ionized forms. The chief emissions in the visible region, with approximate intensities in Rayleighs for a bright aurora and temperate latitude airglow, are shown in Table 1. There are many other emissions in the infrared and ultraviolet. In bright aurorae, the colors can be seen visually; faint aurorae appear grayish white since they approach the color vision threshold.

An auroral arc is a narrow horizontal band of light up to hundreds of kilometers long (usually geomagnetic east-west). The term arc derives from its appearance from the earth's surface due to perspective. A band is a portion of an arc showing, distortion normal to its length. Auroral rays have been likened to searchlight beams; they lie along the geomagnetic field direction and may be several hundred kilometers long. Arcs and bands may be homogeneous or rayed. Particularly dramatic displays of the aurora are shown in Figs. 1, 2 and 3.

Isolines of auroral occurrence are approximately centered on the geomagnetic poles. The auroral zones are defined as the regions of maximum occurrence. They are roughly circular with a radius of approximately 23° of latitude. The northern auroral zone reaches its lowest geographic latitude over eastern Canada; the southern, over the ocean south of Australia. At times of geomagnetic disturbance, the aurora appears at lower latitudes and in very great magnetic storms may be observed in the tropics. The frequency of occurrence of aurorae at lower latitudes correlates with the cycle of solar activity.

Fig. 1. A beautifully looped curtain aurora over Alaska. (*Geophysical Institute, University of Alaska*.)

Within recent years, it has been found that a relatively uniform auroral glow exists over the polar cap, extending through and beyond the classical auroral zone, on which auroral forms appear as bright patches that are visible merely because of contrast with their surroundings. Another relatively recent finding is the thesis of a local time dependence in the daily maximum of auroral occurrence which is at about 68° geomagnetic at midnight and 75 to 80° at noon. An inner auroral zone at 75 to 80° geomagnetic could possibly explain the observed results. See Table 1.

Many auroral forms are probably caused by the precipitation of particles (mainly electrons) into the ionosphere. Their origin is obscure, but studies suggest that they are derived from the outer regions of the magnetosphere, and are accelerated and precipitated in an irregular manner on the high latitude side of the outer radiation belt through some mechanism (e.g., turbulence) which is probably related to the solar wind. It is doubtful if precipitation of trapped particles from the outer radiation belt causes aurora directly, except in great magnetic storms.

A strong ionospheric current system is seated approximately in the classical auroral zone, but the detailed relation between aurorae and the electric currents is obscure.

TABLE 1. CHIEF AURORAL AND AIRGLOW EMISSIONS IN THE VISIBLE REGION[a]

Emission	Spectral Region or Wavelength	Approximate Height (Kilometers)	Approximate Intensity (Rayleighs)	
			Bright Aurora[b]	Nightglow
Ol	5577 Å	90–110	100.000	250
	6300, 6364 Å	160	>50.000	150
NII	Blue to red		25.000	
H (Balmer Series)	Red, blue	E-layer	1.000	
N_2 (1st Positive)	Red	D-layer	50.000	
	Violet	D-layer	100.000	
(2nd Positive)				
N_2^+ (1st Negative)	Blue-violet		165.000	
O_2^+ (1st Negative)	Red-yellow	D-layer	10.000	
Nal	5890, 5896 Å	80–90		100 (winter)
				20 (summer)
OH	Red-yellow	60–100		100
O_2 (Herzberg)	Blue-violet	90–100		15

[a] Adapted from Chamberlain: "Physics of the Aurora and Airglow." Academic Press, New York, 1961, to which reference should be made for data including ultraviolet and infrared emissions.
[b] International Brightness Coefficient III (brightness of moonlit cumulus clouds).
Note: Emissions are highly variable or absent with type and latitude of aurora. Heights are given only when well-defined.

Fig. 2. Auroral draperies. The drapery at the left is seen nearly edge-on. (*Hessler: Chamberlain, "Physics of the Aurora and Airglow," Academic Press.*)

Fig. 3. Homogeneous horseshoe band. (*Hessler: Chamberlain, "Physics of the Aurora and Airglow," Academic Press.*)

The so-called radio aurora signifies the ionization in the E-layer that is associated with magnetic disturbances, and gives rise to characteristic type radio reflections in the VHF (30 to 300 MHz) band and less often at higher frequencies. It has been suggested that radio aurora may be identified with the optical aurora, but little evidence exists for this.

The chief characteristic of the ionization is that it is aligned along the earth's magnetic field, the size of the irregularities ranging from meters to kilometers in length. The mechanism producing it is obscure; wind shears and particle precipitation probably contribute.

The pattern of ionization usually shows a systematic movement which, in and below the auroral zone, is statistically very similar to the ionospheric disturbance current system, but there are difficulties in interpreting the movement as that of the electrons in the current system. Other interpretations are that the movement is that of the ionizing sources, or even of sound waves.

Frequency electromagnetic noise emission (hiss), centered around 8 kHz is observed in association with aurora. Satellite observations have sometimes shown correspondence between electron precipitation, auroral light intensity, and hiss, but at other times the correlation is poor. Theories of this noise emission all consider the interaction of a stream of particles with the surrounding plasma. Traveling wave tube amplification, Cerenkov radiation, or Doppler-shifted cyclotron generation by protons have been suggested.

The airglow is subdivided into the dayglow, twilightglow, and nightglow. The sodium intensity in the nightglow and twilightglow is highest in local winter, but seasonal and diurnal variations of the other emissions are not clear, as there are marked latitude effects and distinct patchiness. The origin of the nightglow is obscure, though an important part of the oxygen red emission is excited by electron-ion recombination in the F layer. At the 85 to 100 kilometer level, there are complex chemical reactions involving oxides of nitrogen as well as the free gases and ions. The energy sources are far from understood; winds, turbulence, the quiet day ionospheric current system, thermal excitation, and even particles may contribute.

Considerable knowledge pertaining to auroral activity is being gained from photographs taken from satellites. The most illuminating aspects of recent pictures are the large field of view covering a substantial fraction of the auroral oval and coverage of formerly inaccessible areas. Feldstein and Starkov (see references) have suggested that auroral activity occurs along an oval that surrounds the north geomagnetic pole and along a similar oval around the south geomagnetic pole. The position of the oval varies with geomagnetic activity. Its geomagnetic colatitudes are about 23° on the night side and 15° on the day side during periods of moderate geomagnetic activity. Observations indicate that the aurora frequently displays an eddy-like form with a characteristic length of a few hundred kilometers. Hasegawa (see references) has suggested that this may be the result of kink instability in the field-aligned sheet current proposed by Akasofu and Meng (see references). A short summary of auroral photographic studies conducted by U.S. Air Force Weather Service satellites is given in *Science*, **183**, 4128, 951–952 (1974).

In northern latitudes, auroral displays are called *aurora borealis*, *aurora polaris*, or *northern lights*. In southern latitudes, they are called *aurora australis*.

AURORAL ZONE. A roughly circular band around either geomagnetic pole above which there is a maximum of auroral activity. It lies about 10 to 15° of geomagnetic latitude from the geomagnetic poles. The auroral zone broadens and extends equatorward during intense auroral displays. The northern auroral zone is centered along a line passing near Point Barrow, Alaska, through the lower half of Hudson Bay, slightly off the southern tip of Greenland, through Iceland, northern Norway and northern Siberia. Along this line auroras are seen on an average of 240 nights a year. The frequency of auroras falls off both to the north and to the south of this line, but more rapidly to the south. The most severe blackouts occur in the auroral zone.

See also **Aurora and Airglow**.

AUSCULTATION. This term is applied to the examination of the sounds within the chest, abdomen, heart, or larger blood vessels. It is carried out by listening with a stethoscope, or by applying the ear directly to the surface of the body. See also **Stethoscope**.

AUSTENITE. The solid solution based upon the face-centered cubic form of iron. The most important solute is usually carbon, but other elements may also be dissolved in the austenite. See also **Iron Metals, Alloys, and Steels**.

AUTAN. See **Winds and Air Movement**.

AUTHIGENOUS (or Authigenic). A geologic term proposed by Kalkovsky in 1880, meaning generated on the spot, and referring particularly to the primary and secondary minerals of igneous rocks and the cements of sedimentary rocks.

AUTOCATALYSIS. A word used to describe the experimentally observable phenomenon of a homogeneous chemical reaction that shows a marked increase in rate with time, reaching a peak at about 50% coversion and then dropping off. The temperature has to remain constant and all ingredients mixed at the start for proper observation.

This definition excludes those exothermic reactions which shown and increase in rate with time (like explosions) caused by the rapidly rising temperature.

AUTOCHTHONOUS. A geologic term proposed in1888 for sedimentary rocks which have been formed in place. Now generally used to designate bedrock masses that have remained in place in a mountain belt, the term allochthonous denoting masses that have been moved long distances.

AUTOCLASTIC. A term proposed by Van Hise in1894 for crush breccias or fault breccias which have been fragmented in place.

AUTOCOLLIMATOR. 1. A device by which a lens makes diverging light from a slit parallel, and then after the parallel light has passed through a prism to a mirror and been reflected back through the prism, the same lens brings the light to a focus at an exit slit. 2. A telescope provided with a reticle so graduated that angles subtended by distant objects may be read directly. 3. A convex mirror placed at the focus of the principal mirror of a reflecting telescope and of such curvature that the light after reflection leaves the telescope as a parallel beam.

AUTOCONVECTION. The supposed spontaneous initiation of convection in an atmospheric layer in which density increases with height and in which the lapse rate is greater than the autoconvective lapse rate. Also called *autoconvective instability.* See also **Autoconvective Lapse Rate**.

The term is based on a false analogy with convection in an incompressible fluid. Convection in a gas will initiate spontaneously, through buoyant instability, if the lapse rate is greater than the adiabatic lapse rate.

AMS

AUTOCONVECTIVE LAPSE RATE. The environmental lapse rate of temperature in an atmosphere in which the density is constant with height (homogenous atmosphere), equal to g/R, where g is the acceleration of gravity and R the gas constant. For dry air the autoconvective lapse rate is approximately $+3.4 \times 10^{-4}\,^{\circ}\mathrm{C}$ per centimeter. Also called *autoconvection gradient.*

AUTOCORRELATION. The correlation of the members of a time-series among themselves.

Autocorrelation Coefficient. If ξ_t is a stationary stochastic process with mean m and variance σ^2 the autocorrelation coefficient of order k is defined by

$$\rho_k = \rho_{-k} = \frac{1}{\sigma^2} E(\xi_t - m)(\xi_{t+k} - m)$$

where the expectation relates to the joint distribution of ξ_t and ξ_{t+k}.

In a slightly more limited sense, if ξ_t is the realization of a stationary process with mean m and variance σ^2 the autocorrelation coefficients are given by a similar formula where the expectation is to be interpreted as

$$\lim_{n_2 - n_1 \to \infty} \frac{1}{(n_2 - n_1)} \sum_{j=n_1}^{n_2} (x_{i+j} - m)(x_{i+j+k} - m)$$

The expression is also applied to the correlations of a finite length of the realization of a series. Terminology on the subject is not standardized and some writers refer to the latter concept as serial correlation, preferring to denote the sample value by the Latin derivative "serial" and retaining the Greek derivative "auto" for the whole realization of infinite extent.

Autocorrelation Function. The graph of the autocorrelation coefficient as ordinate against the order k as abscissa is called the correlogram. When the series is continuous in time, the set of auto coefficients may be summarized in an autocorrelation function. This is the autocovariance divided by the variance, e.g., for a series with zero mean and range $a \le t \le b$, defined at each time point, is given by

$$\rho(\tau) = \frac{1}{b - t - a} \int_a^{b-t} u(t)u(t + \tau)\,\mathrm{d}t \Big/ \frac{1}{a - b} \int_a^b u^2(t)\,\mathrm{d}t$$

The limits a and b may be infinite subject to the existence of the integrals or sums involved.

The numerator of this expression is called the autocovariance function.

SIR MAURICE KENDALL, International Statistical Institute, London, UK

AUTODEPOSITION. A generic term coined to describe a fairly recent (late 1970s) development in which conversion coatings and organic coatings are applied to metal substrates in a single stage. The process is analogous to the electrodeposition of organic coatings, but in autodeposition, the coatings are deposited by means of chemical action rather than under the influence of an electric current and there is no need for a separate conversion coating stage. See also entry on **Conversion Coatings**.

Autodeposition baths are comprised of colloidal dispersions of film-forming coating materials, such as latexes or polymer emulsions, acids and oxidizers. Cleaned metal surfaces are immersed in the coating composition where the substrate metal is lightly attacked by the activating system of acid and oxidizer. This results in the formation of metal ions which overcome the stabilizing charges on the polymer particles and cause them to deposit on the metal surface. The thickness and type of conversion coating which forms simultaneously is determined by the kind and degree of activation.

Autodeposition is characterized by the growth of the coating with time of immersion and the ability to withstand water rinsing immediately upon removal from the coating bath and before fusion or curing of the coating by heat without loss of coating.

The elimination of the conversion coating sequence used in conventional industrial coating processes means that autodeposited coatings can be applied in fewer steps and in smaller finishing areas. There are no solvents in the commercial baths. This reduces air pollution to virtually zero and completely eliminates fire hazard. The coatings exhibit excellent adhesion, impact resistance, flexibility, and chemical resistance. There is no "throwing power" limit, such as that in electrodeposition. The coatings can be applied to any partially enclosed surface that can be contacted by the bath and are not attacked by "solvent wash." As of the early 1980s, the largest application of autodeposition systems is in the automotive industry.

AUTOGAMY. A process of nuclear reorganization in protozoa in which the nucleus divides, each half undergoes a maturation, and the two persisting functional nuclei reunite. In the modified process known as paedogamy the individual forms a cyst within which it divides into two cells which reunite after the nuclear transformation is completed.

AUTOGENOUS. Self-generated, originating within the body. The term is usually applied to vaccines that are made from a patient's own bacteria as opposed to stock vaccines which are made from cultures grown from standard strains.

AUTOGIRO. See **Helicopters and V/STOL Craft**.

AUTOIMMUNE DISEASE. The term autoimmunity describes the inappropriate reaction of the immune system against one or more of the organism's own tissues. It does not necessarily imply any tissue damage or dysfunction. When there is tissue infiltration, damage and/or dysfunction, the condition is termed autoimmune disease.

The purpose of the body's immune system is to fight off infection, such as viruses or bacteria, and normally the immune system can make a very fine distinction between exogenous antigens (as, for example, manifested by those microorganisms) and self antigens, against which it does not normally react (self-tolerance). Autoimmunity has traditionally been considered to represent a breakdown in self-tolerance, although the mechanisms of this breakdown may not be the same in each case and, in any event, are still not fully understood. Four major mechanisms are responsible for tolerance to self: clonal deletion, clonal anergy, clonal ignorance and active regulation.

Autoimmunity is characterized by the inappropriate or excessive activity of immune effector cells directed to tissue(s) in the body of the organism. Thus, B lymphocytes may produce autoantibodies, and these may or may not have functional effects on the target tissue; immune complexes may be deposited in blood vessels; T lymphocytes may aggregate in tissues (or a tissue) with or without resultant destruction; and the complement system may activate phagocytic mononuclear cells. Generally speaking, in autoimmune disorders that are characterized by tissue damage, the damage is mediated by T lymphocytes. However, there are some conditions in which cellular function may be disturbed primarily by antibodies (e.g. Grave's disease, myasthenia gravis). The development of these diseases, including the disturbances in target cell function, depends on a complex interplay between the antigen(s) on the target cells, the antigen-presenting cells (APCs), the helper or inducer T lymphocytes, T-effector lymphocytes, regulatory or cytotoxic T lymphocytes, B lymphocytes, antibodies and various cytokines (cytokines are soluble factors with various functional properties that are released by many cell types, including immune cells). In turn, these elements stimulate the target cell to express molecules of various types, such as intercellular adhesion molecules, heat-shock proteins, class I and class II histocompatibility antigens, other autoantigens and so forth that will further modify the immune process.

Controversy abounds regarding the nature of the autoimmune process, the role of antigen and of antigen presentation, and the involvement of microorganisms in these mechanisms. At times, the immune response may be induced by a foreign antigen such as is carried by a virus, while on many other occasions no such foreign antigen can be identified (although there are many homologies between antigens of microorganismic origin and autoantigens). Where no exogenous antigen can be found, the abnormality may lie largely, if not entirely, in the regulation of the immune system: a breakdown in tolerance has occurred.

Classification of Autoimmune Diseases

Autoimmune diseases may arise spontaneously in animals and humans, and several experimental models have been induced in animals. This account focuses on spontaneous disorders in humans, which may be divided into organ-specific and nonorgan-specific autoimmune diseases. In the former, antibodies or specifically sensitized T lymphocytes are directed against a component or components of one organ of a given host. In nonorgan-specific conditions, antibodies or specifically sensitized T lymphocytes are directed against components of different organs of a given host. Examples of this type of autoimmune disease would be disseminated lupus erythematosus (DLE) and rheumatoid arthritis. In such cases, it is unclear whether the immune system is responding to several antigens or whether the immune response is more restricted, responding to common antigenic determinants present in the different organs. The autoimmune polyglandular endocrine failure group of diseases should be considered, not as examples of nonorgan-specific autoimmune disease, but rather as examples of multiple organ-specific disease, as it is clear that the target-cell antigens involved are quite different from one another, hence the antibodies are likewise separate.

Major Autoimmune Diseases

Organ-Specific Autoimmune Diseases. A brief description will follow for a few of the main examples of this group, categorized by organ or system.

Endocrine System. The autoimmune diseases of the endocrine system include Grave's disease (autoimmune hyperthyroidism), Hashimoto (autoimmune) thyroiditis, IDDM, autoimmune Addison disease (adrenocortical failure), hypoparathyroidism, autoimmune hypophysitis and autoimmune gonadal failure. These entities may occur singly, or more than one condition may appear in one individual or one family. This appears to be due to genetic overlap, as it cannot be accounted for by antigenic overlap in most instances; indeed the antigens in the different glands are not homologous. These disorders may also be associated with organ-specific autoimmune diseases outside the endocrine system, such as myasthenia gravis, pernicious anaemia, vitiligo, alopecia areata, autoimmune hepatitis, primary biliary cirrhosis, idiopathic thrombocytopenic purpura and others.

Some of the major autoimmune endocrinopathies will be more fully described below.

Grave's Disease. Grave's disease is the commonest form of hyperthyroidism (overactive thyroid). It is mediated by an antibody directed against the thyroid-stimulating hormone (TSH) receptor on the thyroid cells, which acts as an agonist for TSH, thus stimulating the thyroid cells to hyperactivity. Mild to moderate lymphocytic infiltration is seen in the hyperplastic thyroid gland. The eyes are frequently involved with an autoimmune inflammatory reaction as well (Graves ophthalmopathy), the nature of which is still not understood. Patients are very nervous, lose weight, have a rapid heart beat, sweating, weakness and tremor. Grave's disease can be treated with medication that suppresses the thyroid, or with thyroid ablation with radioactive iodine or surgery. See also **Thyroid Gland**.

Hashimoto (autoimmune) Thyroiditis. This condition is characterized by marked lymphocytic infiltration of the thyroid gland, often with lymphoid follicles and variable fibrosis. Thyroid enlargement (goitre) is common. Thyroid cell damage is largely due to the action of T lymphocytes (possibly directed against thyroperoxidase and thyroglobulin), and is the commonest form of spontaneous hypothyroidism. Antibodies to thyroperoxidase and thyroglobulin are usually found in the circulation, and correlate with, but do not cause, the thyroid cell damage. Antibodies to the TSH receptor which interfere with TSH binding and action may be associated with hypothyroidism in some cases of atrophic thyroiditis.

Insulin-Dependent Diabetes Mellitus. IDDM is secondary to lymphocytic infiltration of pancreatic islets, with T lymphocyte-mediated damage directed specifically to b cells (which produce insulin). Several candidate antigens are present within the b cells, with glutamic acid decarboxylase (GAD) most strongly suspected. Destruction of over 80% of the b cells (which may take years) is necessary before the production of insulin becomes inadequate, blood glucose rises, and diabetes is initiated. Antibodies to GAD and other islet cell antigens act as markers for IDDM. See also **Diabetes Mellitus**.

Autoimmune Adrenocortical Failure (Addison Disease). Autoimmune destruction of the adrenal cortices is mediated by T lymphocytes, probably directed against 17- a and 21-hydroxylase. Antibodies against these enzymes act as markers for this condition, which is frequently associated with other autoimmune diseases in the syndrome of autoimmune polyendocrine failure. When damage is severe, inadequate cortisol and aldosterone concentrations are produced, with dire consequences of sodium loss, hypotension, hypoglycemia and weight loss. See also **Addison's Disease**.

Hematopoietic Disorders. Autoimmune hemolytic anaemia, idiopathic thrombocytopenic purpura and autoimmune neutropenia are caused by autoantibody binding to erythrocytes, platelets and neutrophils, respectively. The target cells are destroyed by phagocytic macrophages and/or by complement-mediated lysis.

Gastrointestinal Disorders. Pernicious anaemia is due to an immune reaction directed against gastric parietal cells, resulting in reduced absorption of vitamin B_{12}, in turn leading to macrocytic anaemia and a neurological condition (i.e. subacute combined degeneration of the spinal cord). Antibodies to the parietal cells act as a marker for the disease. Other probable autoimmune conditions of the gastrointestinal tract (e.g. autoimmune sprue, Crohn disease, ulcerative colitis, autoimmune hepatitis and primary biliary cirrhosis) are not discussed further here. See also **Colitis and Other Inflammatory Bowel Diseases**.

Neuromuscular Diseases. Myasthenia gravis is an uncommon neuromuscular disease, characterized by progressive muscular weakness with muscular activity. This is another antibody-mediated disease, in which the antibody is directed against acetylcholine receptors at the neuromuscular junction, blocking the reception of impulses normally initiated at the acetylcholine receptor by acetylcholine. Several patients with this disorder also have thymic hyperplasia or even thymomas. See also **Myasthenia Gravis**.

Neurological Disease. Multiple sclerosis involves demyelinization of central nervous tissue, leading to a relapsing–remitting or a chronic progressive paralytic course. While the pathogenesis is incompletely understood, available evidence indicates that it is a T-cell disease, with an association with HLA-DR2. See also **Multiple Sclerosis**.

Eye. Diseases specific to the eye which are considered to be of autoimmune origin include various forms of uveitis, sympathetic ophthalmia and Sjögren syndrome (keratoconjunctivitis sicca). The eye may also be involved in systemic (nonorgan-specific) autoimmune disease, such as rheumatoid arthritis, DLE, ankylosing spondylitis and Reiter syndrome. Sjögren syndrome is most common with rheumatoid arthritis. Involvement of the lachrymal and salivary glands leads to dryness of the eyes and mouth.

Heart. Rheumatic heart disease, with valvular damage, can be considered an autoimmune disease, although the inciting antigen clearly appears to be of bacterial origin, namely *Streptococcus hemolyticus*. Cross-reactivity with multiple cardiac antigens appears to explain the involvement of the heart. Other conditions with a probable autoimmune basis include idiopathic cardiomyopathy and endomyocardial fibrosis. The heart can also be affected in nonorgan-specific systemic autoimmune diseases, such as DLE and rheumatoid arthritis.

Skin. Bullous pemphigus and dermatitis herpetiformis are serious skin eruptions, the former with bullae and the latter with vesicular rashes, both due to autoimmune processes. The skin, like the heart, can also be involved in systemic autoimmune disorders, such as DLE, rheumatoid arthritis, polyarteritis nodosa and scleroderma. Vitiligo, an autoimmune disorder of the skin in which the melanocytes are the immune target, causes patches of skin depigmentation and is associated with autoimmune thyroid disease in 20% of cases.

Kidney. Goodpasture disease is caused by autoantibodies specific for type IV collagen in the kidney glomerular basement membrane.

Nonorgan-Specific Autoimmune Disease. Examples of nonorgan-specific autoimmune diseases include DLE, rheumatoid arthritis, polyarteritis nodosa, ankylosing spondylitis and, possibly, scleroderma. Only the first two are discussed here.

Disseminated Lupus Erythematosus. DLE attacks many organs of the body, causing a butterfly rash across the bridge of the nose, with fever, joint pains, central nervous system damage, heart damage, thrombocytopenia and kidney damage. The latter can be the most serious complication of this disease. In this condition, antibodies are produced against several nuclear components of cells, most notably against native double-stranded deoxyribonucleic acid (DNA). Occasionally, antibodies are also produced against denatured, single-stranded DNA, and against nucleohistones. These various antibodies are believed to form circulating soluble complexes with DNA derived from the breakdown of normal tissue such as skin. These soluble complexes are filtered from the blood by the kidneys, and thus become trapped against the basement membrane of the glomeruli where they may form characteristic irregular deposits, leading to inflammation (glomerulonephritis) and loss of protein from the kidneys (proteinuria). Similar deposits may also be seen in arteriolar walls and synovial spaces of the joints. Many other tissues can be affected in this condition, as noted above, and may lead to very serious complications and death. Several possible inciting factors have been suspected, including bacteria and drugs. The disease may run a course of remissions and exacerbations over years. See also **Systemic Lupus Erythematosus**.

Rheumatoid Arthritis. This is a chronic systemic disease in which joint manifestations are most dominant, although the condition may also involve the eyes, skin, heart and intestinal tract. The joint synovium is inflamed and densely infiltrated with lymphocytes, plasma cells, dendritic cells and macrophages. Lymphoid follicles may also be seen. Various immune elements participate in this disorder, including T lymphocytes, complement, antigen–antibody complexes, cytokines, enzymes and mediators, leading to the destruction of joint cartilage, with further exposure of the cartilaginous cells to the immune system, leading to perpetuation of the disease. The inflammation is characterized by rheumatoid factor, an abnormally produced IgM antibody, which is directed against a determinant on the Fc portion of the patient IgG molecules. Rheumatoid factor–IgG complexes may deposit in the joint synovia, contributing to the activation of the complement cascade, which releases chemotactic factors, in turn attracting inflammatory neutrophils. It is also thought that autoreactive T lymphocytes may have an important role in driving the inflammation. The joints may ultimately be destroyed by this process. Generally, other tissues are not as seriously involved. See also **Rheumatoid Arthritis**.

ROBERT VOLPÉ, University of Toronto, Toronto Ontario, Canada

AUTOINTOXICATION. Term used rarely to describe poisoning by a substance generated within the body and which the body is unable to eliminate without treatment.

AUTOIONIZATION (or Preionization). Some bound states of atoms have energies greater than the ionization energy. An atom that is in a discrete energy state above the ionization point can ionize itself automatically with no change in its angular momentum vectors if there is a continuum with exactly the same characteristics. This process is called autoionization.

AUTOLYSIS. The energy derived from biological oxidations in living cells serves to promote anabolic processes, i.e., to produce relatively complex, highly ordered molecules and structures, and thus normally keeps living cells in a steady state remote from equilibrium. In organisms that lack cellular nutrients or oxygen (or in dead organisms or cells that have been disrupted so as to destroy much subcellular organization), the opposing catabolic tendency toward equilibrium, including the tendency toward degradation of macromolecules to simpler monomeric subunits, is not counterbalanced. These degradative processes, many of them enzymatically catalyzed, are collectively termed autolysis. Autolytic processes may include, for example, hydrolysis of proteins catalyzed by proteolytic enzymes or hydrolysis of nucleic acids catalyzed by nucleases. Autolysis of tissues (e.g., liver homogenate) has sometimes been used as a method for releasing bound molecules (e.g., vitamins or coenzymes) into free soluble form.

AUTOMATED LAMELLAR KERATOPLASTY (ALK). The basic principle of the ALK procedure was developed by a Colombian eye doctor in 1949, but it was not widely accepted for many years and after many refinements. American ophthalmologists began turning to ALK when it was realized that the more established Radical Keratotomy (RK) procedure could be used only to correct mild to moderate cases of nearsightedness. ALK is still used in the United States to treat a few specific cases of relatively high degrees of myopia and some cases of hyperopia.

In performing the ALK procedure, the surgeon employs a sophisticated surgical instrument known as a microkeratome to create a flap from the center tissue of the cornea. This flap is about 160 microns thick, or about one-third the depth of the cornea, and about nine millimeters in diameter. The flap is hinged at the top of the corneal surface and is folded back during the rest of the procedure. The surgeon continues to use the microkeratome, to remove or ablate the underlying stromal tissue in the central zone of the cornea, to the degree needed to correct the vision condition. The flap is then replaced without sutures, and a protective shield is placed over the eye. Improved vision is normally achieved within a few days.

The accuracy of the ALK procedure is not as high as that of the Photorefractive Keratectomy (PRK) or Laser In-Situ Keratomileusis (LASIK) procedure. Therefore the LASIK procedure which allows the

accuracy of PRK with the quicker visual recovery seen in ALK has become the procedure of choice for most patients. See also **Laser In-Situ Keratomileusis (LASIK)**; **Photorefractive Keratectomy (PRK)**; and **Refractive Eye Surgery**.

Vision Rx, Inc., Elmsford, NY

AUTOMATIC PICTURE TRANSMISSION (APT) SYSTEM. See **Nimbus Satellite Program**.

AUTOMATIC PILOT. Equipment which automatically stabilizes the attitude of a vehicle about its pitch, roll, and yaw axes. Also called *autopilot*.

AUTOMATION. Possibly more aptly termed *automation engineering*, automation is a design engineering philosophy that is directed toward enchancing the automatic nature (sometimes called automaticity) of a machine, process, or other type of work system.[1] The objective of automation is to cause the work system to be as automatic, i.e., self-acting, self-regulating, and self-reliant, as may be possible — but against the real and practical backdrop of various economic, environmental, social, and other restraints. Because of these restraints, the work systems encountered on a day-to-day basis are only *partially automated*.

One definition of automation[2] was proposed in 1947 as "the automatic handling of workpieces into, between, and out of machines." As viewed in the late 1980s, this is a limited definition, although still accurate as far as it goes. Some authorities claim that automation is a contraction of the more-difficult-to-say word, *automization*. Still other scholars claim that automation was coined from *auto*matic and operation.

As pointed out by Mumford,[3] the curse of labor was described by the early Egyptians, who mentioned the daily hardships, the filth, the danger, the nightly weariness of producing goods. Later, the oppression of labor was recognized by the Greeks in the fifth century B.C. and by the Florentines in the twelfth century A.D. Prior to the last century or two, earlier people tended to look toward a force (leading to the modern concept of automation) that would abolish all work and, as described by Mumford, "the most desirable life possible would be one in which magical mechanisms or robots would perform all the necessary motions under their own power, without human participation of any kind. In short, the idea of the mechanical *automation*, which would obey all orders and do all the work." Thus, the negative connotations of automation in terms of adverse effects on the economy of a human work force did not arise seriously until the present century.

Numerous scientific and engineering disciplines make up the technical foundation for automation. Very prominent are electronics, electrical, mechanical, chemical, metallurgical, and industrial engineering; measurement and control technology, computer, information, and communication sciences — all supported by the principles of physics and mathematics.

Advantages/Limitations of Automation

As is apparent from the numerous technical articles in this encyclopedia, advanced automated systems are available today and further advances seem close at hand. Thus, a former question, "Is automation possible?" has been displaced by the query, "Is automation profitable?" As is essentially true of all business concerns, automation is welcomed most where it contributes to profit. Of the several dividends yielded by manufacturing processing automation, two are uppermost — improved productivity and better product quality.

1. *Improved productivity* of machines and people is a dividend that almost always translates into greater profitability and return on investment. Several factors enter into improved productivity, but two are most important:
   (a) *Increased production capacity* — more goods produced per manufacturing floor area, machines installed, and the human work force. In terms of machines, automation usually increases the duty cycle for machines, thus yielding more machine hours per day.
   (b) *Better inventory control* (flow of materials and energy throughout the plant) of raw materials, goods in process, and finished goods. There is an axiom — "To automate well means to understand and plan exceedingly well." Some authorities have observed that just analyzing a plant's operations and procedures when considering further automation is very worthwhile even though only a limited amount of automation may be immediately installed. For the first time, such analysis may cause an in-depth understanding of the intricacies and interrelationships of a given production situation. A number of special techniques, most supported by excellent software for computerized analysis, have been developed in recent years. These include such concepts as *group technology* and other aspects of material resources and requirements planning (MRP). These concepts are described in a condensed fashion later in this article.
2. *Enhanced product quality*, which improves competitive position and reduces waste, and reworks. Improved competitive position naturally translates into higher volume and its usual attendant economic advantages.

   It is interesting to note that some automation has entered the factory, not necessarily by choice, but rather by the force of improved manufacturing and processing operations that far exceed the limitations of human dexterity, awareness, cognition, speed, and strength, among other factors. Some manufacturing and processing variables, such as temperature, pressure, chemical composition, flow, weight, etc., are not directly measurable by people. Human inadequacies in these areas were among the first of the "external" forces that introduced a need for automation.
3. *Upward shift of workers' role*, that is, from numerous arduous, low-skilled duties to higher-skilled supervisory and maintenance responsibilities.
4. *Reduction of personal accidents* through the assumption of accident-prone duties by automated machines and processes.

Some of the limitations of automation include:

1. *High cost* of designing, building, and maintaining automated equipment. This cost is finding considerable relief because of the continuing lower cost of electronic components and equipment, although some of these savings are offset by continuing inflated costs of software. Successful efforts to date and that will continue into the future in terms of standardizing equipment, communication networks, and software will also relieve cost as a barrier to automation.
2. *Vulnerability to down time* because of increasing complexity of automated equipment. This vulnerability, however, is being reduced at an accelerated rate because of improved equipment self-diagnostics, fault-tolerance techniques, and more economic approaches to designing redundancy into automatic systems.
3. *Loss of flexibility*. This was a very important restraint on automation until relatively recently. Introduction and refinement of the concept of flexible manufacturing systems (FMS) has largely negated this restraint.
4. *More management attention*. Actions in highly-automated systems occur sometimes at an almost unbelievably high rate and allow little or no time for human decisions. Currently, with state-of-the-art technology, a machine or process can be driven to make quite a lot of off-spec and scrap material before effective supervision can get into control of a runaway situation. Through the assistance of information networks, ranging from corporate to plant-wide to cells and individual machines and processes, managers can be appraised of factory floor situations on essentially a second-by-second basis. Thus, more and better management personnel is needed as a plant increases its content of automation. In the more distant future, a much greater

[1] Work, as used here, is the action or effort expended in production. Work refers to the application of machine energy, human energy (muscle and brain-power), and any other auxiliary energy used in the production of goods and/or services. Work may apply only to the manipulation of information, which occurs in data processing and office automation. Or, it may apply to the manipulation of both information and materials to produce physical goods, that is, the products of industrial manufacturing and processing.

[2] D.S. Harder, who in 1947, was a vice president of Ford Motor Company.

[3] As found in "The Myth of the Machine: Technics and Human Development," by Lewis Mumford, Harcourt, Brace & World, Inc., New York, 1966.

portion of the almost instantaneously needed decision making will also be done automatically. However, assignment of this important responsibility to computers needless to say will require exceedingly careful attention and analysis by very sharp management personnel.

5. *Persistance of automation's negative image*. Surprising to many authorities has been the acceptance of automation technology by the labor force and the successful negotiation of new union contracts — even though the basic fact remains that jobs are eliminated by automation. Of course, automation also creates new and certainly higher-skilled jobs. As the public and the press and other media which serve it become better acquainted with the real nature of automation, earlier predictions of very adverse effects on the labor force will continue to be tempered. Fortunately, too, automation is frequently identified with the other aspects of so-called "high technology," contributing to a reasonably good press for automation.

Applications for Automation Technology

Nearly all human endeavors, including education, recreation, health care, national defense, communication, transportation, industrial manufacturing and processing, research and development, and business and commerce have been impacted by automation.

Office Automation. Sometimes simply referred to as computerization, office automation involves information as the input, the work in process, and as the final product. The information may be of many purposes and formats — payroll preparation, transportation reservations and scheduling, banking and security transactions, statistical and census compilations, inventory control, accounts receivable and payable, insurance risks and records, cost and price analysis, statistical quality control, electronic mail, and almost any activity that can be described as routine *paperwork*. Increased productivity per office worker is indeed a major advantage, but possibly more important is the rapidity with which information required to make business management decisions can be communicated over long distances and integrated with information from various institution and corporate entities.

Office automation has contributed in a very marked way in the furtherance of manufacturing and processing automation systems.

Manufacturing Automation. Manufacturing automation, in the long term, most likely will well exceed office automation in terms of investment. However, there will be so much blending, integration, and information exchange between the management of offices and factories that it will become increasingly difficult to determine any sharp demarcation between these two activities.

The tempo to automate production has hastened very much during the latter half of the 1980s, but what appears as intense activities now will pale in terms of investments in automation to be made during the remainder of this century. The somewhat lagging acceptance of automation on the part of the bulk of manufacturing industries is considered by many authorities as simply a "wait and see" attitude. Numerous segments of manufacturing are awaiting the experiences of the comparatively few leading users of the present time, notably the application of automation technology by the automotive and electronics industries, as examples, of current leaders in the field. These industries have been under much pressure to improve both quality and productivity from forces that are national and international. Competitive pressures have warranted unusually high investments in manufacturing research and development. It is largely these industries, for example, that have funded advanced communication links and more effective robotization, including machine vision.

Patterns of Industrial Production. Manufacturing automation has developed along two principal paths, which reflect the rather distinct natures of two kinds of products:

1. *Fluid and bulk materials process industries*, as typified by the chemical, petroleum, petrochemical, metals smelting and refining, and food processing fields, among others, which largely react, separate, combine, and otherwise process materials in a liquid, slurry, gaseous, or vaporous state. During much of the manufacturing, raw materials, materials in process, and final products are in the form of fluids or bulk solids. Except at the molecular level, these materials are not in the form of discrete, identifiable pieces. Fluids and bulk materials are handled in enclosures, such as vats, bins, and other vessels, and are transported within pipes and atop bulk belt and other types of conveyors. A major exception in a number of these fluid/bulk industries is the final product, which may be a discrete can, box, tank car, barrel, etc.

   A rather high degree of automation has existed in the fluid/bulk industries for several decades, particularly since World War II when many of the former batch processes became continuous in nature. Fluid/bulk industries traditionally have been capital rather than labor intensive. For many years and continuing into the present, the most commonly measured and controlled variables have been temperature, pressure, flow, and liquid level and, as previously mentioned, these are quantities that essentially are impossible for humans to measure accurately, if at all, without the aid of instruments. The automation of measurement and control of these variables for many years was identified as *instrumentation and automatic control* — the term automation was rarely used in this regard.

   A typical automatic control system of the type used in the chemical and process industries is detailed in article on **Control System**.

2. *Discrete-piece manufacturing industries*, as typified by the manufacture of machines and parts, assemblies and subassemblies, etc., generally have been quite labor intensive because the production variables present — dimension, position, displacement, proximity, motion and speed have been at least partially within the grasp of measurement and hence control by people. Technologically, too, it has been much more difficult to develop sensors to automatically measure and devices to automatically control, without human supervision, these manufacturing variables than, for example, the development of instrumentation for the fluid/bulk industries.

   Applications of automation that typically are found in the discrete-piece manufacturing industries are illustrated by Figs. 1, 2, 3, 4, 5 and 6.

Fig. 1. Robotic system incorporating both machine vision and end-effector pressure sensors is designed for unloading randomly positioned parts from a storage bin. (*ORS-i-bot*™, ORS Automation, Inc.)

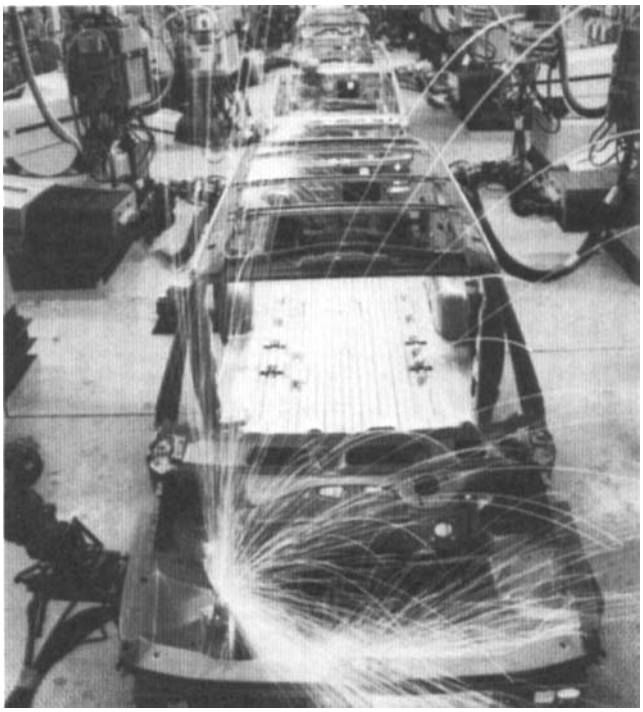

Fig. 2. Automatic welding line where the work (unitized car body parts, such as side aperture panels, roof panels, flat floor pan, and fenders) is brought to computer-controlled robots by way of conveyor line. (*Chrysler Corporation, Windsor, Ontario Assembly Plant.*)

The progress of automation has been closely tied to the ease with which an operation may be automated. Thus, it is no surprise that automation of the fluid/bulk industries preceeded the discrete-piece industries by several decades.

This observation is further proved by a number of discrete-piece industries that currently remain well behind the leaders in automation.

For example, still one of the most labor-intensive industries is the manufacture of garments and apparel. The skills of sewing have been very difficult to transfer to a machine control system. Unlike working with rigid materials such as metals and plastics, textiles are soft, pliable, and from the standpoint of machine design they are much more difficult to manipulate. Further, the geometry of the parts of a garment and the dependence for appearance upon the nature of the seam for shape and drape are factors that do not enter in the assembly of something made from harder, more rigid materials. These kinds of difficult technical problems, coupled with an industry that is generally not accustomed to high capital expenditures, have substantially slowed the pace of automation in the garment and other like fields.

Scientific Foundation for Automation

Principal scientific and technological developments that contributed to the feasibility of automation have included:

1. *Feedback*, the fundamental principle and basic mechanism that underlies all self-regulating processes. Some experts have defined feedback as information about the output at one stage of a process or operation that is returned, that is *fed back* to an earlier stage so as to influence its action and hence to change the output per se. Ingenious self-regulating devices and machines date back many years. The flyball governor, invented in 1788 to control Watt's steam engine, exemplifies the application of feedback long before a theory for feedback and closed-loop control was put forth. One of the earliest uses of closed-loop feedback was its application to the power steering of ships, adapted decades later to the power steering for automobiles.
2. *Information and communication theory* was not tackled formally until after World War II, when C.E. Shannon published "A Mathematical Theory of Communication" in 1948. In that same year, N. Wiener published "Cybernetics or Control and Communication in the Animal and the Machine." The concepts put forth by Wiener stirred up excitement during that early period. Cybernetics is essentially comprised of three concepts: (1) Animal or machine systems, (2) communication between systems, and (3) regulation or self-regulation of systems.
3. *Sensors and measurement systems* did not develop historically according to any particular master plan. Generally, sensors were developed so that more could be learned concerning the nature of physical and chemical phenomena — *not* as tools for achieving automation. Measurement of dimension and weight, for example, had its roots in antiquity and its needs were largely the basis upon which early trade could be conducted. Although mechanically based sensors have been used, and will continue to be used, in automation systems, the measurement field progressed much more rapidly after the details of electromagnetics and electrical circuits were established earlier by such investigators as Ampere, Volta, and Ohm in the late-1700s and early-1800s — then to be followed in the first half of the 1800s by Faraday, Henry, Wheatstone, Kirchoff, and Maxwell. Even before the appearance of electronics, it usually was found much easier to measure and control a machine or process by electrical rather than mechanical, pneumatic, or hydraulic means. But in the absence of electronics, non-electrical methodologies essentially by default became the approaches of choice. Even today, wide use of mechanical, pneumatic, and hydraulic technologies persist. The comparatively new field of micromechanical sensors is successfully re-establishing some of the earlier non-electronic approaches.
4. *Servopower*, electric, hydraulic, and pneumatic, made possible a host of actuators, ranging from valves, louvers, and dampers in the fluid/bulk industries and machine and workpiece positioners in discrete-piece manufacturing. Automation was assisted by the appearance of combined-technology devices, such as electromechanical, electrohydraulic, and electropneumatic relays and subsystems. The continuing progress in the design of electric motors, decreasing size and weight for a given horsepower rating along with increased energy efficiency, is contributing to the furtherance of automation. During the past decade or two, outstanding progress has been made in DC and AC motor controls, in the refinement of stepping motors, and in the practical application of linear motors.
5. *Computer and memory power* have been of outstanding importance to automation even though these elements have not always been sophisticated. The Hollerith card, which appeared in 1890 (frequently referred to for many years as the IBM card), most likely had its roots in the card-programmed Jacquard loom invented in 1801. In repeat-cycle automated machines, the memory required for operation in earlier machines was designed right into the mechanics of the machine — a practice that still can be found in printing and packaging machines, whose automaticity dates back a number of decades. As the degree of automaticity and complexity of a machine or process increases, there are continuing requirements for more information storage and retrieval at faster and faster rates. Prior to the entry of digital electronics, mechanical computing and memory systems (for example, desk calculators of just a few decades ago) were large, slow (in today's terms), and frequently quite difficult to alter (program). With the majority of controllers of the last few decades being electronic, it is easy to forget that the earlier mechanical, pneumatic, and hydraulic controllers had to incorporate non-electronic computers to calculate the error signal in a closed-loop feedback system. Actually, the words *memory* and *computing* were rarely used in the process control field prior to the appearance of electrical and electronic instruments, even though all the elements were there under different designations.
6. *Digital technology*, which for practical purposes encompasses the advances of solid-state microelectronics, introduced vastly improved computing speeds for automated systems which, in combination with improved response speeds of detectors and sensors, greatly enhanced the performance of control systems. Modern computerization, of course, stems directly from digital technology. The two very marked trends of decreased size and cost for microelectronics have greatly

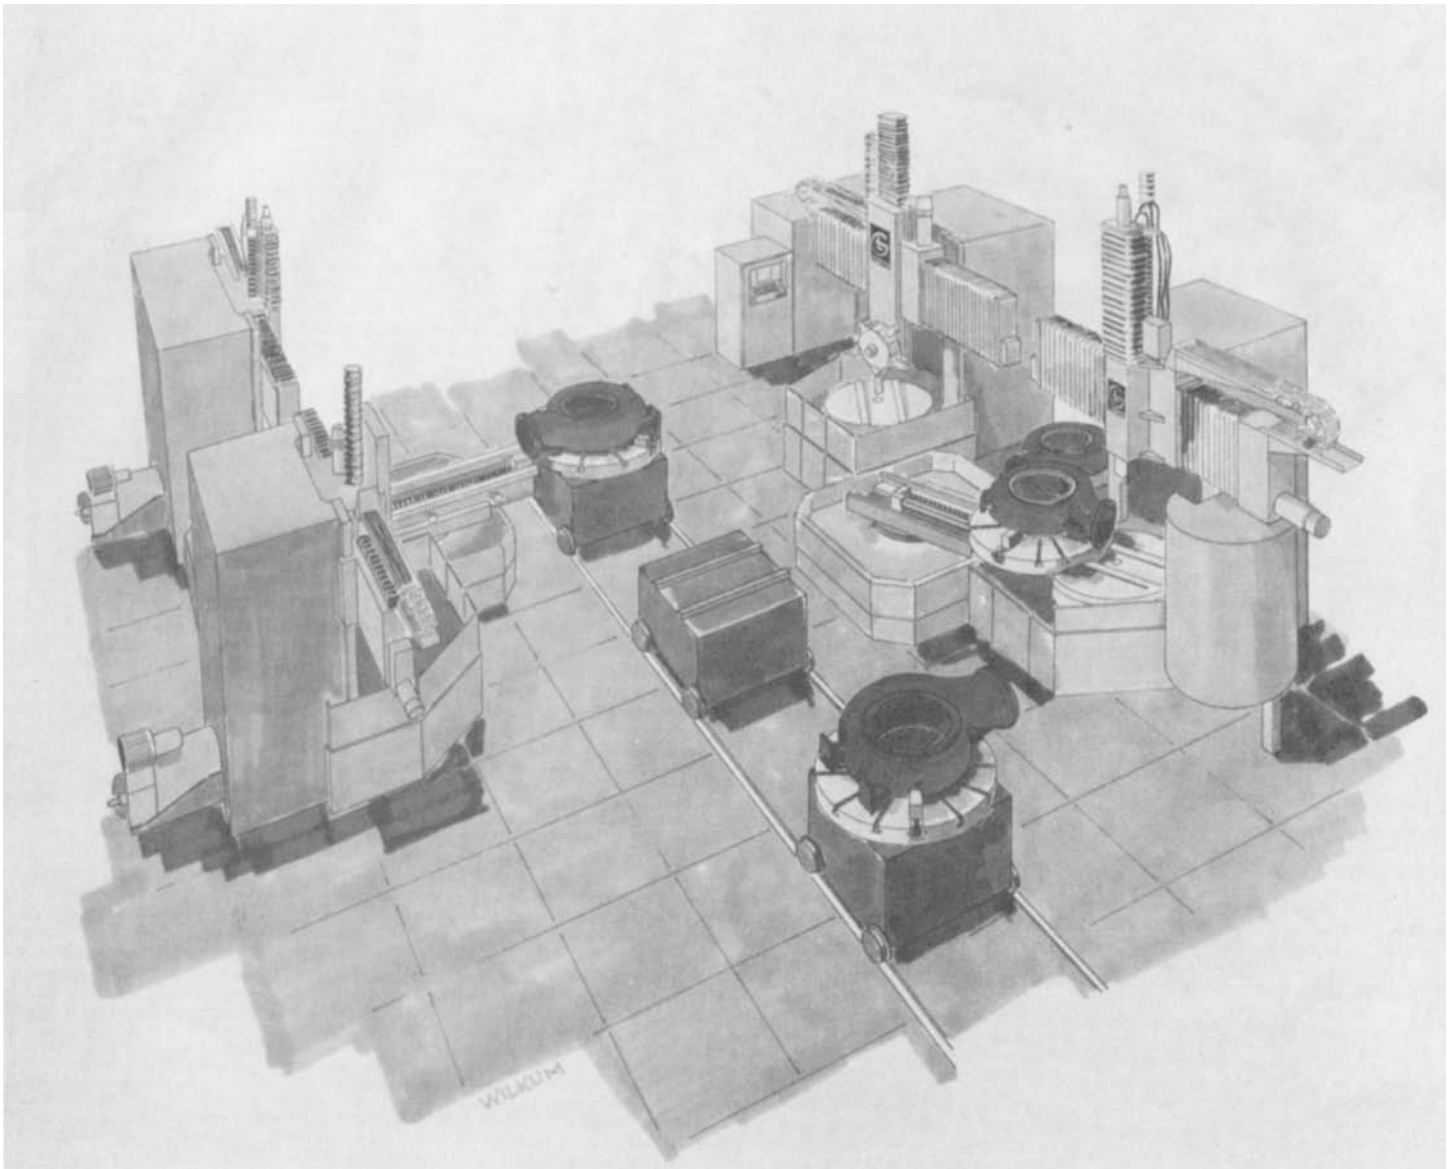

Fig. 3. Manufacturing systems can take advantage of automation even if relatively small and simple. Machining of large castings in system shown here is handled by four numerically controlled (NC) vertical turning centers with workpiece and rotary pallet automatically moved from transport to vertical turret lathe by sliding pallet shuttles. (*Giddings Lewis*.)

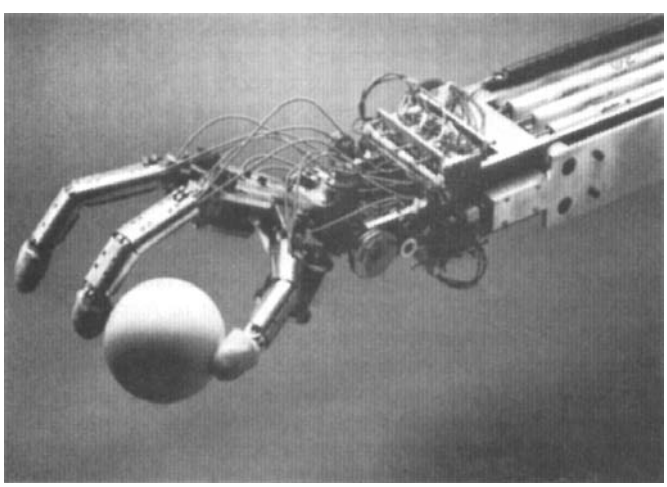

Fig. 4. Multifinger robot hand. The hand has fourteen joints which are driven by special "shape memory" alloy actuators. The fingers are dexterous and gentle (egg in view) and are appropriate for a number of automatic assembly and maintenance operations. (*Hitachi America, Ltd.*)

influenced the availability of components in terms of application feasibility and economics. The question is sometimes asked, "Why is small size so important in regard to the electronic components widely used in automated systems?" First of all, size is directly related to the economics of component part production. Second, the example of having to mount detectors on robot arms (where the space available is limited) serves to answer the question from a practical applications standpoint. Obviously, many similar examples could be given.

7. *Mechanization*, presently simply taken for granted, was a major step toward automation. Mechanization was the logical next step toward automation after the emergence of metal hand tools (in contrast with the earlier stone and wood tools). Mechanization conferred the first degree of automaticity to a system. See article on Robots and Robotics.
8. *Systematization and engineering analysis* were and continue to be key elements for achieving successful automation plans and installed systems. As mentioned earlier, just good planning and thinking in depth about the prospects of automation for a manufacturing process can be extremely beneficial. Traditionally, production supervisory personnel have been the real storehouse of knowledge pertaining to all aspects of production — from incoming materials through warehousing and shipping.

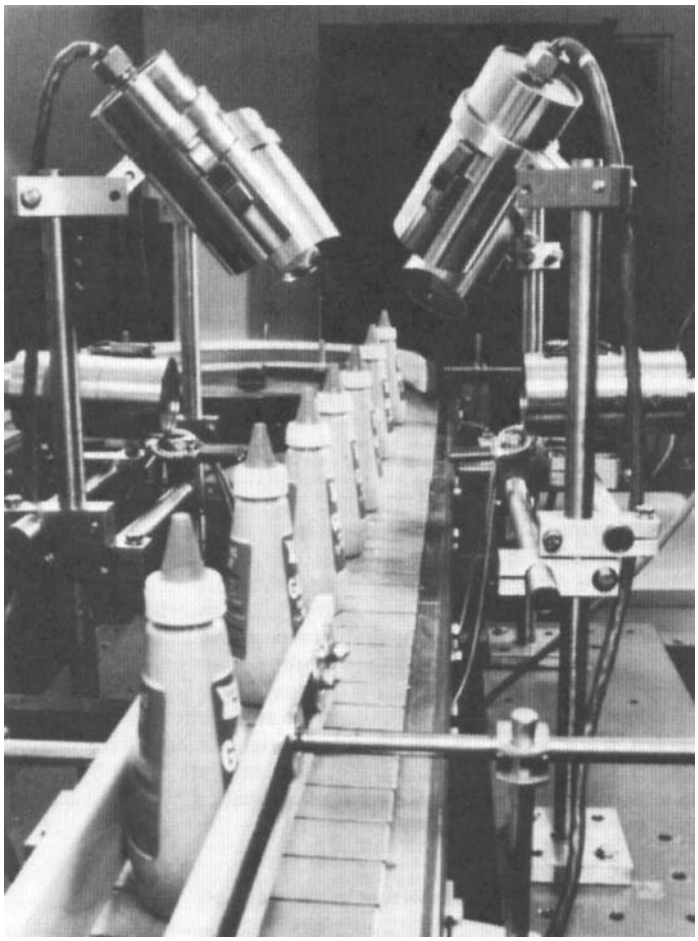

Fig. 5. Four machine-vision cameras are used in this production line to check labeling and other container characteristics. (*System QR4000, Cutler-Hammer Products, Eaton Corporation.*)

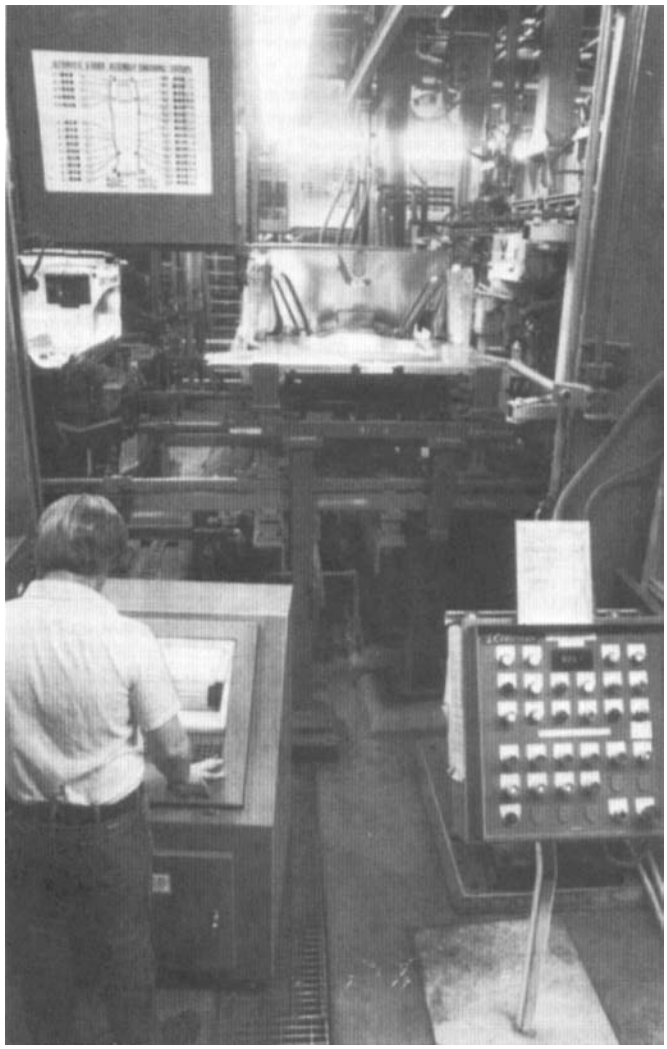

Fig. 6. After car body welding is completed, underbody subassemblies for front-wheel-drive cars move into an automatic probe checking station shown here where thirty critical measurements are verified to assure sound, dimensionally precise platforms upon which to build the rest of the vehicle. Data from the fixture are fed to a computer that prints out a copy for the operator in foreground. A board that flashes "go or no-go" lights for a quick visual verification in included. This is shown on the panel at upper left. This installation is one of over a thousand computers of varying capacity used at this Orion Township, Michigan, plant of General Motors Corporation.

Because advanced manufacturing automation minimizes (sometimes displaces) the subtleties of human judgment that can be applied directly on the factory floor in the form of minor machinery adjustments or procedural changes in the interest of maintaining smooth, uninterrupted production throughput, all of the vagaries of production which are deeply implanted in the minds of production supervisors must be brought out into the open prior to more extensive automation. This detailed, but very important information is not always easy to retrieve. As suggested by a major firm, one must "sweat out the details" if success is to be achieved via automation.

9. *Information display technology*, which has progressed beyond earlier expectations prior to the extensive use of the cathode ray tube, has contributed immeasurably to the expansion of automation technology — largely by automating the human/machine/process interface per se. Ingenious ways of plotting and presenting information, now widely assisted by the use of color, have provided a way to interlock designing for manufacture with manufacturing itself in so-called CAD/CAM (computer assisted design/manufacturing).

Contributions of Automation to Engineering and Science

The prior recitation of the scientific and engineering developments upon which modern automation is based provides only part of the story. Within the past decade, with the firm establishment of automation in many major industries, the reverse transfer of technology has occurred at least to some degree. Pressures brought about by automation have impacted information communication — as represented by the possibility (once a dream) of integrating and interlocking manufacturing operations on a corporate and plant-wide basis through the development of hierarchical two-way information transfer (communication) systems. This is exemplified by the great progress that has been made in the design of local area networks (LANs), which in turn are parts of wide area networks. Many examples can be given. One of the earlier and outstanding developments is MAP (Manufacturing Automation Protocol).

The concept of distributed control is another. Introduced in the mid-1970s, this control architecture combined three technologies — microprocessors, data communications, and CRT displays. Automation today is affecting the design of future computers, the development of more effective programming languages, and the technology of expert systems; although not exclusively, automation is a major source of pressure to develop the concept of artificial intelligence (AI), which in past years has not exhibited the kind of practicality that is expected within the relatively near future. Progress is being made in the application of AI to machine vision in connection with the performance of robots.

Automation requirements of the automotive industry literally gave birth to the concept of the programmable controller as a replacement of electromagnetic relay systems. The acceptance of the programmable controller was almost immediate and over the past decade has expanded at a phenomenal rate.

Not the least of automation's contributions to technology has been its impact on the entire philosophy of manufacturing. For example, the concept of flexible manufacturing systems (FMS). This actually grew out of earlier dissatisfaction with attempts to automate various machines and

processes. With the kinds of hardware available in the 1930s and 1940s, systems were essentially limited to *hard automation*, an approach that usually was advantageous only for high-volume, long-term production runs. In fact, the popular approach to automation in the 1940s and 1950s was to design a product *for* automation (there is still wisdom in this approach). It was found that products designed strictly with automation in mind often turned out unattractive aesthetically and minimized the options in design that the consumer expected. Although no universal automated system appears on the distant horizon, automation of the late 1980s is many times more flexible. The analytical planning required to create successful flexible manufacturing systems almost immediately led to the concept of computer-integrated manufacturing (CIM). This is the logical organization of individual engineering, production, and marketing and support functions into a computer-integrated system. Functional areas, such as design, inventory control, physical distribution, cost accounting, procurement, etc. are integrated with direct materials management and shop-floor data acquisition and control. Shop-floor machines serve as data-acquisition devices as well as production machines.

Status of Automation — 1990s

Prior to the 1970s, the automation of industrial production was mainly an extension of mechanization, that is, the use of systems that did not incorporate feedback. Attempts to automate were largely of an unplanned, scattered, piecemeal nature. Even by the late-1980s, just a few plants worldwide (considering the vast number of manufacturing facilities, large and small) have been automated across the board in a way that matches the rather distorted public image of automation on a grandiose scale. A few notable examples will be found in the automative and electronics industries. Plant-wide, *all-at-once automation* is found in a comparative handful of plants that either are new facilities built from the ground up in very recent years, or are plants that have been fully refurbished from the receiving to the shipping dock. In either case, such new and modernized facilities represent tremendous capital outlays that are well beyond the resources of most manufacturers and processors.

Plant owners and managers have patiently learned that automation is best approached by stages in a carefully planned and tightly controlled manner. What has changed most during the past few years is the attitude of top management toward automation. Greater motivation is shown because of increasing courage and confidence. Growing numbers of firms are pioneering automation on a vastly increased scale by targeting larger sections and departments of their plants — as contrasted with a former posture of experimentation and *automation by trial* in terms of a few machines or manufacturing islands.

The incentive to automate, of course, is fundamentally economic. Competitive pressures, frequently from the international marketplace, have been great and largely unexpected. Thus, any endeavor that will trim costs in the long run, such as automation, must be given serious consideration. This factor accounts for the present *uneven* application of automation from one industry to the next. Those industries that have been hurt the most by competition will be among the pioneers of automation. Very large firms in these categories not only have invested heavily in the procurement of automation hardware and software, but also have participated in a major way in automation research and development.

Technologies Closely Coupled with Automation

Closely coupled with automation are several concepts that have revolutionized manufacturing philosophy. Some of these concepts are defined briefly here and will be found in other areas of this encyclopedia. Check alphabetical index.

CAD (Computer-Aided Design)

This acronym can also be taken to mean computer-aided or computer-assisted drafting. Uncommonly, a combined acronym (CAD/D) may be used. This designates a system that assists not only in the preparation and reproduction of drawings, but that also develops the information or intelligence associated with the drawing. Most CAD/D systems have six major components (four hardware; two software):

1. A central processing unit (CPU).
2. Storage — where drawings and graphics are stored electronically.
3. Workstation — the interface between operator and computer.
4. Plotter station — where images stored in the computer memory are printed on drafting media.
5. Operating system (OS) — the master control program that coordinates the activities of all four of the aforementioned hardware components.
6. Application program — user software that creates working environment for creating designs and preparing drawings.

Major Functions of CAD. There are four principal functional categories:

1. *Design and Geometric Modeling.* In this function, the designer describes the shape of a structure with a geometric model constructed graphically on a cathode ray tube (CRT). The computer converts picture into a mathematical model, which is stored in the computer database for later use.
2. *Engineering Analysis.* After creation of a geometric model, the engineer can calculate such factors as weight, volume, surface area, moment of inertia, center of gravity, among several other characteristics of a part. One of the most powerful methods for analyzing a structure is *finite element analysis*. Here, the structure is broken down into a network of simple elements and the computer uses these to determine stress, deflections, and other structural characteristics. The designer can see how a structure will behave before it is built and can modify it without building costly physical models and prototypes. The procedure can be expanded to a complete systems model and operation of a product can be simulated. When combined with engineering, CAD is sometimes referred to as CAE (Computer-Aided Engineering); or sometimes the combined acronym, CAD/CAE, is used.
3. *Computer Kinetics.* The user can examine effects of moving parts on other parts of the structure or design and analyze more complex mechanisms.
4. *Drafting.* A CAD system can automatically draft drawings for use in manufacturing. Engineers can draw on geometric and numerically coded descriptions produced by CAD to create numerical control tapes, which permit direct computer control of shop machines, determine process plans and scheduling, instruct robots, computerize testing, and generally improve the management of plant operations.

CAM (Computer-Aided Manufacturing)

This acronym generally refers to the utilization of computer technology in the management, control, and operation of a manufacturing facility through the direct or indirect interface between a computer and the physical and human resources found in a manufacturing organization. Developments in CAM are found in four main areas:

1. *Machine Automation.* Originally confined to numerical control, machine automation has been expanded and now consists of a chain of increasingly sophisticated control techniques:
   (a) At the lower end of the scale is *fixed automation* with relays or cams or timing belts and timing chains. Relay logic has been extant in industrial production for decades. Essentially during the past two decades, many relay installations have been replaced by electronic means, notably in the form of programmable controllers.
   (b) Further up the scale of automaticity is plain numerical control (NC) whereby a machine is controlled from a pre-recorded, numerically coded program for fabricating a part. In these systems, machines were hard-wired and were not readily reprogrammable.
   (c) At a higher point in the scale of automaticity, the machine is directly controlled by a minicomputer, which stores machining instructions as software that is relatively easy to reprogram. Known as CNC (computer numerical control), this approach has the advantages of much higher storage capability and greatly increased flexibility. Nearly all new numerical control systems today are CNC oriented. However, as recently as the late 1970s, CNC was considered a costly exception to the traditional approach.
   (d) At the highest point in the scale of automaticity as presently viewed is the plant-wide and even corporate-wide interconnection

of machines on the floor with vast and complex information networks, wherein decisions at the factory floor level are influenced by information flowing down from the corporate computer hierarchy — and, in the other direction, information from machines flows upward to enrich the database of the headquarters computer. This is further described under CIM.

2. *Robotics.* Robots are now used rather widely for performing materials-handling and manipulating functions in CAM systems. Robots can select and position tools and workpieces for CNC tools, operate such tools as drills and welders, or perform test and inspection functions.
3. *Process Planning.* This activity considers the detailed sequence of production steps from start to finish. The process plan describes the state of the workpiece at each work station. An important element of process planning is *group technology*, in which similar parts are organized into families to allow standardized fabrication steps, thus permitting savings by avoiding duplicate tooling and system engineering. This approach differs some from traditional practice where parts were usually fabricated close to their assembly into a subsystem. Similarity of fabrication techniques may take precedence over what otherwise might appear as the logical location for such work.
4. *Factory Management.* This involves the coordination of operations of an entire plant and is a key objective of CIM. Systems tie together individual machine tools, test stations, robots, and materials handling systems into *manufacturing cells* and the cells are integrated into a larger system. Integrated management requires extensive, highly detailed, and usually costly software programs. The nomenclature used for this software is not consistent. The term Manufacturing Planning and Control Systems (MPCS) has been used as a grand designation. Two very important areas in this grouping are MRP-I (Materials Requirement Planning) and MRP-II (Manufacturing Resources Planning).

Bridging CAD and CAM Systems

CAD employs pictorial, graphics-oriented computer databases, whereas CAM involves a large amount of text-oriented information. It is necessary to find a way for the computer doing the drawing to speak the same language as the computer directing the manufacturing plant.

Layering is one way to link the systems. This involves structuring the CAD and CAM databases. This makes it possible for various people to input data without losing control of the overall design and manufacturing process. Also, it permits shop people to see information that is meaningful to them without sorting through and attempting to understand the rest of the information that is normally included in a drawing. This can be accomplished by organizing information into an arrangement resembling layers or slices within the databases. The engineers or users in other departments of an organization can provide pertinent information or examine any or all layers of information in accordance with need.

CIM (Computer-Integrated Manufacturing)

The concept of CIM was introduced in 1973. It has been defined by some authorities as the automation and integration of a manufacturing enterprise through the use of computers. Others have defined CIM as the logical organization of individual engineering, production, and marketing/support functions into a computer-integrated system. Functional areas, such as design, inventory control, physical distribution, cost accounting, planning, purchasing, etc., are integrated with direct materials management and shop-floor data acquisition and control. Thus, the loop is closed between the shop floor and its controlling activities. Shop-floor machines serve as data-acquisition devices for the control system and often its direct command. Strategic plans smoothly give way to tactical operations, at known cost.

CIM is obviously a very ambitious target. The internal research into nearly every aspect of a firm's business is required to prepare complex software for CIM. This is very time consuming and costly. Until there is some universality of approach and until it becomes easier to follow the successful CIM examples of others, the average plant may need a number of years on the learning process prior to adopting CIM on a large scale. At present, CIM appears to be most practical for very large firms, particularly those with multiple product lines that change every year or so (notably, the automotive industry).

Fortunately, many of the gains from automation can be made without having to go to the high technological level demanded by CIM.

FMS (Flexible Manufacturing System)

The definition of FMS has widened over the last few years. Traditionally, FMS has been considered to be the mingling of numerical control (NC) with automated materials handling and computer systems. When simple tape-programmed NC was introduced in the late 1950s, a major selling point was the ability of such a system to permanently remember from data stored on punched paper tape how given parts were made. This enabled manufacturers to run batches of the same parts with long time intervals between batches. All that was necessary was to retrieve the tape from file and to run the machine tool on a fresh supply of blanks. Duplication from batch to batch was quite exacting. Finished part inventories could

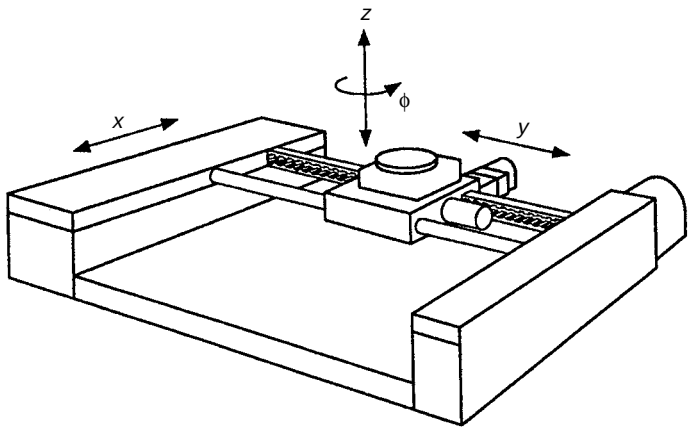

Fig. 7. Automatic printed-circuit (PC) board component placement machine requires positioning a placement head at 75 cm (30 inches) per second with a resolution of 0.025 mm (0.001 inch) or better. Control of *X*, *Y*, and *Z* axes, component alignment, and gripper are required from computer programming. A belt-driven gantry is controlled by an indexer, and two servomotor drives are used for *X*-*Y* positioning. *Z* motion and rotational alignment are controlled by a computer microstepping drive. Joystick inputs are used to move the head manually and to teach positions to the computer. (*Parker-Hannifin Corporation, Compumotor Division.*)

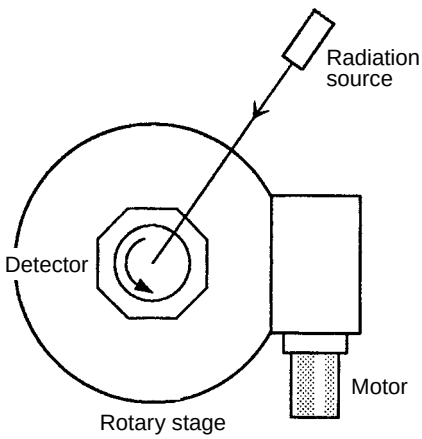

Fig. 8. A system is required to plot the response of a sensitive detector, which must receive equally from all directions. Detector is mounted on a rotary table which requires to be indexed in 3.6° steps, completing each index within 1 second. (For setting up purposes, the table can be positioned manually at 5 r/min. The table incorporates a 90:1 worm drive.) The maximum required shaft speed (450 r/min) is well within the capacity of a stepper, which is an ideal choice in simple indexing applications. Operating at a motor resolution of 400 steps per revolution, the resolution at the table is a convenient 36,000 steps per revolution. In this case it is important that electrical noise be minimized to avoid interference with the detector. Two possible solutions are to use a low-EMI linear drive or to shut down the drive after each index. (With a stepper driving a 90:1 worm gear there is no risk of position loss during shutdown periods.) (*Parker-Hannifin Corporation, Compumotor Division.*)

be trimmed drastically. Better quality control over parts and workmanship were key objectives of the early NC systems. The ability to store tapes was an added benefit of the system and proved to be one of the main advantages as experience was gained.

Improvements in computer control and the creative concept of automated material transport between machines spawned what is known as a flexible manufacturing system. Now, instead of applying CNC (computer numerical control) to only one or at most two machine tools, groups of machine tools can be operated from the same controls. Direct labor still may be used to unload and load workpieces in a centralized area and to handle tool replacements. These functions also can be fully automated if economically justified. Generally, each individual palletized workpiece is automatically sent to required work stations in the unique order appropriate for its processing. The order of processing and the actual work done may differ for each part in the system at any one time. Provisions are made for automatic rerouting of parts if a given workstation becomes unavailable or overloaded. The computer system notifies the system manager of any malfunctions, monitors tool life, and signals any required normal tool replacements. Production, down time, and individual machine utilization statistics are recorded and reported as required.

Because FMS installations are among the most common applications for automation found in industry, they are mentioned frequently in the literature. These systems may be extended in complexity and sophistication to whatever extent management may be willing to fund. The FMS concept is not limited to machine tools.

Motion Control Systems

A majority of equipment that fits the definition of automation does not involve robots. However, robots were an important incentive toward the development of motion control. The control of motion is a key function of automated manufacturing systems, whether or not robots per se are involved. Dating back a few decades, motion sensors of high precision and reliability were developed, many of which incorporate stepping motors as a source of motion power. See also article on **Stepper Motors**. Other machine drives, of course, include gear drives, tangential drives, and lead or ball screw drives. See Figs. 7, 8, 9, 10 and 11.

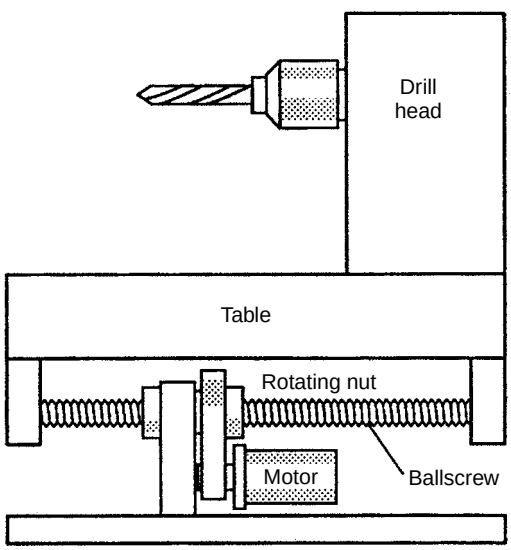

Fig. 9. A stage of a transfer machine is required to drill a number of holes in a casting using a multihead drill. The motor has to drive the drill head at high speed to within 2.5 mm (0.1 inch) of the workpiece and then proceed at cutting speed to the required depth. Drill is now withdrawn at an intermediate speed until clear of the work and then fast retracted, ready for the next cycle. Complete drilling cycle takes 2.2 seconds, with a 0.6-second delay before the next cycle. Due to proximity of other equipment, the length in the direction of travel is very restricted. An additional requirement is to monitor the machine for drill wear and breakage. The combined requirements of high speed, high duty cycle and of monitoring the drill wear all point to use of a servomotor. By checking torque load on the motor (achieved by monitoring drive current), one can watch for increased load during the drilling phase, pointing to a broken drill. Application will require a ball-screw drive to achieve high stiffness together with high speed. One way of minimizing the length of the mechanism is to attach the ball screw to the moving stage and then rotate the nut, allowing the motor to be buried underneath the table. Since access for maintenance will then be difficult, a brushless motor is suggested. (*Parker-Hannifin Corporation, Compumotor Division.*)

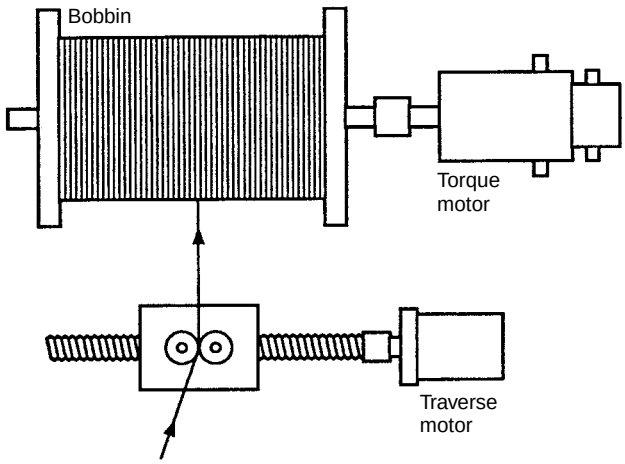

Fig. 10. Monofilament nylon is made by an extrusion process that results in an output of filament at a constant rate. Product is wound onto a bobbin rotating at a maximum speed of 2000 r/min. Tension in filament must be held between 0.1 and 0.3 kg (0.2 and 0.6 lb) to avoid stretching. Winding diameter varies from 5 to 10 cm (2 to 4 inches). Prime requirement is to provide a controlled tension, which means operating in a torque mode rather than a velocity mode. If the motor produces a constant torque, the tension in the filament will be inversely proportional to the winding diameter. Since the winding diameter varies by 2:1, the tension will fall by 50 percent from start to finish. A 3:1 variation in tension is acceptable, so constant-torque operation is acceptable. Requirement leads to use of a servo operating in the torque mode. (Need for constant-speed operation at 2000 r/min also makes a stepper unsuitable.) Rapid acceleration is not needed, so a brush servo would be adequate. In practice, this suggests a servo in velocity mode, but with an overriding torque limit. The programmed velocity would be a little over 2000 r/min. In this way the servo will normally operate as a constant-torque drive, but if the filament breaks, the velocity would be limited to a programmed value. The traversing arm can be adequately driven by a stepper. However, the required speed will be very close to resonance, so a microstepping system would be preferable. An alternative would be to use a half-step drive in conjunction with a toothed-belt reduction of about 3:1. A ball-screw drive can be used to achieve high stiffness together with high speed. (*Parker-Hannifin Corporation, Compumotor Division.*)

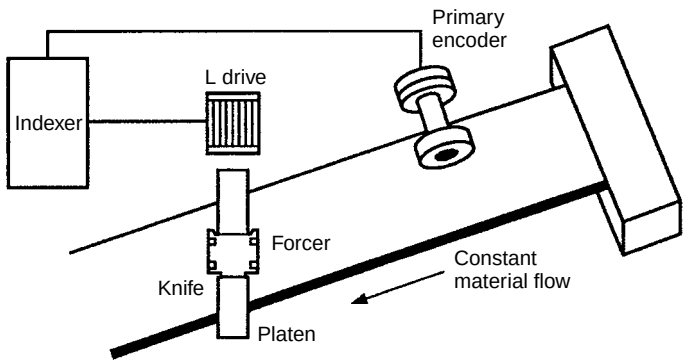

Fig. 11. Plastic sheet cutting. Process produces a continuous flow of sheeted plastic to be cut into prescribed lengths before it is fully cured. Material is cut as it exits a machine and cannot be stopped. Depending on ambient conditions, the speed can vary. Clean angle cuts are required. In system shown, an encoder is mounted to a friction wheel driven by the plastic material. This speed signal is an input to a self-contained indexer (controller), which references all linear (cutoff-knife) velocity and position commands to the encoder, allowing precise synchronization of the web. Placing the knife at an angle to the flowing material allows for precise, straight cuts while material is moving. This is an excellent application for a linear motor. (*Parker-Hannifin Corporation, Compumotor Division.*)

AUTOMATISM. See **Brain Injury**; and **Coma**.

AUTOMOTIVE ELECTRONICS[1]. Electronic devices and systems over the last several years have changed the character of the automotive vehicle in numerous ways, including engine control, the suspension system, steering, power train, braking, comfort, safety, and entertainment systems, in addition to fuel economy, among other important factors. As this article points out, this trend is destined to continue through the year 2000 and for the unforeseeable future.

Although solid-state electronics has been applied to motorcars and other automotive vehicles since the 1960s, the use of electronics in their design and operation did not start its impressive rise in terms of availability and consumer acceptance until the mid-1970s. As noted in Fig. 1, the steady and rapid rise commenced in the 1980s and has continued through 1993. The extent to which electronic systems have been integrated into motor vehicles has depended largely on the availability of new and high-performing electronic components and systems at an acceptable cost, coupled with much research on the part of the automotive manufacturer to determine how electronics can cost-effectively improve vehicle performance, safety, and comfort, without adding excessive costs. It will be noted that one manufacturer (Ford), for historical and planning purposes, has broken down the trends of Fig. 1 into three phases or stages. These are further depicted in Fig. 2.

Stage One — 1960s to Mid-1970s. Solid state electronic devices were first widely used in automobiles in the 1960s. Over the following 15 years, diodes, discrete transistors, and analog integrated circuits (ICs) were used to solve problems in stand-alone electronic components. See Fig. 3. The earliest installation in autos (Ford) of an all solid-state radio occurred in 1961. Solid-state ignitions were first incorporated in 1973. See Fig. 4. A stand-alone electronic clock appeared in the instrument panel

[1] This is one of a series of articles in this *Encyclopedia* that discuss various aspects of automotive technology, including construction materials and alternate vehicle fuels and energy sources. See *Alphabetical Index*.

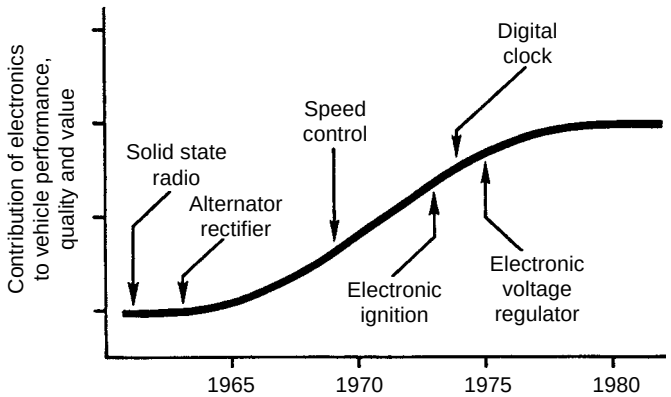

Fig. 3. Use of stand-alone electronic components typical of the early applications in automotive electronics. (*Ford Motor Company, Electronics Division.*)

in 1974. These early applications provided a learning experience with the emerging electronic technology. More importantly, they demonstrated that electronics could achieve the levels of reliability required by the automotive industry, while providing dependable and affordable service to the customer. For example, new electronic devices increased the dependability of many automobile components. Radio failures became much less frequent. Car clocks became more reliable. Electronic ignition eliminated the routine maintenance associated with changing the breaker points.

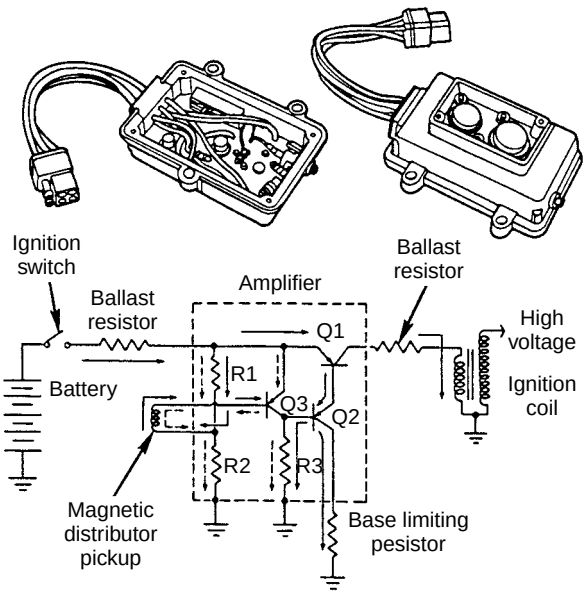

Fig. 4. Solid-state ignition module and circuit diagram. First used in 1973. (*Ford Motor Company, Electronics Division.*)

Stage Two — Mid-1970s to Early 1990s. In the mid-1970s, new electronic capabilities became available to the automotive industry. Their applications were sufficiently different to define another stage in the evolution of automotive electronics.

The primary source of new capability was the microprocessor. It came along at a time when the industry was experiencing upheaval. Gas lines, safety standards, and emission controls created unprecedented challenges. The microprocessor led to many solutions.

Stage Two was characterized by a shift from independent components to increasingly sophisticated systems which link components together. See Fig. 5. These systems first were used for engine controls. For example, Ford introduced the EEC-1 in 1978. Several sensors were linked with a computer which, in turn, was linked to various output devices, such as the ignition module. Similarly, multiple electrical and electronic components were tied together in driver information and entertainment applications. Electronics have been used to integrate functions that previously, for example, had been separate clock and radio displays.

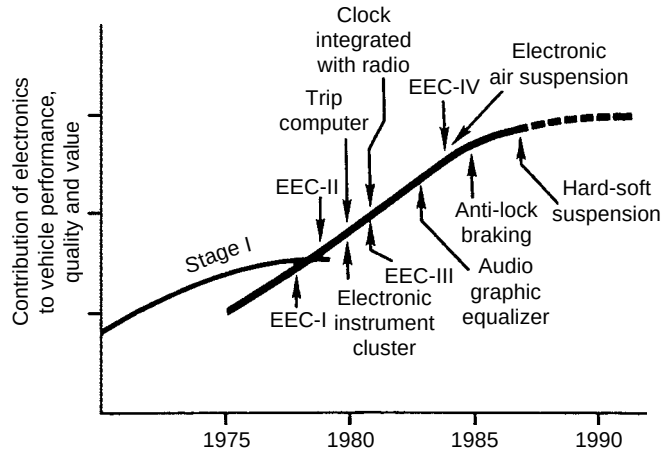

Fig. 5. Linking of electronic components into fewer, more sophisticated systems typifies automotive electronic technology during the period from the late 1970s to the late 1980s. (*Ford Motor Company, Electronics Division.*)

Late Stage Two developments will make more widespread use of advanced packaging techniques, such as surface-mounted devices, increased processor speed and capacity, increased memory, and refined input/output (I/O) methods to obtain optimal functional performance from the auto's special-purpose subsystems.

Powertrain control will be adapted to a greater range of conditions, and there will be more integration between engine and transmission. Anti-lock braking will be more common. See Fig. 6. Improved displays will offer drivers more choices of format and content. Cellular telephone communications will be increasingly common. All of these improvements should create vehicles that are more responsive, useful, and reliable.

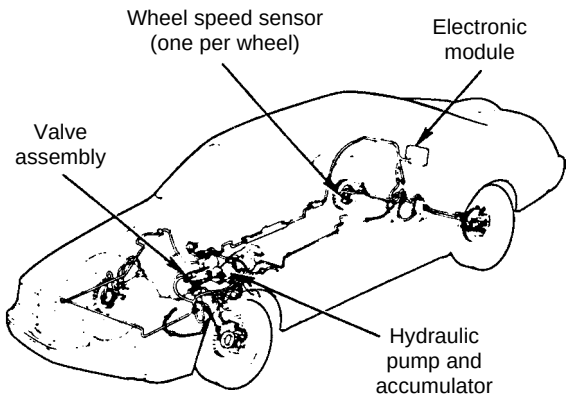

Fig. 6. Four-wheel anti-lock braking system. This is one of the first features of Stage Three in the evolution of automotive electronics. (*Ford Motor Company, Electronics Division.*)

As the vehicle's subsystems evolve during the mid-to-late 1990s, they formed a total vehicle *network*. Sensors, processors, and actuators will be interconnected, with power and control signals distributed in a highly efficient manner. This functional integration will lead to Stage Three.

Stage Three — 1990 to 2000+. This development phase of automotive electronics was characterized by the emergence of a vehicle with a totally integrated electrical and electronic system. Designers escaped from the mechanical function replacement and "add-on" approaches that characterized Stages One and Two. They sought to optimize the performance of the total vehicle through electronics. The total system has much greater flexibility and adaptability, with extensive software control of multifunction features. There are greater opportunities for auto buyers to customize their vehicles. Vehicle characteristics, such as ride quality, handling properties, steering effort feedback, and brake "feel" information are incorporated in a display format, and even engine power versus economy trade-offs are selectable and controllable by the driver.

Operating as an information-based system, the automobile's on-board electronics use extensive computing capacity, multiplexed circuit technology (networks), and program memory capacity that will be considered very large by previous standards.

Some early Stage Three features have appeared. See Fig. 7. These include speed control integrated with engine control and transmission

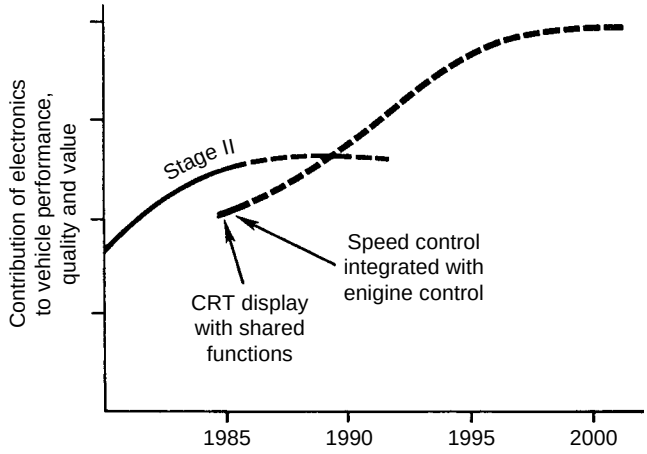

Fig. 7. Stage Three will evolve around functional integration of electronics. (*Ford Motor Company, Electronics Division.*)

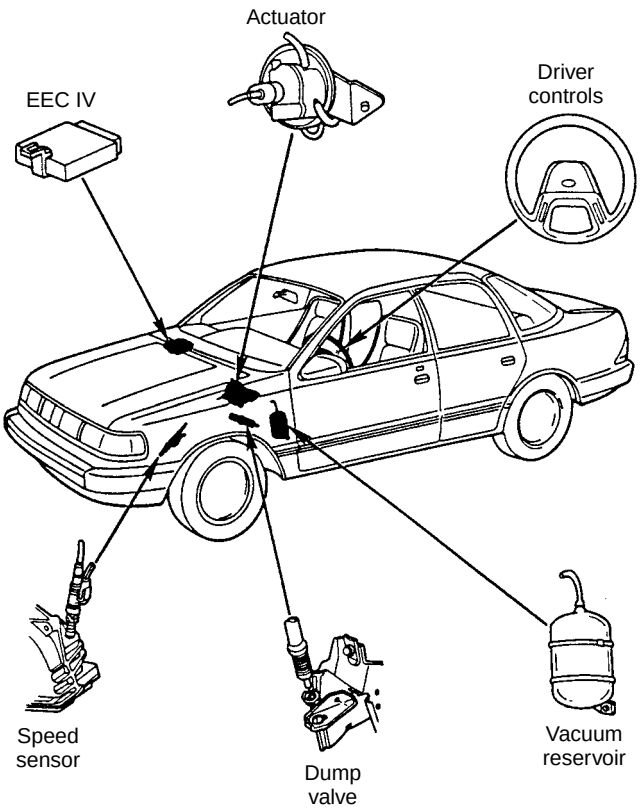

Fig. 8. Integration of speed control system electronics into electronic engine control is another example of the fast-moving trend in electronics that will lead to the automobile of the year 2000. (*Ford Motor Company, Electronics Division.*)

controls integrated with engine controls. See Fig. 8. These examples represent only the beginnings in the systematic integration of functions. Stage Three introduced: (1) torque-demand powertrain control, which fully integrated the response of the engine and transmission; (2) vehicle dynamics, which integrated braking, steering, and suspension; (3) electric power management based on new power generating components and sophisticated load management controls, and (4) multipurpose soft switches and shared displays for driver information, climate control, and entertainment functions. Stage Three, now underway, was to be fully evolved by the year 2000. At that time was predicted that the value of electronics for the average automobile will reach $2,000. See Fig. 9.

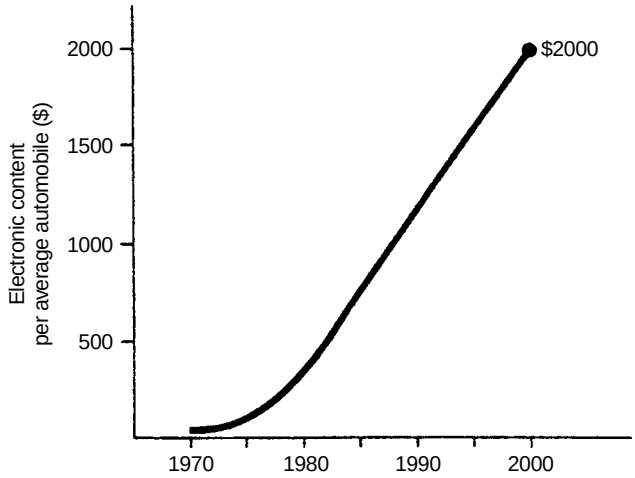

Fig. 9. Automotive electronics content for an average car will reach $2,000 by the year 2000. (*Ford Motor Company, Electronics Division.*)

The realization of Stage Three incorporated impressive new capabilities, as reflected by what is a typical window sticker for a car in the year 2000. (In predicting some of these features, the assumption was made that fuel availability and cost would be similar to the 1990's time frame.) See Fig. 10.

Powertrain. The engine compartment will contain a lightweight, supercharged or turbocharged four-cylinder or six-cylinder, multi-valve engine of 1.5 to 2.5 liters displacement. See Fig. 11. It will be equipped with multi-point electronic fuel injection and distributed ignition, which is *distributor-less*, and will have a high-voltage coil at each spark plug. The system will control the engine on a cylinder-by-cylinder basis.

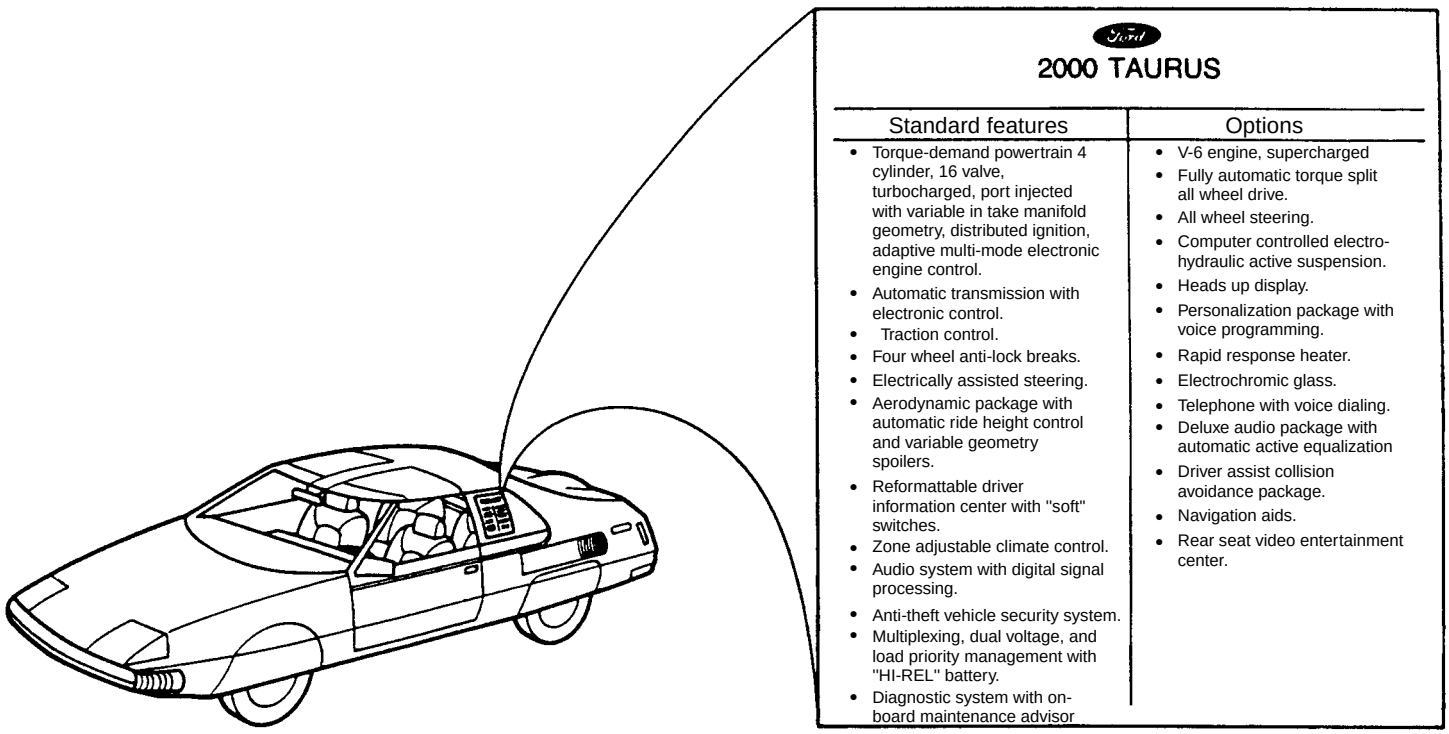

Fig. 10. Envisioned "window sticker" on a year 2000 Taurus with Stage Three electronics. (*Ford Motor Company, Electronics Division.*)

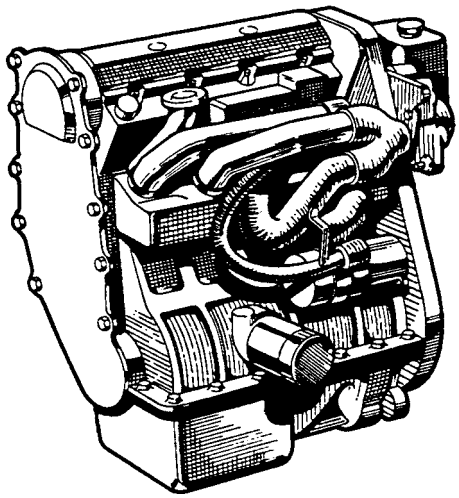

Fig. 11. Four-cylinder engine performance will improve with Stage Three electronics. (*Ford Motor Company, Electronics Division*.)

The powertrain will be electronically controlled by a highly advanced system. Engine operating parameters will be adaptively controlled over the full range of torque and RPM, and will allow the driver to select for either performance or economy. Variables under active and continuous electronic control will include manifold boost pressure, fuel mixture, spark timing, valve timing, and variable intake manifold geometry.

The information needed to manage the engine control will come from a small number of high-performance sensors. The sensors will monitor, analyze, and transmit data on fundamental engine performance parameters. Improved sensors will be necessary before this is possible. Primary data will include combustion chamber conditions and exhaust gas chemistry. These data will be compared by the master controller to a performance algorithm of much greater sophistication than exists today. Then all controlled variables will be adjusted to optimize vehicle performance in accordance with the algorithm. This will be a significant improvement over current systems that measure secondary parameters, such as inlet charge temperature and barometric pressure.

The engine will be closely coupled with a transmission of advanced design. The transmission either will be continuously variable (see Fig. 12) or will have a highly adaptive shifting capability. Transmission and engine will be electronically controlled as a unit in response to the driver's demand for power. Responding to engine speed, vehicle speed, and command input from the driver, the powertrain controller will decide when to supply torque by increasing engine output, altering the drive ratio, or both. Figure 13 contrasts the degree of powertrain integration typical of Stages Two and Three. In some cases, the transmission will drive all four wheels and utilize a sophisticated electronic control scheme.

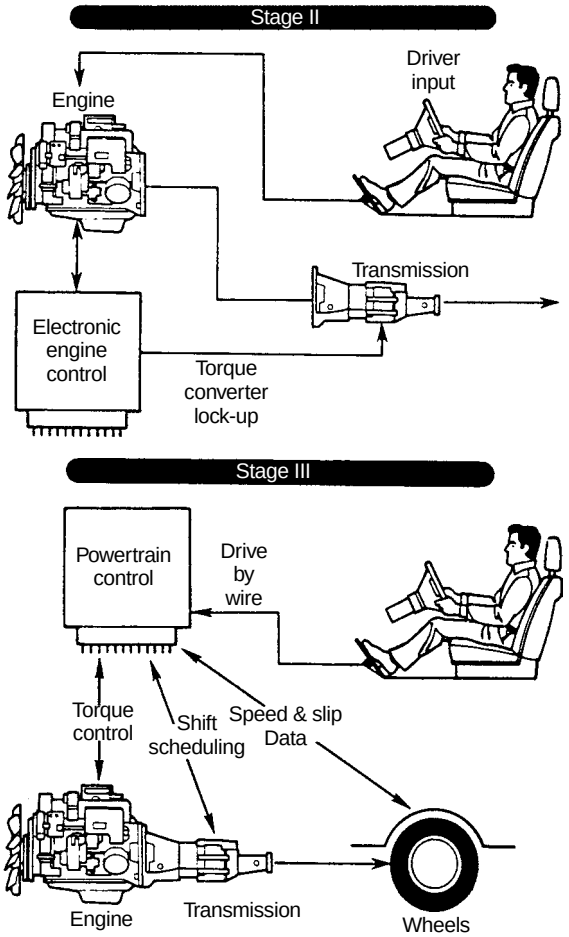

Fig. 13. Electronic powertrain systems for Stages Two and Three. (*Ford Motor Company, Electronics Division*.)

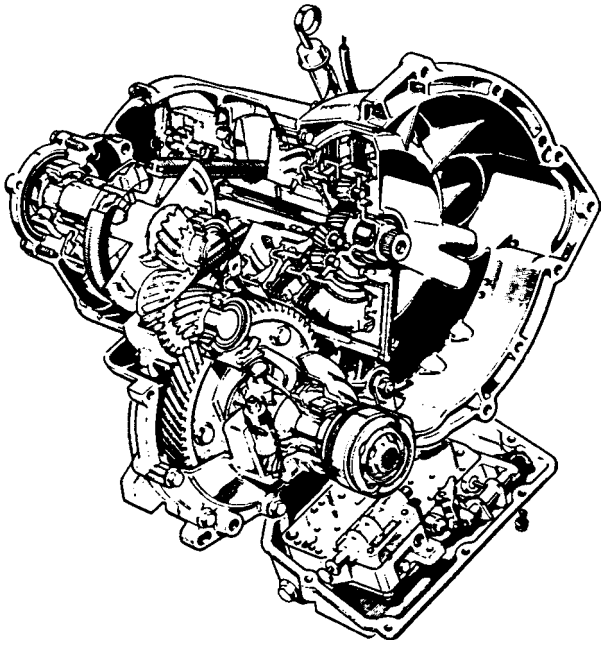

Fig. 12. Continuously variable transmission (CVT). (*Ford Motor Company, Electronics Division*.)

It is planned that drivers in the year 2000 will find that the powertrain will perform smoothly under all conditions. Changes in transmission ratio and adjustments in engine speed will seem nearly imperceptible as compared with those in present cars. The powertrain management system also will enhance safety and improve performance in ways that are meaningful to all users (i.e., by keeping the driver in control at all times).

Chassis. Perhaps the most revolutionary new features and performance enhancements resulting from Stage Three systems integration will occur in the area of the chassis system, consisting of steering, brakes, and suspension. Drivers will experience a new level of performance from these chassis systems through their synergistic interaction, achieved through an integrated electronic network, as shown in Fig. 14.

Electronics capability will allow adaptive control of the suspension — springs, shock absorbers, and suspension geometry — which were restricted to a passive response in Stages One and Two. See Fig. 15. In order to control ride height, aerodynamic angle of attack, and dynamic response of the body, an electronic system will sense displacements and accelerations in the suspension system and will control spring rate and damping independently, at each wheel. A first step in this direction was the introduction of ride height control in 1984. See Fig. 16.

In the year 2000, electrically actuated front-wheel steering will be found on most model cars. In the advanced cars, the suspension control

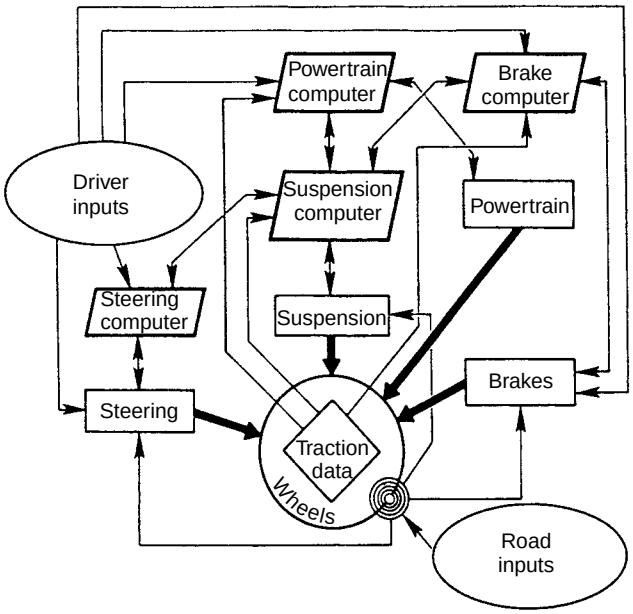

Fig. 14. Stage Three chassis control system. (*Ford Motor Company, Electronics Division.*)

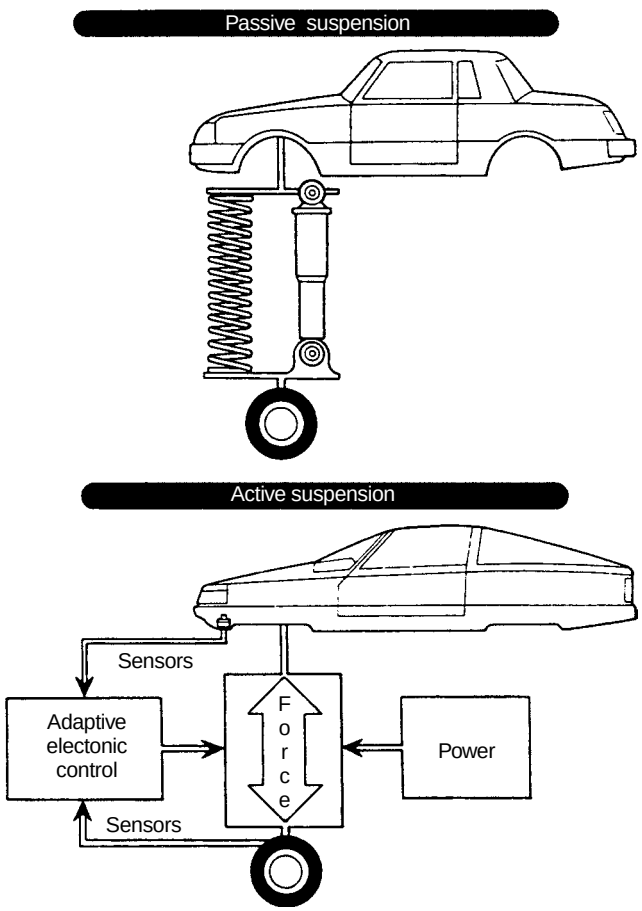

Fig. 15. Suspension evolution to active control. (*Ford Motor Company, Electronics Division.*)

will be *semi-active*. There will be continuous modulation of devices like valves to control shock absorber damping, but with no external power input. In some high-performance vehicle applications, however, *fully active* suspensions will incorporate controlled energy input from a dedicated power source. While the ultimate evolution of both semi-active and active systems will probably be electromechanical, those systems in use by the

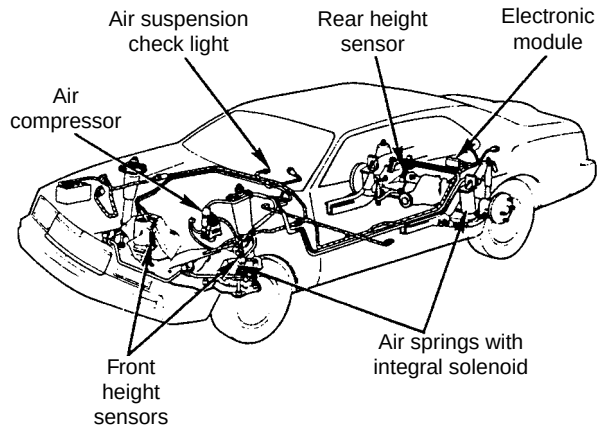

Fig. 16. Air suspension ride-height control. (*Ford Motor Company, Electronics Division.*)

year 2000 will use electrohydraulic control units. In either case, the driver will experience a marked improvement in both handling quality and ride comfort.

Electrically actuated front-wheel steering (Fig. 17) will be found on most cars by the year 2000. Among the advantages of these systems will be compactness, energy efficiency, and adaptability. Also, most cars will incorporate all-wheel steering. See Fig. 18. This will improve agility at all speeds and will enhance low-speed maneuverability. Control of the steering angle of the rear wheels will be electronic, changing according to both the vehicle's speed and input from the steering wheel. Drivers of these cars will find that parallel parking is simplified and maneuvering

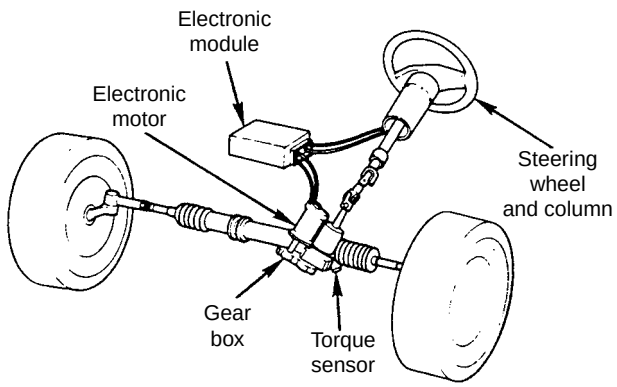

Fig. 17. Electric power steering. (*Ford Motor Company, Electronics Division.*)

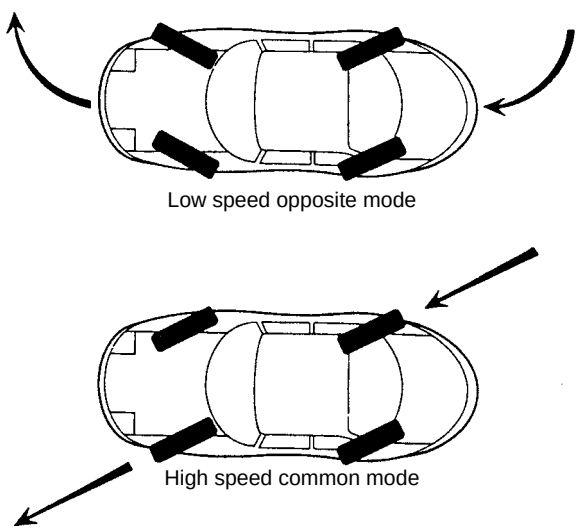

Fig. 18. All-wheel steering. (*Ford Motor Company, Electronics Division.*)

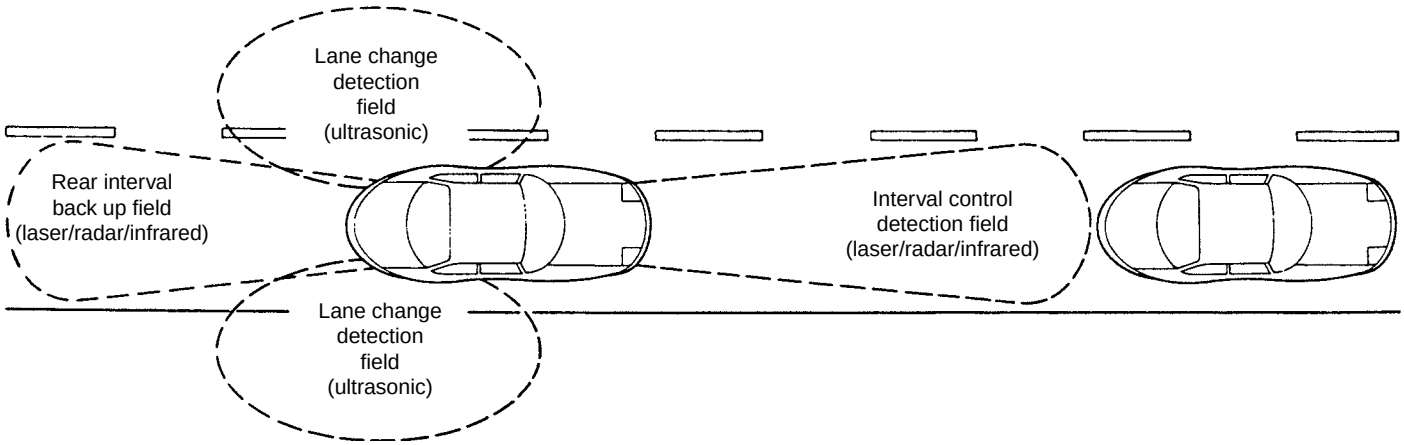

Fig. 19. Collision avoidance aids require sensors to monitor the space around the car. (*Ford Motor Company, Electronics Division.*)

in tight quarters takes little effort. On the highway these changes will be accommodated promptly.

Braking performance will improve steadily as it evolves from the anti-lock braking systems that presently are becoming widely available. By the year 2000 traction control systems will fully integrate braking with the powertrain. The functional flexibility of these systems will be far greater than the simple "anti-lock" capability. Conditions that could cause slipping will be monitored during both acceleration and deceleration. The system will modulate torque and braking inputs to provide maximum acceleration and minimum stopping distance. The driver will be unable to break the wheels loose from the road under any normal driving conditions.

An enhanced traction control system will improve the vehicle's ability to avoid collisions. In some applications the space all around the vehicle will be monitored for the presence of collision risks, using some combination of sensing technologies, such as radar, laser, visual, infrared, or ultrasonic. Not only will the area in front of the vehicle be scanned to detect a rapidly closing interval, but the "blind spots" on the rear quarters will be monitored to assure safe lane changes. See Fig. 19. The output of the sensors will be analyzed by artificial intelligence (AI) software that will direct controllers to reduce acceleration or, in extreme cases, to apply the brakes and tighten seat belts.

For a period of time up to the present, the handling capability of an automobile has been beyond the average driver's skills. Advances in steering, braking, and suspension technology in Stage Three will allow the average driver to employ the full performance potential of the vehicle in exceptional situations (avoiding accidents), without subsequent loss of control. The subtle and rapid corrections needed to deal with the complex dynamic transients will be handled automatically.

Driver Information/Personalization. By the end of Stage Three, human factors design for driver information displays and controls will be markedly advanced. "Cockpit workload" will be reduced. Essential information, such as vehicle speed, will be provided continuously by a holographic heads-up display. See Fig. 20. This will be similar to what is presently used in some aircraft. Other information will be displayed on a re-formattable multifunction display panel. See Fig. 21. It will use one or several display technologies, such as liquid crystals, vacuum fluorescent devices, or light-emitting diodes (LEDs).

The system will display performance data whenever it senses something unusual. Also, the driver will be able to select a particular array of information and the style in which it is presented. For example, the driver will be able to request a complete display of all engine operating parameters, such as RPM, oil pressure, coolant temperature, fuel pressure, and so on. Or the operator will be able to select data in an analog or digital format. Additional information that can be called up will include maintenance information, such as need for lubrication, brake checking, and so on.

Notification of emergency and alarm conditions will be either audible or visible signals. Voice recognition (see Fig. 22) will be used for functions, such as entertainment system control, driver display mode selections, and telephone dialing. Additional control inputs will be made by using programmable multifunction "soft" switches.

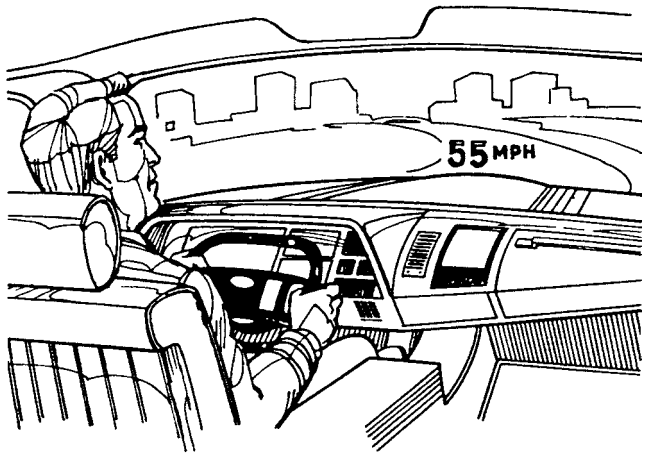

Fig. 20. "Heads-up" display of vehicle speed. (*Ford Motor Company, Electronics Division.*)

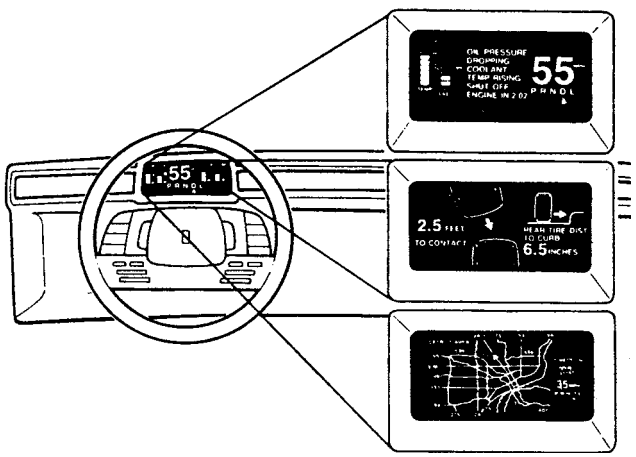

Fig. 21. Re-formattable driver information center. (*Ford Motor Company, Electronics Division.*)

Systems also will include detection of impaired or loss of alertness on the part of the driver. They will focus on actions that are fundamental to the driver's safe operation of the vehicle, such as appropriate steering and braking behavior.

Climate Control. This system will be electronically controlled and electrically powered. The air distribution system will be designed to permit unique temperature variations in different zones of the passenger compartment. Supplemental electric heat will be capable of fast response to peak heating demand (see Fig. 23) and will allow for a reduction of excess heater capacity.

Fig. 22. Voice recognition for dialing cellular telephone. (*Ford Motor Company, Electronics Division.*)

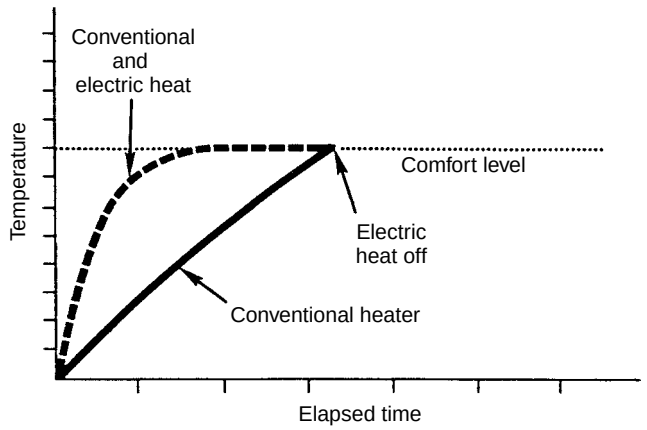

Fig. 23. Auto heater achieves comfort level faster with addition of electric heat. (*Ford Motor Company, Electronics Division.*)

Communication and Navigation. In addition to cellular telephones previously mentioned, navigation aids will be especially useful in commercial delivery, service, and rental vehicles. These systems will operate on the combined principles of dead-reckoning and map matching, utilizing a wide-area digital map that will be stored on a compact disk read-only memory. By the year 2000, global positioning satellites may be used to track a vehicle's geographic location. These systems also will utilize an external data link that will enhance the "on-vehicle" navigation system by providing the driver with current traffic information. There also will be real-time satellite updates on roads and new landmarks.

Summary

Although this article has concentrated on the high points between the present and the goals for the year 2000 and has divided progress in automotive electronics into three stages, obviously there will be more to come during the next several decades. Progress will depend upon further developments in the electronics industry, including "smart" sensors, "smart" actuators, and advances in communications technology, among many other factors that contribute to automotive engineering.

Technical information for this article was furnished by the scientists and engineers of Ford Motor Company, Electronics Division, Dearborn, Michigan, and is gratefully acknowledged by the Editors

AUTONOMIC NERVOUS SYSTEM. The term *autonomic* signifies automatic or unconscious activity. Thus, the autonomic nervous system is sometimes referred to as the involuntary nervous system; rarely, the vegetative nervous system. A functional division of the nervous system would consist of ganglia, nerves, and plexuses, through which visceral organs, heart, blood vessels, glands, and smooth muscle receive their innervation. It is widely distributed over the body, especially in the head and neck, and in the thoracic and abdominal cavities. The autonomic system is not under voluntary control and the processes in which it is concerned are beneath consciousness for the most part. It is influenced to a great degree by the endocrine glands, particularly the adrenal and its hormone, epinephrine.

In general the autonomic nervous system may be divided into two groups both of which may send nerves to the same organs but act antagonistically, producing opposite results. One is known as the parasympathetic, which arises from the mid-brain, hind-brain, and sacral region of the cord and is stimulated by the drug pilocarpine and inhibited by atropine. The other is known as the sympathetic, which arises from the thoracic and lumbar regions of the spinal cord and is stimulated by epinephrine.

Under normal conditions there is a balance between the two systems allowing for perfect function of a bodily organ. For instance, the heart is slowed by the parasympathetic system and accelerated by the sympathetic. Movement of the stomach is increased by the parasympathetic and is inhibited by the sympathetic. The pupil of the eye is contracted by the parasympathetic and dilated by sympathetic stimuli.

Psychosomatic disturbances may take place in any of the involuntary organs of the body systems. These include the digestive, the respiratory, the heart and circulatory, the genitourinary, the endocrine system, and the skin. Gastrointestinal reactions, such as nervous diarrhea, will affect various individuals with different degrees of intensity. The emotional component of diarrhea has been recognized for centuries. It also has been recognized for centuries that certain skin disorders contain an emotional element. Eruptions arising from emotional disturbances are termed *psychogenic* skin eruptions. Most persons who show the characteristics of a nervous dermatitis, like other psychosomatic patients, appear to carry their emotional problems close to the surface of their minds, rendering them more accessible to psychiatric treatment.

As pointed out by Nauta and Freitag (*Sci. Amer.*, **241**, 3, 109, 1979), "The autonomic nervous system is not self-governing at all. Its functions are integrated with voluntary movements no less than with motivations and affects. In short, its roots are in the brain; one's experiences from moment to moment dictate not only the contractions of one's skeletal muscles but also large functional shifts in the body's internal organs. The term autonomic has nonetheless won out in the English-speaking world. Other languages use other terms. In German one speaks of *das viszerale Nervensystem*, in French of *le système nerveux végétatif*."

See also **Central and Peripheral Nervous System and The Brain**.

AUTONOMOUS SCIENCECRAFT EXPERIMENT. See **Space Technology 6 (ST6) MISSION**.

AUTOREGRESSION. A stochastic relation connecting the value of a variable at time t with values of the same variable at previous times. For example the linear equation

$$u_t = \alpha_1 u_{t-1} + \alpha_2 u_{t-2} + \varepsilon_t \tag{1}$$

where ε_t is a random variable. Two common forms of autoregressive relations are the Markov scheme

$$u_t = \alpha_1 u_{t-1} + \varepsilon_t \tag{2}$$

and the Yule scheme (1).

These equations bear a formal resemblance to the equations of linear regression — hence the name — but raise special problems in the estimation of the constants. They may be regarded as a class of stochastic processes.

See also **Stochastic Process**.

AUTOSYN. (A trade name, from autosynchronous, often capitalized). A remote-indicating instrument or system based upon the synchronous-motor principle, in which the angular position of the rotor of one motor at the measuring source is duplicated by the rotor of the indicator motor, used, e.g., in fuel-quantity or fuel-flow measuring systems, position-indicating systems, etc.

AUTOTOMY. Self-mutilation. Through the presence of a special modification near the base of the limb, some crustaceans and insects are able

to drop off appendages by which they are seized. The autotomy of the arms of starfish and of the tails of lizards are other common examples. Autotomy is followed by regeneration.

AUTOXIDATION. A word used to describe those spontaneous oxidations, which take place with molecular oxygen or air at moderate temperatures (usually below 150 °C) without visible combustion. Autoxidation may proceed through an ionic mechanism, although in most cases the reaction follows a free radical-induced chain mechanism. The reaction is usually autocatalytic and may be initiated thermally, photochemically, or by addition of either free-radical generators or metallic catalysts. Being a chain reaction, the rate of autoxidation may be greatly increased of decreased by traces of foreign material.

Many organic and a variety of inorganic compounds are susceptible to autoxidation.

AUTOZOOID. Members of polyp colonies whose function is to feed the colony.

AUTUMNAL EQUINOX. 1. That point of intersection on the celestial sphere of the ecliptic and the celestial equator occupied by the sun as it changes from north to south declination, on or about September 23. Also called *September equinox, first point of Libra*.

2. That instant the sun reaches the point of zero declination when crossing the celestial equator from north to south.

AUTUNITE. This mineral is a hydrous phosphate of calcium and uranium, crystallizing in the tetragonal system, usually in thin tabular crystals. Good basal cleavage; hardness, 2–2.5; specific gravity, 3.1; luster, subadamantine to pearly on the base; color, lemon yellow; streak, yellow; transparent to translucent; strongly fluorescent.

Originally from near Autun in France, whence the name, it is a secondary mineral associated commonly with uraninite. In the United States, it occurs sparsely in the pegmatites of Connecticut, New Hampshire and North Carolina. Autunite also is known as *calco-uranite*.

See also **Uraninite**.

AUXOMETER (or Auxiometer). An apparatus for measuring the magnifying power of a lens or any optical system.

AUXOSPORE. An auxospore is a special type of spore which occurs in diatoms and which seems to be a means of rejuvenating the cells. Rejuvenescence is necessary, since in the normal process of cell division one of the two daughter cells is always smaller than the parent cell. Consequently very small cells are ultimately formed. In some species of diatoms, auxospore formation is preceded by the escape of the protoplast from the walls of the cell. The free protoplast then enlarges and secretes about itself a wall. In time new valves more or less like those of the original diatom are formed. In other species of diatoms, auxospore formation is preceded by the union of the protoplasts of two similar diatom cells, the process being therefore sexual.

AVALANCHE (Electronics). The term avalanche is used in counter technology to describe the process that is essentially a cascade multiplication of ions. In this process, an ion produces another ion by collision, and the new and original ions produce still others by further collisions, resulting finally in an "avalanche" of ions (or electrons). The terms "cumulative ionization" and "cascade" are also used to describe this process.

The term avalanche or avalanche effect is sometimes applied to the Zener effect in semiconductors.

AVALANCHE (geology). 1. (Also called *snowslide*). A large mass of snow, ice, soil, or rock, or mixtures of these materials, falling or sliding very rapidly under the force of gravity. Velocities may sometimes exceed 500 km/hr (311 mi/hr). Avalanches may be characterized as loose and turbulent, or slab; either type may be dry or wet according to the nature of the snow forming it, although dry snow usually forms loose avalanches and wet snow forms slabs. A large avalanche sweeps a current of air along with and in front of it as an *avalanche wind*, which supplements its already tremendous destructive force. 2. (Also called *landslide*.) A mass of earth material (soil, rock, etc.) moving rapidly down a steep slope. See also **Winds and Air Movement**.

AVALANCHE WIND. See **Winds and Air Movement**.

AVERAGE. A simple but subtle concept which attempts, in some sense, to summarize a set of numbers $x_1, \ldots, x_n$ in a single number. In statistics, the commonest forms of average are

(a) The arithmetic mean M, defined by

$$M = \frac{1}{n}\sum_{j=1}^{n} x_j$$

(b) The geometric mean G, defined by

$$\log G = \frac{1}{n}\sum_{j=1}^{n} \log x_j$$

(c) The harmonic mean H, defined by

$$\frac{1}{H} = \frac{1}{n}\sum_{j=1}^{n} \frac{1}{x_j}$$

When the individual numbers x are not regarded as of equal importance, they may be weighted by numbers $w_1, \ldots, w_n$. For example the weighted arithmetic mean is given by

$$\frac{1}{\sum_{j=1}^{n} w_j} \sum_{j=1}^{n} (w_j x_j)$$

See also **Arithmetic Mean**.

AVERAGE DEVIATION. If $\overline{x}$ is the mean of observations $x_1, \ldots, x_n$, the mean deviation is given by

$$M.D. = \frac{1}{n}\sum_{j=1}^{n} |x_j - \overline{x}|$$

If x has a frequency distribution $f(x)$ the analogous definition is

$$M.D. = \int_a^b f(x)|x - m|\,\mathrm{d}x$$

where m is the mean and the distribution ranges from a to b.

Owing to its relative mathematical intractability the mean deviation is usually discarded in favor of the standard deviation.

The average deviation is a minimum when deviations are measured from the median.

AVERY, OSWALD THEODORE (1877–1955). Oswald Avery was a Canadian born US medical microbiologist whose work with pneumococcus led not only to important advances related to pneumonia but, surprisingly, to the discovery of the genetic role of DNA. The son of a Baptist minister, Avery was born in Halifax, Nova Scotia and came to New York at the age of 10 when his father became pastor of aBaptist mission there. After graduating from Colgate University in 1900, he entered the College of Physicians and Surgeons at Columbia University, receiving his degree in 1904. He tried medical practice, but finding it unsatisfactory soon moved to laboratory work, obtaining his first extensive experience in microbiology at the Hoagland Laboratory in Brooklyn. In 1913 he was recruited to the recently established Hospital of the Rockefeller Institute for Medical Research where for the next 35 years he carried out his research on the principal cause of bacterial pneumonia, the pneumococcus (now designated *Streptococcus pneumoniae*).

Avery's talents as an investigator lay in focusing on important problems and appropriate goals for their research, and then inspiring his younger associates in the pursuit of these goals. He was revered by his colleagues and associates, who knew him as "Fess," short for Professor. His success in providing superb training for young medical scientists is exemplified by the election of 10 of them to membership in the US National Academy of Sciences.

With Alphonse Dochez, he found a specific soluble substance produced by pneumococcithat was detected in the blood and urine of pneumonia patients. They showed that it was the antigen that distinguished the many different types of pneumococci from one another, was present in the capsule surrounding the organism, and was the principal determinant of virulence. Antibodies to the antigen protected against infection. Reasoning that it was important to determine the nature of this substance, he enlisted the aid of the biochemist, Michael Heidelberger,in a study showing that it was a polysaccharide, with the differenttypes of pneumococci making polysaccharides of different composition. This was the first evidence that polysaccharides could serve as antigens.

The transformation of one type of pneumococcus to another was described by Fred Griffith in London in experiments carried out in the mouse (1928). His work was confirmed byothers, including one of Avery's associates, Martin Dawson, who then succeeded in obtaining transformation in the test tube. Another Avery associate, J. Lionel Alloway, prepared soluble extracts that would induce transformation. Again Avery saw that it was important to determine the nature of the substance in the extracts responsible for transformation. The change was permanent in the transformed cells, which continued to produce more of th transforming substance, suggesting genetic transfer. Beginning in 1934, Avery pursued studies to determine the nature of the active material, first with Colin MacLeod and later with the author. The experimental model used extracts from type III pneumococci to induce change of type in nonencapsulated cells derived from type II pneumococci. It was finally possible to report in 1944 that the transforming substance was deoxyribonucleic acid (DNA). See also **McCarty, Maclyn (1911–2005)**.

AVES *(Birds)*. The vertebrate class Aves contains all living birds, nearly 10,000 species worldwide. Through the evolution of flight, birds have become one of the most widely distributed groups of all the animals. Subsequent adaptation to the various habitats they reached le to tremendous diversity of form and function. Birds are an integral part of our life as, for example, food, pests, indicators of the health of our environment and as religious and cultural symbols. Their ecology has a major impact on our everyday lives.

Basic Design

The basic body structure of birds is remarkably uniform for a group of animals with such varied lifestyles and that occupy such a wide range of habitats. They are bipedal (two-legged) vertebrates (animals with backbones) and, uniquely among animals, they have feathers. Feathers are characteristic modifications of the outer skin, probably originating from highly modified reptilian-like scales. They have several major functions. Down and contour feathers help to maintain the body at a constant temperature by trapping air close to the body. Contour feathers also streamline the body for flight. The flight feathers of the wing (the remiges) and the tail (the rectrices) primarily provide lift and control during flying. In certain taxa, modified feathers are also important in roles such as swimming, waterproofing, sound production, signaling, camouflage and attracting a mate.

The avian body is structured for flight and the need for low weight has been a major force shaping bird anatomy. Bones have hollow, spongy or strutted internal structures to reduce their weight; the entire skeleton of the frigate bird, for example, is lighter than the weight of its feathers. The skeleton is further lightened and strengthened by the loss and fusion of bones. Pneumatization, the presence of filled air sacs inside the bone, further aids weight minimization for flight in the birds that fly; these are less developed in the diving birds where extra air would be a hindrance to diving. The furcula, probably better known as the wishbone, acts as a powerful spring for the wings, compressing and rebounding in rhythm with the bird's wing beats. In the flightless birds, the same wing machinery has been adapted to other functions, such as powerful paddles for underwater swimming in the penguins.

The hallux is the large, opposable, single rear toe found in most birds, which is designed to lock onto a branch when the bird is in a relaxed position, permitting birds, for example, to sleep while perching. All birds also have toothless bills covered with a horny sheath. There is tremendous variation in the form of these bills, depending on the particular mode of feeding that a particular species exploits.

The energetic demands of flight and regulation of a high body temperature (40–44° C (104–111°) have resulted in several physiological adaptations required to maintain a high metabolic rate, including flow-through lungs and a four-chambered heart to ensure adequate oxygen transfer from the blood. No live young are produced; without exception, birds lay eggs which contain the provisioning for development of the embryo into young hatchlings.

The neural system is highly developed and the brain is 6–11 times larger than that of reptiles of a similar size. Birds can hear in the range of infra-sounds (below the range of humans), they can detect magnetism, an important cue for navigation in many migratory birds, they can use olfaction to map their way home around their home range, and their vision stretches into the ultraviolet (UV) range. Kestrels, for example, can detect areas of high prey availability using the scent marks which many mammals use for marking out their home range, and which reflect light in the UV range. See also **Birds**.

Fossil History

Birds generally have a poor representation in the fossil record due to their fragile bone structure. However, of those that have survived, the most famous of the fossil birds is *Archaeopteryx lithographica*, an extinct species known from only seven fossils. It was alive at the time of the dinosaurs in the late Jurassic period, 155–135 mya. About the size of a crow, this bipedal, feathered "reptile'," with a blunt snout and many small reptilian teeth, is thought to have been capable of weak flapping flight but not sustained flights. Providing a direct link between the reptiles and the birds, *Archaeopteryx* is often considered the best fossil evidence of the process of evolution. See also **Fossil Record**; and **Paleognathae (Flightless Birds)**.

Later fossil birds come from the more advanced group called the *Enantiornithes*. *Sinornis santensis*, for example, was a toothed, sparrow-sized bird sharing many of the features seen in *Archaeopteryx*. Dating from approximately 140 mya, it had a strengthened and modified hand, forearm and pectoral girdle for flight, the ability to raise the wings high over the body and fold them, and a perching foot with an opposable rear toe (hallux). The successors of the Enantiornithes, the Ornithuriae, emerged approximately 100–80 mya. Fossils from this group have been very rare. They include the Ichthyorniae and the Hesperornithormes, which superficially resembled the modern divers (Gaviiformes), ranging in size from a small chicken to a penguin. They seem to have disappeared with the dinosaurs in a mass extinction that occurred at the end of the Mesozoic. However, the recent discovery of a new fossil bird, *Apsaravis*, estimated to be about 80 million years old, has complicated matters. It has 27 features that link it to modern birds and are diagnostic of the ornithurine group but it also has 12 primitive traits that were thought to be unique to the Enantiornithes, suggesting that some of the fossils previously assigned to this group may have to be re-examined.

Fossils preceding *Archaeopteryx*, which should demonstrate the true origin of the birds, are surrounded by even more controversy. The main point of contention has been whether birds really evolved from dinosaurs or from some more distant reptilian ancestor. The dinosaur hypothesis, which has gained stronger support, suggests birds evolved from a particular group of dinosaurs, the theropods, more than 150 mya. The alternative theory suggests that birds arose much earlier from a large group of primitive reptiles called the *Thecodontia* in the early Mesozoic era more than 200 mya. This is the same group thought to have given rise to the dinosaurs and crocodiles and pterosaurs (flying reptiles). See also **Reptilia**.

The latest twist in the tale has been the publication of the description of a feathered lizard, *Longisquama insignis*, thought to have lived 75 million years before *Archaeopteryx*. Most believe feather-like structures may have evolved more than once; others argue the finding means a feathered bird ancestor arose well before the dinosaurs. The issue is still being debated but most scientists argue that the presence of feather-like appendages is not enough to establish it as the common ancestor of birds. See also **Lizards**.

Phylogeny

Birds, like other groups of animals, are classified into groups based on their shared evolutionary ancestry. The basic unit of classification is the species,

which takes two names – first its group or genus name, then the species name. The dabbling ducks for example are grouped together in the genus *Anas* and the mallard is called *Anas platyrhynchos* (platyrhynchos = flat beak), the closely related pintail *Anas acuta* (acuta = sharp/pointed).

Closely related species are placed in the same genus, related genera are grouped into families and families are grouped into orders. Some orders contain only a few species; for example, five in the case of the divers (Gaviiformes), which have few closely related species. The Passeriformes, on the other hand, contains well over half of all species of living birds. Birds are classified into 29 different major lineages or orders which comprise hierarchical sets of families and genera; 187 families, over 2,000 genera and over 9,600 species.

The class Aves has been divided into two subclasses: the Archaeornithes, containing only *Archaeopteryx* and the other fossil toothed birds, and the Neornithes which contains all living birds. The basis for grouping individuals has previously been on shared characteristics, generally anatomical characteristics, such as feather arrangements, shapes of the skeletal system and morphology of the muscles. The problem with this approach is that similarities may be explained by three different causes. They may be derived from a recent common ancestor, a distant common ancestor, or a completely different ancestor where separate lineages facing the same problem in their evolutionary history have adapted to solve the problem in the same way as their unrelated counterparts (convergent evolution). The advent of molecular techniques has helped to verify much of our current bird classification and reorganize other parts. The most widely cited family tree of all the birds is also described in Figure 1. However, this continues to change as new molecular techniques are developed. New evidence, for example, has challenged the view that the ratites are a primitive basal group in the tree and suggested they may have evolved much later from flying birds. Molecular evidence has also suggested that the passerines may actually be more basal than previously considered (Fig. 1).

As more genetic information becomes available the true relationship between the modern birds will hopefully be better understood. Establishing the exact relationships between particular birds is an essential part of studying ornithology as it allows scientists to determine whether the characteristics, behavior and life histories of different species arise from their phylogeny or from other more immediate causes in their environment.

Diversity

About 300 billion individual birds, and nearly 10,000 species, now inhabit the earth, ranging in weight from 2 grams (0.07 ounce) (hummingbird) to 100,000 grams (221 pounds) (ostrich), each adapted to a specific

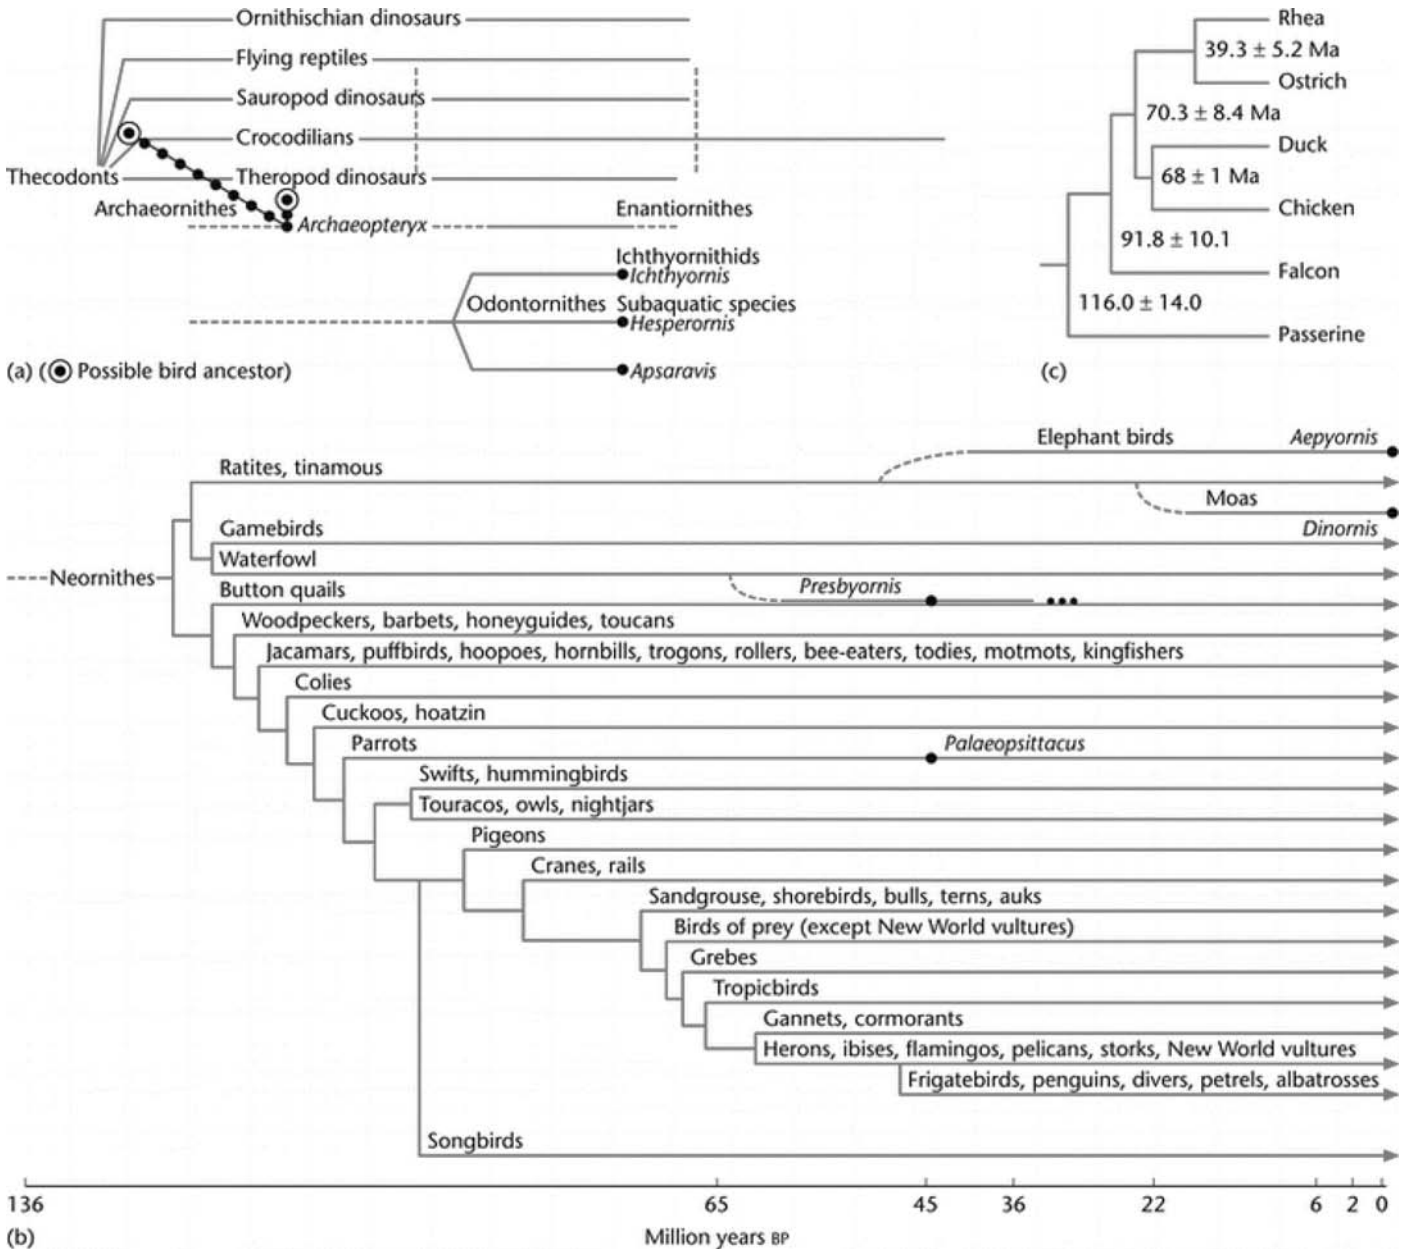

Fig. 1. **(a)** One of the proposed phylogenies of the fossil and modern birds. The exact relationship between the extinct fossil species is hotly debated. **(b)** The phylogeny of the modern birds suggested by DNA-hybridization studies.**(c)** One of the more recent models proposed based on new molecular evidence

ecological niche, climate, location and way of life. See also **Swifts and Hummingbirds (Aves, Apodiformes)**.

From the basic anatomy of their common ancestor, birds have adapted to fill many different niches from ocean wanderers to forest frugivores. This occurs through the process of adaptive radiation; and is well illustrated by a trait important in the identification of different bird species–bill morphology. One excellent example is the Hawaiian honeycreepers. A small flock of North American finches landed on one of the Hawaiian islands over a mya. They flourished in the new habitat and spread through the archipelago. As populations became isolated, subtle differences between bill structure were acted on by different selective pressures created by the slightly different ecological niches in these different populations. Competition between individuals would mean the individuals with the best beak shape for gaining the most food in that particular habitat would be more likely to survive and pass on genes for the right sort of bill type. Today, the relatives of these common ancestors vary in their bill morphology from short heavy bills for cracking nuts to long sickle-like bills for sipping nectar (Fig. 2). More structurally varied habitats tend to have the highest species diversity.

Adaptive radiation of the birds has resulted in species that demonstrate some incredible feats. Some birds are flightless and rely on other means of locomotion; the ostrich is believed to able to reach speeds up to 60 miles (95 km) per hour and the emperor penguin, *Aptenodytes forsteri*, can dive to depths of 265 meters (869 feet), staying underwater for up to 18 minutes. Among the flying birds, the peregrine falcon, *Falco peregrinus*, can reach speeds of 110 miles (175 km) per hour when diving from the air; the Arctic tern, *Sterna paradisaea*, can cover as many as 22,000 miles in its migration between the Arctic and Antarctic regions of the world and the sooty tern, *Sterna fuscata*, can travel for 3 years without ever touching ground. The megapodes produce chicks that can look after themselves from hatching and the royal albatross will spend 9–12 months caring for its single chick. The plumage of birds, however, has to be their most diverse trait and is often the basis on which we tell different species apart. Sexual selection has thought to have played an important role in driving selection for brighter

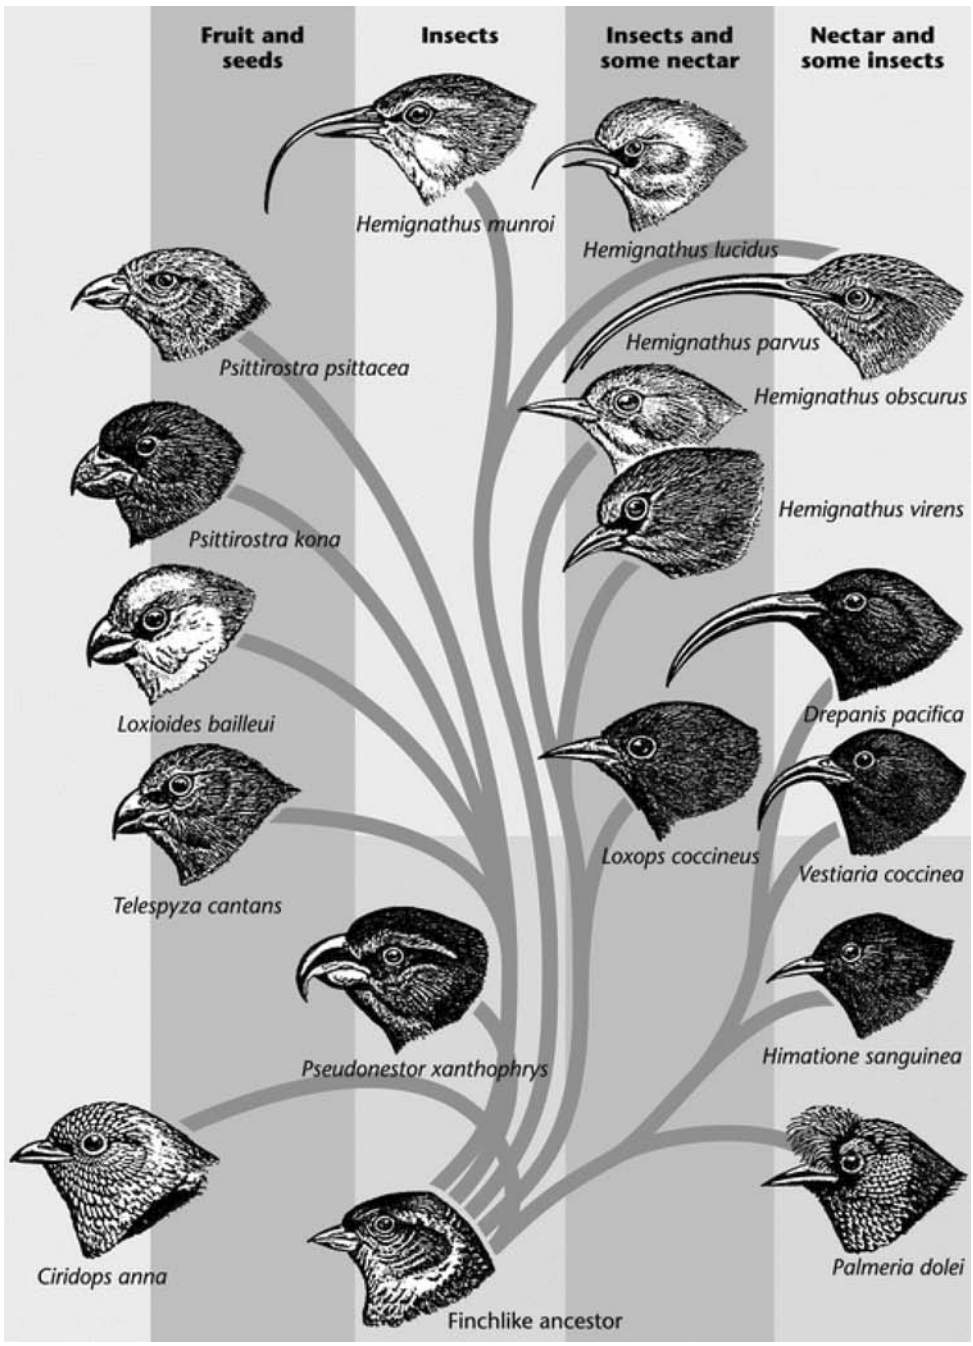

Fig. 2. The adaptive radiation of the Hawaiian finches. The bill of each species has become adapted to its own particular ecological niche through the process of natural selection

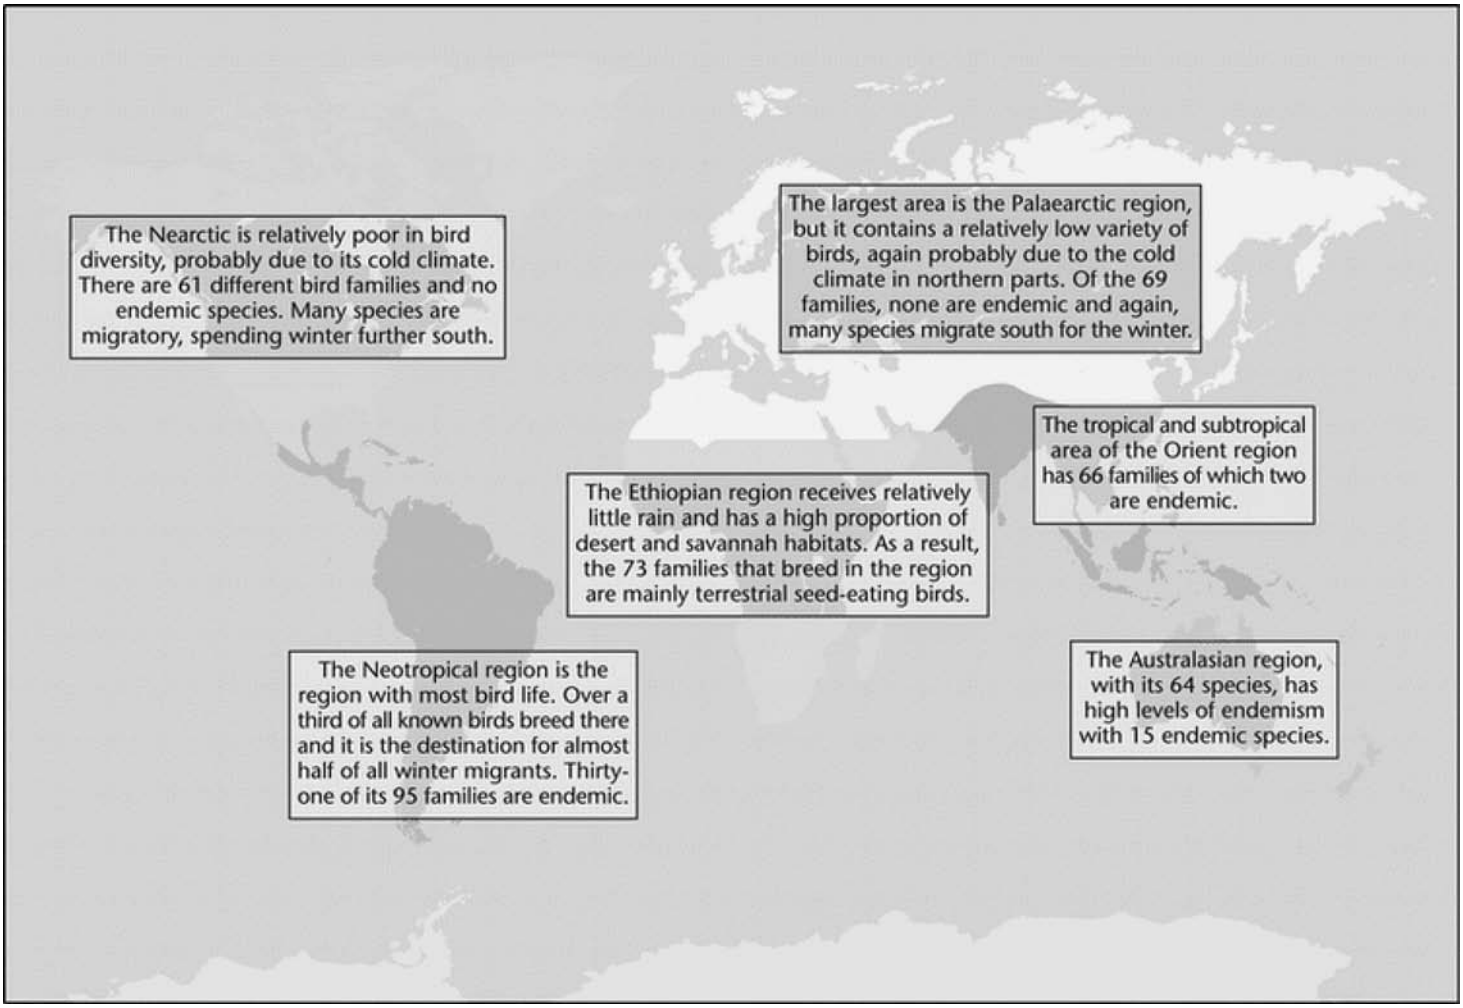

Fig. 3. The major zoogeographical regions of the world and their characteristic bird abundance

or more elaborate plumage. Female choice of bright plumage that signals a partner of good quality may have resulted in such elaborate traits as the peacock's tail.

Habitats and Abundance

Although flight has enabled birds to circumvent many natural physical barriers to their distribution, most species are generally confined to a particular geographical or ecological range. There are exceptions, such as the osprey, *Pandion haliaetus*, which has near worldwide distribution. However, more generally, particular avifaunas, geographical assemblages of species, are recognized in different parts of the world. These are the Nearctic (North America), Neotropical (Central and South America), Palearctic (Europe and Asia), Ethiopian (Africa), Oriental (southeast Asia) and Australasian (Australia and New Guinea) (Fig. 3). The area of the world in which a particular species is found is called its range. A species of bird that is native to and restricted to a particular region is called an *endemic*.

The distribution and range of birds will change over time. Some can be explained by major geographical changes such as the last ice age, the separation of the continents or changing climate. Birds living in the cloudforest of Costa Rica, for example, are now extending their range to higher altitudes as increasing sea temperatures affect air temperatures and the water content of the air. Other changes in distribution have been brought about by human activity, such as removing or providing new habitat with changing farm practice. The most abundant bird in the world for example, the red-billed quelea, *Quelea quelea*, is thought to have 1.5 billion breeding adults and they regularly devastate grain crops as they move in swarms across the country, despite major control efforts.

The area where one type of habitat borders with another, such as the edge of a forest or where moorland breaks into farmland, will provide a greater variety of vegetation for a particular area of land and hence a greater variety of food and shelter. Edge habitats are therefore typically high in species abundance. Short-term changes in abundance can also arise from seasonal movements of birds, as different species migrate in and out of different areas throughout the year.

It is important to monitor both species diversity and abundance. After a baseline of diversity and richness has been established for a particular area, any differences in species composition and number may indicate changes in habitat quality. Particularly sensitive 'indicator species' can also be monitored to alert us to any environmental degradation; monitoring seabird abundance, for example, can provide important clues about the current state of fish stocks or whether pollution levels might be having adverse effects in the marine environment.

Oddities within the Phylum

With such diversity in the class Aves, general rules tend to be broken.

Most birds construct some form of nest in which to rear their young. However, some birds are brood parasites. These birds never build their own nest, but lay their eggs in the nest of another species. The host bird, who has not realized it, has another bird's egg in its nest, will then rear the parasite's young as if they were its own. Only about 1% of all bird species are brood parasites and these are confined to the cuckoos, the cowbirds, the honeyguides, the widowbirds, the cuckoo weaver and a single species of duck–the black duck.

Most parents have to collect food items to feed their young or regurgitate their own stomach contents on returning from feeding themselves. Only a few birds manufacture chick food within the body. Pigeons, flamingos and emperor penguins feed nutritional oesophageal fluids to their young. Pigeons' "crop milk" is the best known of these and is full of fatty cells that are sloughed off the lining of a structure called the crop. Oesophageal

fluid is more or less the sole source of food for chicks of the greater flamingo.

The hoatzin, sole member of the family Opisthocomidae, is the only tree-dwelling bird where the chicks habitually leave the nest very soon after hatching. The nestlings have two hooked claws on their wings which they use to grip onto the branches of the tree as they crawl around on leaving the nest. The adults are cooperative breeders and two to six adults may help build the nest and care for the offspring. See also **Hoatzins (Aves, Galliformes)**.

The majority of birds are sexually dimorphic with the male tending to have brighter, more colorful plumage than the female. This is assumed to be because sexual selection has acted more strongly on males because females prefer brightly coloured males. However, there are several species where the sex roles are reversed, where bright plumaged females defend breeding territories and less colorful males incubate the eggs and care for the young. A vivid illustration of the power of sexual selection, these birds include some of the jacanas (Jacanidae), plovers (Charadriidae), sandpipers (Scolopacidae) and button-quail (Turnicidae); in these species, females also tend to show less parental care, have a higher potential rate of reproduction than males and compete between each other over males.

A few of the more primitive groups of birds possess an intromittent organ, analogous to a penis, by which sperm is transferred. This is extremely rare in birds, occurring in only 3% of all species. In most bird species, sperm transfer results from the meeting of the cloacae; the cloaca is the combined sexual and excretory opening found in all bird species. The intromittent organ is confined to the ratites, tinamous, cracids, screamers and the wildfowl and is thought to be the ancestral mode of sperm transfer in birds.

Habits and Lifestyles

Animals are designed by natural selection to leave as many breeding offspring as they can in the next generation; a bird's time therefore tends to be divided between attracting a mate and rearing offspring, finding food and surviving to the next breeding season.

Much bird behavior can be explained as a means of increasing reproductive success; bright plumage to attract a mate, elaborate song to signal a good territory to females, fighting to outcompete rival males. Although these traits often appear detrimental to survival, sexual selection will select for traits that increase chances of finding a mate or producing many successful offspring. As an example, a bird with a much louder mating call than his competitors may be more likely to be depredated before a male with a less conspicuous call, but if that male is more attractive to females and has left more offspring, he is the more successful and genes for loud calling will spread through the population.

The majority of bird species form monogamous pair bonds. However, it is now known that these monogamous bonds do not necessarily equate to sexual fidelity. Both males and females participate in extra-pair copulations outside the pair bond and these copulations can result in extra-pair young. In the barn swallow, for example, approximately one in three young in the nest are not fathered by their mother's mate and a similar pattern has been found in the majority of other bird species.

The degree of parental care shown by birds varies considerably. The precocial or nudifugous species, such as the wildfowl, produce young that can feed themselves from hatching and care is limited to brooding the chicks and guiding them away from danger. Imprinting in newly hatched nudifugous birds such as hens, geese, ducks, partridges, where they learn to follow the first object seen or heard, usually the parent species is an adaptation to this type of precocial lifestyle. The capacity to imprint is highest during a short time span known as the critical period, which occurs just after hatching. Altricial species, including most common songbirds, produce naked and helpless young which the parents must feed and care for if they are to survive. One or both parents may be responsible and there is little division of the sex roles when both parents help. In cooperative breeders, individuals other than the parents will also help to rear the young. Helpers are often young breeders that may not be able to breed immediately due to lack of breeding sites or resources. This can be beneficial to the helper if it puts them in a better position to inherit resources as they become available. Helpers are often related to the birds they are helping as well. Kin-selected benefits can therefore be gained because related individuals share genes; by helping relatives produce offspring, some of the helper's genes will be passed on through their relatives.

Parents must then survive to the next breeding season. This generally involves finding enough food and shelter from the climate and avoiding being eaten by other species trying to do the same. Foraging for food can take up a considerable amount of a bird's day, but natural selection has shaped animals into optimal foragers, using a mode of feeding that gives the highest energetic returns for energy spent trying to find it. The rule of this cost–benefit analysis for food finding can be modified in response to how risky an animal perceives its likelihood of being eaten; for example, many birds will switch to finding food in a less exposed environment, even if that food is more difficult to find, after they have seen a predator in the vicinity of where they are feeding. If food is likely to be scarce at particular times of year, food hoarding or caching might be practiced; some birds, such as the marsh tit, will stash seeds in crevices when they are locally abundant and return to the site of storage later. Acorn woodpeckers will fill dead trees with food items and then aggressively defend them from other individuals.

In temperate parts of the world, the majority of bird species are migratory. Most species migrate from summer breeding grounds to a more hospitable wintering ground and back again. The costs of such a long flight in terms of risks of adverse weather, shortage of fuel, and loss of navigational cues have to be balanced against the gains of better wintering conditions or better food sources. Hence, migration routes are not the same for all members of a species; some species have migratory and nonmigratory parts of the population (known as partial migrants), and migratory routes often vary between males and females, young and old. Accurate navigational skills are essential for migration and a wide range of navigation systems exist. At one extreme, geese and swans have to spend several years traveling with their parents to learn, in detail, the routes to be followed and the staging posts where feeding is possible. At the other extreme, the cuckoo is deserted by its parents before it even hatches from the egg and, being reared by another species, must find its own migratory route south unaided. A migratory journey can be continuous or broken into a series of short flights. Most songbirds can cover 300–600 kilometers (186–372 miles) per night, but one of the most amazing feats must be the migration of the Arctic tern, which covers 32,000 kilometers (19,884 miles) each year, traveling between feeding grounds in the Arctic and Antarctic.

Some species also migrate in order to molt; birds replace their feathers at least once a year. Some species do this continuously over a fairly long period. Others, such as many of the wildfowl, lose all their flight feathers at once; these species tend to migrate into large open areas to molt away from predators.

Bird ringing or banding (attaching small metal rings to birds) has provided considerable information about where birds go and how long they live. However, more recently, attaching small transmitters to birds and tracking them using satellites has provided more exact information on migration routes. Ospreys that bred in Speyside in the Highlands of Scotland, and have subsequently been reintroduced to other parts of Britain, have been tracked precisely in real time as they traveled between Scotland and West Africa over their winter migration.

Different species vary in their navigational abilities and a mixture of visual landmarks, odor landmarks, solar cues, stellar cues and geomagnetic cues are all employed to varying degrees, by different species, to guide them on the correct route home. Pigeons, for example, appear to develop an olfactory map based on cues in the environmental air to find their way home from unfamiliar locations and can make use of visual landmarks on reaching more familiar areas.

Life Histories

An animal's life history strategy is the comparative effort that it puts into survival and reproduction with the aim of maximizing its lifetime reproductive success. The strategy is influenced by longevity, age at first breeding, the number of young produced each year, and how well these young survive. The amount of effort put into each will be a trade-off in the allocation of resources to another.

Survival. Some birds live only a year or two, while others have a lifespan similar to a human being; the royal albatross has been recorded living for more than 60 years and some captive parrots have lived to 80 years. In general, large species survive longer than smaller species, seabirds longer than land birds, and tropical species longer than temperate species;

for example, only 30% of blue tits survive from year to year, as opposed to over 95% in the royal albatross. The major causes of mortality are predation, starvation and weather. Mortality tends to be highest in a bird's first year and males and females often differ in survival rate; hence, many populations of birds have a male biased sex ratio. This may be due to the higher costs of reproduction faced by females in most species.

Reproduction. Some birds lay just one egg, while others can lay up to 20. The blue tit, for example, breeds in its first year and will lay 10–12 eggs, each laid about a day apart. Incubation, nestling and post-fledging care takes about 50 days in total and two clutches can be produced each season for a maximum lifespan of about 8 years. In contrast, the wandering albatross tends to live about 50 years, begins breeding at the age of 10 and produces only one egg at a time. Rearing a chick to maturity takes about 14 months so annual breeding is not possible. Because of their fast breeding rates, small species can more readily recover from a population decline than larger species and are therefore better able to withstand heavy predation and interference from humans.

Since the majority of birds breed more than once, allocation of effort to particular breeding attempts has been a central concept in the study of life history strategies in birds. This area of research has been strongly influenced by the work of David Lack, who suggested that the number of eggs a female can produce has been shaped by natural selection to correspond to the maximum number of young that can be reared. However, experimental work has found that birds often lay less than they can physically raise. This is because other costs involved with reproduction have to be taken into account, such as the cost of incubating and producing the eggs.

In some species, reproductive parameters depend on where they are nesting and different populations will adapt to their surrounding conditions. The song thrush, for example, will produce one clutch per season in its northern range and two in its more southern range. Environmental factors, such as latitude, habitat and time of season, can all influence these different components of life history strategies.

AVIAN INFLUENZA. Avian influenza is an infection caused by avian (bird) influenza (flu) viruses. These influenza viruses occur naturally among birds. Wild birds worldwide carry the viruses in their intestines, but usually do not get sick from them. However, avian influenza is very contagious among birds and can make some domesticated birds, including chickens, ducks, and turkeys, very sick and kill them.

Infected birds shed influenza virus in their saliva, nasal secretions, and feces. Susceptible birds become infected when they have contact with contaminated secretions or excretions or with surfaces that are contaminated with secretions or excretions from infected birds. Domesticated birds may become infected with avian influenza virus through direct contact with infected waterfowl or other infected poultry, or through contact with surfaces (such as dirt or cages) or materials (such as water or feed) that have been contaminated with the virus.

Infection with avian influenza viruses in domestic poultry causes two main forms of disease that are distinguished by low and high extremes of virulence. The "low pathogenic" form may go undetected and usually causes only mild symptoms (such as ruffled feathers and a drop in egg production). However, the highly pathogenic form spreads more rapidly through flocks of poultry. This form may cause disease that affects multiple internal organs and has a mortality rate that can reach 90-100% often within 48 hours.

Human Infection with Avian Influenza Viruses

There are many different subtypes of type A influenza viruses. These subtypes differ because of changes in certain proteins on the surface of the influenza A virus (hemagglutinin [HA] and neuraminidase [NA] proteins). There are 16 known HA subtypes and 9 known NA subtypes of influenza A viruses. Many different combinations of HA and NA proteins are possible. Each combination represents a different subtype. All known subtypes of influenza A viruses can be found in birds.

Usually, "avian influenza virus" refers to influenza A viruses found chiefly in birds, but infections with these viruses can occur in humans. The risk from avian influenza is generally low to most people, because the viruses do not usually infect humans. However, confirmed cases of human infection from several subtypes of avian influenza infection have been reported since 1997. Most cases of avian influenza infection in humans have resulted from contact with infected poultry (e.g., domesticated chicken, ducks, and turkeys) or surfaces contaminated with secretion/excretions from infected birds. The spread of avian influenza viruses from one ill person to another has been reported very rarely, and transmission has not been observed to continue beyond one person.

"Human influenza virus" usually refers to those subtypes that spread widely among humans. There are only three known A subtypes of influenza viruses (H1N1, H1N2, and H3N2) currently circulating among humans. It is likely that some genetic parts of current human influenza A viruses came from birds originally. Influenza A viruses are constantly changing, and they might adapt over time to infect and spread among humans. See also **Influenza**.

During an outbreak of avian influenza among poultry, there is a possible risk to people who have contact with infected birds or surfaces that have been contaminated with secretions or excretions from infected birds.

Symptoms of avian influenza in humans have ranged from typical human influenza-like symptoms (e.g., fever, cough, sore throat, and muscle aches) to eye infections, pneumonia, severe respiratory diseases (such as acute respiratory distress), and other severe and life-threatening complications. The symptoms of avian influenza may depend on which virus caused the infection.

Studies done in laboratories suggest that some of the prescription medicines approved in the United States for human influenza viruses should work in treating avian influenza infection in humans. However, influenza viruses can become resistant to these drugs, so these medications may not always work. Additional studies are needed to demonstrate the effectiveness of these medicines.

Avian Influenza A (H5N1)

Avian influenza A (H5N1) in Asia and Europe. Influenza A (H5N1) virus–also called "H5N1 virus" –is an influenza A virus subtype that occurs mainly in birds, is highly contagious among birds, and can be deadly to them.

Outbreaks of avian influenza H5N1 occurred among poultry in eight countries in Asia (Cambodia, China, Indonesia, Japan, Laos, South Korea, Thailand, and Vietnam) during late 2003 and early 2004. At that time, more than 100 million birds in the affected countries either died from the disease or were killed in order to try to control the outbreaks. By March 2004, the outbreak was reported to be under control. Since late

June 2004, however, new outbreaks of influenza H5N1 among poultry were reported by several countries in Asia (Cambodia, China [Tibet], Indonesia, Kazakhstan, Malaysia, Mongolia, Russia [Siberia], Thailand, and Vietnam). It is believed that these outbreaks are ongoing. Influenza H5N1 infection also has been reported among poultry in Turkey Romania, and Ukraine. Outbreaks of influenza H5N1 have been reported among wild migratory birds in China, Croatia, Hong Kong (SARPRC), Mongolia, and Romania.

As of February, 2006, human cases of influenza A (H5N1) infection have been reported in Cambodia, China, Indonesia, Thailand, Turkey, Vietnam, and most recently, Iraq. For the most current information about avian influenza and cumulative case numbers, see the World Health Organization (WHO) website at http://www.who.int/csr/disease/avian_influenza/en/.

Human Health Risks During the H5N1 Outbreak. H5N1 virus does not usually infect people, but about 160 human cases have been reported by the World Health Organization since January 2004. Most of these cases have occurred as a result of people having direct or close contact with infected poultry or contaminated surfaces. So far, the spread of H5N1 virus from person-to-person has been rare and has not continued beyond one person.

Of the few avian influenza viruses that have crossed the species barrier to infect humans, H5N1 has caused the largest number of detected cases of severe disease and death in humans. In the current outbreaks in Asia and Europe more than half of those infected with the virus have died. Most cases have occurred in previously healthy children and young adults. However, it is possible that the only cases currently being reported are those in the most severely ill people, and that the full range of illness caused by the H5N1 virus has not yet been defined.

So far, the spread of H5N1 virus from person to person has been limited and has not continued beyond one person. Nonetheless, because all influenza viruses have the ability to change, scientists are concerned that H5N1 virus one day could be able to infect humans and spread easily from one person to another. Because these viruses do not commonly infect humans, there is little or no immune protection against them in the human population. If H5N1 virus were to gain the capacity to spread easily from person to person, an influenza pandemic (worldwide outbreak of disease) could begin. For more information about influenza pandemics, see http://www.cdc.gov/flu/pandemic/ and http://www.pandemicflu.gov.

No one can predict when a pandemic might occur. However, experts from around the world are watching the H5N1 situation in Asia and Europe very closely and are preparing for the possibility that the virus may begin to spread more easily and widely from person to person.

Treatment and Vaccination for H5N1 Virus in Humans

The H5N1 virus that has caused human illness and death in Asia is resistant to amantadine and rimantadine, two antiviral medications commonly used for influenza. Two other antiviral medications, oseltamavir and zanamavir, would probably work to treat influenza caused by H5N1 virus, but additional studies still need to be done to demonstrate their effectiveness.

There currently is no commercially available vaccine to protect humans against H5N1 virus that is being seen in Asia and Europe. However, vaccine development efforts are taking place. Research studies to test a vaccine to protect humans against H5N1 virus began in April 2005, and a series of clinical trials is under way. For more information about H5N1 vaccine development process, visit the National Institutes of Health website. http://www3.niaid.nih.gov/news/newsreleases/2005/avianfluvax.htm.

AVIATION WEATHER OBSERVATION. See **Meteorology**.

AVOGADRO CONSTANT. The number of molecules contained in one mole or gram-molecular weight of a substance. The most recent value is $6.0220943 \times 10^{23} \pm 6.3 \times 10^{17}$. In measurements made by scientists at the National Bureau of Standards (Gaithersburg, Maryland) and announced in late 1974, the uncertainty (as compared with previous determinations) of the number was reduced by a factor of 30.

AVOGADRO LAW. The well-recognized principle known by this name was originally a hypothesis suggested by the Italian physicist Avogadro, in 1811, to explain the puzzling rule of proportional volumes observed in chemical reactions of gases and vapors. It states simply that equal volumes of all gases and vapors at the same temperature and pressure contain the same number of molecules. Though this assumption accords with the facts and aids the kinetic theory of gases, just why it should be true is by no means self-evident, unless one starts with the much more recent Maxwell-Boltzmann law of equipartition of energy, which also requires proof. That Avogadro's law is true cannot be said to have been positively established until the experiments of J.J. Thomson, Millikan, Rutherford, and others determined the value of the electron as an electric charge and thereby made it possible to count the number of atoms of different elements in a gram. The actual number of molecules contained in one mole (gram-molecular weight) of a substance is the Avogadro constant.

At any fixed temperature and pressure, the density of carbon dioxide gas, for example, is approximately 22 times greater than the density of hydrogen gas. Thus, the mass of 1 liter of carbon dioxide is 22 times the mass of 1 liter of hydrogen gas. According to Avogadro's principle, the number of molecules in 1 liter of carbon dioxide is the same as the number of molecules in 1 liter of hydrogen. Thus, it follows that a carbon dioxide molecule must have a mass that is 22 times larger than the mass of a hydrogen molecule. Since the molecular weight of hydrogen (H_2) was set equal to 2, carbon dioxide was assigned a molecular weight of 22×2, or 44. Cannizzaro was the first to use gas densities to assign atomic and molecular weights. Avogadro's principle also may be used to assign molecular weights in a slightly different way. At standard temperature and pressure, the volume of a mole of any gas is 22.4 liters. The molecular weight of a gas, therefore, is the mass (in grams) of 22.4 liters of the gas under standard conditions. For most gases, the deviation from this ideal value is less than 1%. See also **Avogadro Constant**; and **Combustion**.

AVULSION. A sudden cutting off or separation of land by a flood, or by an abrupt change in the course of a stream, as by a stream breaking through a meander or by a sudden change in current whereby the stream deserts its old channel for a new one. Generally, in legal interpretation, the part thus cut off or separated belongs to the original owner.

AXELROD, JULIUS (1912–2004). Julius Axelrod was an American pharmacologist and Nobel Prize winner who elucidated the chemical mechanism of neural transmission. Axelrod, the son of Polish immigrants, was born in New York on 30 May 1912 and studied chemistry at New York City College, obtaining his BSc in 1933. After a period as a bacteriological laboratory assistant at the New York University Medical School (where he took his MA in bacteriology in 1943), from 1935 to 1946 he was a chemist at the Laboratory of Industrial Hygiene, where he lost his left

eye in an explosion. Between 1946 and 1955 he held further research positions at the Goldwater Memorial Hospital and the National Heart Institute in Bethesda, Maryland. From 1955, when he obtained a PhD from the George Washington University, Washington DC, to 1984, he was Director of Pharmacology at the Laboratory of Clinical Science of the National Institute of Mental Health (NIMH) at Bethesda. Since retirement in 1984 he has continued there as a guest researcher in the Cell Biology Laboratory. He was elected a Fellow of the Royal Society in 1979. He is married with two sons. See also **National Institutes of Health (NIH)**.

In the 1950s, while working with Bernard D. Brodie on the pharmacology of analgesics, notably amphetamines and other drugs related to catecholamines, Axelrod discovered the enzymes involved in their metabolism. (Catecholamines are compounds derived from the amino acid tyrosine.) Noradrenaline (norepinephrine) had been isolated from nerves by U. S. von Euler in 1946, but its function remained obscure. When Axelrod joined the NIMH in 1955, he decided to use the same techniques for noradrenaline and adrenaline (epinephrine), both of which are catecholamines. He successfully explored the fate of noradrenaline after its secretion from nerve terminals and showed how a methylating enzyme identified as catechol-O-methyltransferase (COMT; E.C.2.1.1.6) switched off its activity. By using radioactive tritium labelling he was also able to plot the distribution of adrenaline within animal tissues and to establish how it was taken up by the sympathetic nervous system. He found that after use, any excess hormone was reabsorbed by nerve terminals, to be stored in adjacent reservoirs. By investigating the effects of drugs on the ability of nerves to release and absorb catecholamines, Axelrod showed that the system was under hormonal and neural control, thus forming the basis for further significant advances in neurophysiology. In 1970 Axelrod shared the Nobel Prize in Physiology or Medicine with Sir Bernard Katz and Ulf von Euler for his research on the metabolic pathway of the catecholamine neurotransmitters noradrenaline and adrenaline, his identification and isolation of the enzymes involved, and his study of the pharmacology of the effects of drugs upon the release of such amines. Axelrod is an inspiring example of a man who aspired to no more than being a competent laboratory assistant, but who instead unexpectedly found himself able to become a world leader in research. Admiring pupils and co-workers honoured him with a Festschrift when he was sixty. Axelrod has also worked on the pineal gland and described the biosynthesis of melatonin and its precursor, serotonin, and its relationship with circadian rhythms. See also **Katz, Bernard (1911–2003)**.
